OGOD (one gene - one disorder): A hypothesis based on the analogy of the one gene - one poly-peptide (one enzyme) theorem. The majority of diseases in humans (and animals) cannot be reconciled with a single gene mutation, and most of the symptoms (syndromes) are under multigenic control although particular genes may have a major effect. ► [behavior in humans](#), ► [one gene—one enzyme theorem](#); Plomin R et al 1994 Science 264:1733.

Oguchi Disease: This condition is characterized by a recessive human chromosome-2q mutation or

deletion in the arrestin protein modulating light signal transduction to the eye or by defects in the arrestin and the rhodopsin kinase genes. Night vision is impaired but otherwise vision is normal. ►night blindness, ►arrestin, ►retinal dystrophy, ►eye diseases

Ohm ($\Omega = 1\text{V/A}$): A unit of resistance of a circuit in which 1 volt electric potential difference produces a current of 1 ampere.

OH[•] (hydroxyl radical): This is responsible for the oxidative damage of superoxide and hydrogen peroxide. ►superoxide, ►hydrogen peroxide, ►Fenton reaction, ►ROS

Ohno's Law: The gene content of the X chromosome is basically the same in all mammals. Some exceptions are seen in humans, marsupials and in the monotreme, *Platypus* where genes in the short arm of the X chromosome may be of autosomal origin. There are other exceptions such as the chloride channel gene (*Cln4*) is autosomal in the mouse *Mus musculus* but it is X-linked in *Mus spretus*. Similarly, the human steroid sulfatase (STS) gene is near the pseudo-autosomal region whereas in lower primates it is autosomal. The rationale of Ohno's Law is that translocations between autosomes and X chromosome would upset the sex determination gene balance. In the X chromosomes of various mammals sequence homologies are conserved. FISH probes have, however, revealed some rearrangements. ►sex determination, ►FISH; Ohno S 1993 Curr Opin Genet Dev 3:911; Palmer S et al 1995 Nature Genet 10:472.

Oidia: Asexual fungal spores produced by fragmentation of hyphae into single spores.

Oil Immersion Lens: This is the highest power objective lens of the light microscope. It is used with a special non-drying immersion oil, available at different viscosity with a refractive index of about 1.5150 for D line at 23°C, and it increases light-gathering power and improves resolution. ►light microscope, ►objective, ►resolution optical, ►numerical aperture

Oil Spills: It is known that around 22 bacterial genera have genetically determined ability to degrade petroleum hydrocarbons. Although a procedure invented by A.M. Chakrabarty did not involve molecular genetic engineering but only the introduction of two different plasmids into *Pseudomonas* (*P. aeruginosa* and *P. putida*) to degrade several harmful products, it was the first US patent (#4,259,444) issued in 1981 for unique microorganisms. ►patent, ►biodegradation; Díaz MP et al 2002 Biotechnol Bioeng 79:145.

OK Blood Group: This is encoded in human chromosome 19pter-p13. This antigen is present in the red cells of chimpanzees and gorillas but not in rhesus monkeys, baboons or marmosets. ►blood groups

Okadaic Acid ($\text{C}_{44}\text{H}_{68}\text{O}_{13}$): An inhibitor of PP1 and PP2a protein phosphatases. ►PP-1

Okayama & Berg PROCEDURE: This procedure permits cloning of full length mRNA genes. The mRNA is extracted from post-polysomal supernatant of reticulocyte lysate of rabbits, made anemic by phenylhydrazine injection. The globin mRNA is recovered in the alcohol-precipitate of phenol extract or with the aid of a guanidinium thiocyanate method. The poly-A tailed mRNA is annealed to plasmid pBR322 that is equipped with a poly-T attached to a SV40 fragment inserted into the vector. In the next step an oligo-G linker is constructed, separated, and purified by agarose gel electrophoresis. Now cloning of the mRNA can begin. The poly-A tail is annealed to the poly-T end of the vector. Using reverse transcriptase, a DNA strand, complementary to the mRNA strand, already in the plasmid, is generated. Using terminal transferase enzyme poly-C tails are added to one strand of the plasmid vector as well as to the DNA strand of the RNA-DNA double strand. Now the oligo-G linker is added to the oligo-C ends and the plasmid is made circular by DNA ligase. Then the mRNA strand is removed by RNase H and replaced by a complementary DNA strand, generated by DNA polymerase I and the construction is completed by ligation into a circular cloning vector. This new vector, containing the full length cDNA, is transformed into *E. coli* cells for propagation. ►cloning vectors, ►cDNA, ►ribonuclease H, ►linker, ►reverse transcriptase, ►terminal transferase, ►guanidinium thiocyanate, ►phenylhydrazine, ►RNA extraction; Okayama H Berg P 1982 Mol Cell Biol 2:161.

Okazaki Fragments: These are short (generally less than 1 kilobase in eukaryotes and about 2 kb in prokaryotes) DNA sequences formed during replication (of the lagging strand) and subsequently ligated into a continuous strand. Okazaki fragments are needed because nucleic acid chains can grow only by adding nucleotide to the 3' end and the lagging strand template would not allow continuous chain elongation like the leading strand of DNA. Six steps are involved in the generation of Okazaki fragments: (i) polymerase α and primase synthesize an RNA primer for 3' ← ← ← growth on the lagging strand template, (ii) RFC assists in binding the primer to the DNA and in the displacement of polymerase α , (iii) PCNA promotes the assembly of the replicator DNA polymerase δ complex, (iv) RNase H, Fen1 and Dna2 endonuclease digest off the RNA primer under the

control of replication protein RPA as DNA synthesis proceeds, (v) the gaps between the Okazaki fragments are filled by the DNA, and (vi) DNA ligase joins the fragment into a continuous strand of DNA. In eukaryotes the process is more complex than in prokaryotes. ▶DNA replication, ▶replication fork, ▶primosome, ▶RCF, ▶PCNA, ▶Rad27/Fen1, ▶ribonuclease H, ▶DNA ligase, ▶alpha accessory factor, ▶polymerase switching, ▶processivity; Bae S-H, Seo Y-S 2000 J Biol Chem 275:38022; Jin YH et al 2001 Proc Natl Acad Sci USA 98:5122; Bae S-H et al 2001 Nature [Lond] 412:456; Jin H Y et al 2003 J Biol Chem 278:1626.

Okihiro Syndrome: ▶Duane retraction syndrome

Okra (*Abelmoschus esculenta*): An annual vegetable of the Malvaceae with nearly 30–40 species having variable chromosome numbers, generally higher than $n = 34$ –36 as revealed by reports.

OKT3: A monoclonal antibody capable of blocking interleukin production. ▶Oct

Oleuropein: This complex substance is found in olive tree leaf extracts and it is used as a herbal medicine for various ailments.

Olig1: This is a basic helix-loop-helix transcription factor required for the repair of demyelinated lesions of the central nervous system. It is also needed for repairing the myelin sheath in multiple sclerosis. ▶multiple sclerosis, ▶helix-loop-helix; Arnett HA et al 2004 Science 306:2111.

2'-5'-Oligoadenylate: This is synthesized by 2–5A synthetases (2'5'AS), which are induced by interferons and they activate RNase L in defense of viral infection. ▶interferon, ▶ribonuclease L; Bonnevie-Nielsen V et al 2005 Am J Hum Genet 76:623.

Oligo-Capping: Refers to the replacement of the original cap of the mRNA by a short synthetic oligoribonucleotide. The removal is due to tobacco acid pyrophosphatase and the ligation by T4 RNA ligase. In uncapped mRNAs the 5' phosphate is first removed by alkaline phosphatase. The purpose is labeling prior to first-strand DNA synthesis. The 5' end of the mRNA is identified by reverse transcription-polymerase chain reaction. ▶cap, ▶RNA ligase, ▶RT-PCR; Maruyama K, Sugano S 1994 Gene 138:171.

Oligohydramnios: ▶renal tubular dysgenesis

Oligonucleotide: A short nucleotide tract (about 15 to 30 units). See <http://basic.northwestern.edu/biotools/OligoCalc.html>.

Oligopeptides: The natural oligopeptides are generally not more than 50 amino acids long and frequently have regulatory functions. (See database: <http://erop.inbi.ras.ru/>).

Oligostickiness: This is a measure of the binding affinity of 12-base (dodeca-) oligonucleotides to the genome of a species. The affinity is characteristic of genomes as well as of chromosomes of a species and hence facilitates identification. It is also known as chromosome texture. (See Nishigaki K and Saito A 2002 Bioinformatics 28:1153).

OL(1)p53: A phosphorothioate oligonucleotide sequence (5'-d[CCCTGCTCCCCCTGGCTCC]-3') used as antisense DNA to suppress p53 function to pass the checkpoint into the S phase of the cell cycle as a potential treatment for acute myeloblastic leukemia. ▶leukemia, ▶Myb oncogene, ▶antisense DNA, ▶phosphorothioate, ▶p53; Bishop MR et al 1997 J Hematother 6(5):441.

Oleuropein: A phenolic secoiridoid glycoside in the leaves of privet (*Ligustrum*) and when activated by herbivores becomes a protein cross-linking, lysine-decreasing glutaraldehyde-like structure, an α,β -unsaturated aldehyde as a means of self-protection (see Fig. O7). ▶plant defense, ▶host-pathogen relations; Konno K et al 1999 Proc Natl Acad Sci USA 96:9159.

Figure O7. Oleuropein. The left side of the molecule represented here is a catechol and the right side is the secoiridoid moiety

Olfactogenetics: This is concerned with the genetically determined differences in (body) smell and the ability to recognize it. In the human brain the olfactory bulbs situated under the frontal lobes interpret the olfactory signals (see Fig. O8). The mouse olfactory bulbs contain ~two glomeruli for each olfactory receptor. The different olfactory receptors are segregated into groups of glomeruli. Scent is influenced by the chemical nature of secretions and to a large extent by the diet and the microflora of the body. Human polymorphism in olfactory responses is of concern for the cosmetics (perfume) industry. It has been

claimed that the ability to distinguish between various odors is determined by the *H2* locus of mice (an analog of the human *HLA* complex). Some people are incapable of smelling, anosmic for isobutyric acid or cyanide or urinary excretes of asparagus metabolites. The regulation of the olfactory responses involves cAMP or phosphoinositide (IP₃)-regulated ion channels and G protein (G_{olf}) coupled receptor kinases. The olfactory memory in sheep is triggered by nitric oxide that potentiates the release of glutamate and GABA neurotransmitters leading to an increase of cGMP in the mitral cells of the nose, the site of perception of smell. The olfactory memory formation has been localized in the mushroom body of the brain. In *Drosophila* cAMP phosphodiesterase, encoded by gene *dunce* (*dnc*, chromosome 1–3.9), calcium—calmodulin-dependent adenylyl cyclase (encoded by *rutabaga* [*rut*, 1–{46}]), the catalytic subunit of the cyclicAMP-dependent protein kinase A, and the α -integrin subunit encoded by *Volado* (*vol*, located in the X and the 2nd chromosomes) are involved in the control of olfactory memory. There are many other unidentified genes and proteins involved in different olfactory functions. It appears that each neuron of the olfactory epithelium expresses only one olfactory receptor. In the human genome ~900 olfactory receptor (OR) genes (encoding seven-transmembrane proteins) or pseudogenes (60%) have been identified. In humans, the non-functional, pseudogenic olfactory genes are twice as high as in non-human primates and in mice the proportion of pseudogenes of olfaction is only 20% (Gilad Y et al 2003 Proc Natl Acad Sci USA 100:3324). They are common in chromosomes 7 and 17 but are found in most other chromosomes as well, generally clustered as 6–138 genes. Of 856 olfactory receptors in the human genome, 40% is located in chromosome 11 in 28 single- and multi-gene clusters (Taylor TD et al 2006 Nature [Lond] 440:497). In each olfactory sensory neuron only one odorant receptor (MOR in mouse, HOR in humans) gene is expressed (Serizawa S et al 2003 Science 302:2088). A single transacting enhancer element may allow the stochastic activation of only one olfactory receptor allele in the olfactory sensory neurons of mice (Lomvardas S et al 2006 Cell 126:403). No olfactory receptor genes seem to be coded in human chromosomes 20 and Y. Different olfactory sensory neurons in the nose express a different complement of the ORs and transmit the information through their axons to the olfactory bulbs in the brain. In humans, mice and fishes there is another class of chemosensory receptors, TAARs (trace and amine-associated receptors). One group of TAARs recognizes volatile amines in the urine of mouse linked to stress and two groups are involved in sensing compounds enriched in the male urine (Liberles SD, Buck LB 2006 Nature [Lond] 442:645).

Figure O8. Olfactory bulbs in the human brain situated under the frontal lobes

In fishes approximately 100 genes are involved in olfactory functions whereas in rodents there are about 1,300 and humans have around 1,000. In humans many of the olfactory genes are not functional. In mammals only a single odor receptor gene is expressed per cell. Dogs and rats have a superior ability to smell. In dogs 1,094 and in rats 1,493 olfactory receptor genes were identified from shotgun sequences but nearly 20% were pseudogenes (Quignon P et al 2005 Genome Biol 6(10):R83). The *Drosophila* in general expresses two odor receptors per cell whereas the *Caenorhabditis* may express nine chemoreceptors per cell. The *Caenorhabditis* has around 1,500 G-protein-coupled odor receptors (GPCR). *Drosophila melanogaster* has about 60 genes for odorant receptors and an equal number but different gustatory receptor genes. These low numbers are characteristic of other insects as well. A combinatorial use of the olfactory receptors permits the distinction of an almost indefinite variety of odors. The ligands of the receptors also contribute to sensory specificity. Different glomeruli respond qualitatively and quantitatively to the types and intensities of the odors. According to some estimates olfactory receptors may represent 1% of all genes. It has been reported that the major histocompatibility complex is a main source of unique individual odors in animals and women can detect differences among male odor donors with different MHC genotypes. This ability is dependent on the HLA allele inherited by the human female from her father but not from her mother (Jacob S et al 2002 Nature Genet 30:175). In the vomeronasal organ—sensing pheromones—there are ~35 V1R and ~150 V2R receptor family members. The number of human OR genes exceed 1,000 and many of them are pseudogenes. In animals the major histocompatibility complex is a source of olfactory recognition of mating preferences and various other behavioral traits. The rodent ORs rarely, if at all, are pseudogenic. Natural odors are often a blend of several components present in specific ratios. Therefore, an enormous number of odor (fragrance) signals may exist. Several OR genes have been cloned. Pheromones are perceived by >240 proteins of the vomeronasal system including special 7-transmembrane proteins. The removal of the vomeronasal organ interferes with the pheromone

response but not with other odor perceptions. The olfactory pathway also mediates pheromone responses (Shepherd GM 2006 *Nature [Lond]* 439:149). The Ras-MAPK signal transduction pathway mediates odor perception and transmission of sensory signals to the *Caenorhabditis* olfactory neurons. Deficiencies in the olfactory system of the *Caenorhabditis* seem to prolong life. In 2004, Richard Axel and Linda Buck received the Nobel Prize for their work on olfaction. ▶bisexual, ▶cAMP, ▶cGMP, ▶neurotransmitter, ▶nitric oxide, ▶phosphoinositide, ▶IP₃, ▶MHC, ▶signal transduction, ▶*Asparagus officinalis*, ▶pheromones, ▶fragrances, ▶vomeronasal organ, ▶taste, ▶brain human, ▶Kallmann syndrome, ▶Bruce effect, ▶mushroom body, ▶odor-sensing; Pilpel Y et al 1999 In: Higgins SJ (ed) *Molecular Biology of the Brain*, Princeton Univ. Press, Princeton, NJ, pp 93; Buck LB 2000 *Cell* 100:611; Glusman G et al 2001 *Genome Res* 11:685; Firestein S 2001 *Nature [Lond]* 413:211; Mombaerts P 2001 *Annu Rev Genomics Hum Genet* 2:493; Young JM et al 2002 *Hum Mol Genet* 11:535; Nakagawa T et al 2005 *Science* 307:1638; Bargmann C 2006 *Nature [Lond]* 444:295; Shepherd GM 2006 *Nature [Lond]* 444:316; Jefferis GSXE et al 2007 *Cell* 128:1187; Lin H-H et al 2007 *Cell* 128:1205; <http://senselab.med.yale.edu/senselab/ordb/>; www.leffingwell.com.

Olfactory: This is related to the sense of smell. ▶olfactogenetics

0

Oligodendrocyte: Refers to the non-neural cells that form the myelin sheath (neuroglia) of the central nervous system and they coil around the axons. They may become the stem cell of the central nervous system. ▶neurogenesis; Lu QR et al 2002 *Cell* 109:75.

Oligodeoxyribonucleotide Gated Channel: Composed of a 45-kDa protein, this is involved in Ca²⁺-dependent uptake of oligonucleotides through an approximately 5-μm pore. Protein kinase C and a few organic molecules are inhibitors. ▶protein kinases, ▶liposomes, ▶DNA uptake sequences; Salman H et al 2001 *Proc Natl Acad Sci USA* 98:7247.

Oligodontia: The lack of development of six or more permanent teeth is based on frameshift mutation in the PAX9 gene in human chromosome 14. ▶tooth agenesis, ▶hypodontia, ▶PAX; Heilig R et al 2003 *Nature [Lond]* 421:601.

Oligodynamic Action: Refers to the antimicrobial effect of trace amounts of heavy metals. ▶sterilization.

Oligogenes: This is a small group of genes responsible for a particular trait; usually one has a major role. ▶breast cancer, ▶prostate cancer, ▶polygenes, ▶QTL

Oligo-Labeling Probes: These are short (10–20 nucleotides), commonly radioactively or of fluorochrome labeled, synthetic probes for the identification of genes for isolation, labeling in gel retardation assays, screening of DNA libraries, etc. ▶label, ▶probe, ▶gel retardation assay, ▶variant detector assay

Oligomer: A polymer of relatively few units (amino acids, nucleotides, sugars, etc.). An oligomeric protein has a quaternary structure associated with non-covalent bonds.

Oligonucleotide-Directed Mutagenesis (Kunkel mutagenesis): Synthetic oligonucleotide with the mutation sought is annealed to a single-stranded M13 phage DNA template with a number of uracil residues in place of thymine in a strain *dut*⁻ (dUTPase) and *ung*⁻ (uracil-DNA-glycosidase). The *E. coli* transformation medium should contain the 4 deoxynucleotide triphosphates, T4 DNA polymerase and T4 DNA ligase to generate double-stranded circular DNA and M13 phages are selected with the mutation desired. The heteroduplex is introduced into a wild type *dut* and *ung* strain to maintain the mutation. ▶site-specific mutagenesis; Kunkel TA et al 1987 *Methods Enzymol* 154:367.

Oligophrenia Phenylpyruvica: Refers to mental retardation due to phenylketonuria. ▶phenylketonuria

Oligophrenin: This RAS-like GTPase protein (91-kDa) encoded in human chromosome Xq12 is responsible for cognitive impairment. Similar mental retardation genes are scattered in the genome and afflict about 0.15–0.3% of males. Its level is higher in several cancerous tissues. ▶mental retardation, ▶RAS; Pinheiro N A 2001 *Cancer Lett* 172:67.

Oligoribonucleotide Synthesis: ▶silyl-phosphite chemistry

Oligosaccharides: These consist of sugar residues, such as glycans, and they may be present in many metabolically, immunologically and structurally important molecules. Oligosaccharides may carry information for the folding of proteins in the endoplasmic reticulum. Their sequence can be determined by exoglycosidase mediated digestion or by sequencing the amino acids of the protein. In both procedures electrophoretic (MALDI) analysis may be used. ▶glycan, ▶electrophoresis, ▶protein folding, ▶folding, ▶endoplasmic reticulum; Billuart P et al 1998 *Nature [Lond]* 392:923; Lehrman MA 2001 *J Biol Chem* 276:8623.

Oligospermia: This condition is characterized by low sperm content in the semen. Chromosomal

rearrangement (translocations, inversions, ring chromosome, etc.) or aneuploidy may be responsible for this condition. ►sperm, ►semen, ►azoospermia, ►cytoplasmic male sterility

Oligozyme: Refers to nuclease resistant RNA oligomers (29–36 residues) that can cleave specific RNA sequences. ►ribozyme; Kitano M et al 2001 Nucleosides Nucleotides Nucleic Acids 20:719.

Olive (*Olea europea*): There are about 30 species of this oil-producing tree. The cultivated forms are $2n = 2x = 46$ although aneuploids have been identified. Because of its oleocanthal content freshly pressed oil is anti-inflammatory as it lowers cyclooxygenase enzymes COX-1 and COX-2 but has no substantial effect on lipoxygenase. ►cyclooxygenase, ►lipoxygenase; Beauchamp GK et al 2005 Nature [Lond] 437:45.

Olivopontocerebellar Atrophy (OPCAI): The autosomal dominant or recessive, variable types of expressions involve ataxia, paralysis, incoordination, speech defects, and brain and spine degeneration. In some forms eye defects and other anomalies have been observed. In several cases a linkage has been observed to the HLA complex in human chromosome 6p21.3–p21.2, but in others such a linkage was not evident. Patients with this disease exhibit 50% or less glutamate dehydrogenase activity. ►ataxia, ►palsy, ►glutamate dehydrogenase

Omega-3-Fatty Acids: This is a collective name for polyunsaturated fatty acids. The ω name is derived from the first double bond position. The early synthetic products with 1, 2 and 3 double bonds are shown. Mammals lack the enzymes (desaturases) to add double bonds beyond the 9th carbon atom of the fatty acid chain. Therefore, they cannot synthesize these *essential*, unsaturated fatty acids and depend on plants. Fish oil – because of feeding on algae – may also be rich in ω -3 fatty acids (see Fig. 09). In the absence of these fatty acids skin lesions, defects in the lipid membranes, kidney disease, reduced fertility, prostaglandin deficiency, etc. occur. Arachidonic acid, a ω -6-fatty acid, is the precursor of prostaglandins mediating anti-inflammatory responses. Omega-3 fatty acids are known to lower risks of cardiovascular diseases, to reduce depression, bipolar mental afflictions and other nerve disorders. On the other hand, these fatty acids may increase hemorrhages, lower immune responses, etc. According to the Federal Drug Administration, the intake of these fatty acids through food and supplements should be limited to 3mg/day. Some nutritionists have recommended higher doses. Since mammals lack the desaturase enzyme that can

convert ω -6 fatty acids to ω -3, it is of interest to introduce the gene for this enzyme from another animal such as *Caenorhabditis elegans*. Following the transfer of the *fat-1* gene to mice (Kang JX et al 2004 Nature [Lond] 427:504) and pigs (Lai L et al 2006 Nature Biotechnol 24:435) it was possible to produce a high ratio of n-6/n-3 of 0.7 in the muscles of transgenic mice compared to 49.0 in the wild type. In 8 transgenic pigs this ratio was variable but the average was 1.69 versus 8.52 in the wild type controls. For the experiments the humanized version of the pCAGGS-fat-1 expression vector was used with a cytomegalovirus enhancer and driven by the chicken β -actin promoter. The vector containing G418 selective marker was electroporated into fetal porcine fibroblasts. The transgenic cells were then used for nuclear transplantation into pig ova and cloned. A total of 1,633 engineered embryos was transferred to 14 females in estrus which resulted in pregnancies. Five of them were carried to term resulting in 10 live and two dead piglets of which six contained the *fat-1* transgene. Initially all the offspring were completely normal, however three piglets developed heart failure by the age of 3 weeks. This defect appeared to be due to the nuclear transfer procedure rather than to the *fat-1* gene. Although such transgenic pigs are not yet available for commercial meat production, the method appears very promising from the viewpoint of potential improvements in human diet and health. ►fatty acids, ►acetyl-CoA, ►syntxin, ►erucic acid, ►prostaglandins, ►arachidonic acid, ►desaturase, ►cardiovascular disease, ►enhancer, ►promoter, ►cytomegalovirus, ►G418, ►electroporation, ►nuclear transplantation

Figure 09. The ω numbering begins at the C of the methyl end; the n-3 or ω -3 indicate the double bond at the 3rd or 6th carbon from the methyl end. Chemists start the numbering (1) at the other end

Omega Sequence: This is the viral nucleotide sequence in the mRNA 5'-region of eukaryotic genes that enhances translation.

Omenn Syndrome: ►reticulosis familial histiocytic

OMIA (online Mendelian inheritance animals): This is a database for animal (excluding man and mouse) genes and hereditary diseases and disorders. (<http://omia.angis.org.au>).

Omics: Refers to genomics, transcriptomics, proteomics, etc.; the global information gathering and its tools in biology.

OMIM (online Mendelian inheritance man): This is an up-to-date catalog of autosomal dominant, autosomal recessive, X-linked and mitochondrial genes of humans available through the Internet (<http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=OMIM>). The database provides information on relevant literature on ('morbid') genes and connections to other databases. As of May 1 2006 OMIM identified 1,871 genes in which at least one disease related mutation has been described and the number of phenotypes in these genes was 3,112 (McKusick V 2006 Annu Rev Hum Genet Genomics 7:1). By 2007 the number of entries totaled 17,370 (McKusick V 2007 Amer J Hum Genet 80:588). It is also available in book form: McKusick, Victor 1997 *Mendelian Inheritance in Man*. The Johns Hopkins University Press, Baltimore, MD. OMIM proteins are annotated at <http://www.hprd.org/>. ►BI-TOLA, ►OMIA; hereditary disease frequency: <http://www.findbase.org>.

Ommatidium (Plural ommatidia): A self-sufficient element (facet) of the compound eye of arthropods, such as *Drosophila* (see Fig. O10). E- and N-cadherins regulate the shape of the cells but the shapes are also controlled by the physical requirement to minimize surface (Hayashi T, Carthew RW 2004 Nature [Lond] 431:647). ►compound eye, ►rhabdomere, ►cadherins; Wernet MF et al Nature [Lond] 440:174.

Figure O10. *Drosophila ommatidia* with eight photoreceptors inside each. There are about 800 ommatidia per eye

Ommochromes: These are insect eye pigments synthesized from tryptophan and the formation and condensation of hydroxykinurenine into xanthommatin

and complexing with other components into brown pigment granules. ►pteridines, ►w locus, ►pigmentation in animals

Omnibank (OST): A collection of 80–700-nucleotide long rapid amplification cDNA 3' ends by PCR (RACE), generated from mouse embryonic stem cells for the purpose of identification of sequence-tagged mutations. ►stem cell, ►PCR, ►RACE, ►sequenced-tagged sites; Zambrowicz BP et al 1998 Nature [Lond] 392:608.

Omnipotent: ►totipotent

Omp A: Refers to the outer membrane protein A of the bacterial cell. ►Rickettsia

OmpC, OmpF: Bacterial outer membrane proteins are regulated by kinase EnvZ in response to osmolarity (at low osmolarity by C and at high by F). OmpR is an outer membrane regulatory protein. OmpT is a serine protease which cleaves cyclin A. ►cell membrane, ►membrane proteins

Omphalocele: This refers to umbilical hernia. It is probably autosomal recessive with a prevalence of 1 to 2×10^{-4} . ►gastroschisis

OMSSA: The search engine for identifying MS/MS peptide spectra. ►mass spectrum; <http://pubchem.ncbi.nlm.nih.gov/omssa>; <http://pubchem.ncbi.nlm.nih.gov/omssa/download.htm>.

Oncocytoma: ►mitochondrial disease in humans, ►kidney diseases

Oncogene Antagonism Therapy: This therapy leads to transformation by vector constructs carrying tumor suppressor genes, dominant negative genes, suicide genes, antisense nucleotides, toxin genes that may prevent tumor formation or disable tumor cells. ►gene therapy, ►cancer gene therapy, ►suicide vectors, ►antisense technologies

Oncogene Collaboration: Some oncogenes do not transform cell cultures when applied single, e.g., rat embryo fibroblast requires the simultaneous presence of both RAS and MYC for complete transformation. ►oncogenes, ►transformation oncogenic

Oncogene-Induced Senescence: Certain oncogenes accelerate derepression of the *CDKN2a* locus by cooperation with the Polycomb group proteins. ►CDKN2, ►Polycomb; Collado M Serrano M 2006 Nature Rev Cancer 6:472.

Oncogenes: These genes of RNA viruses (v-oncogene) or similar genes in animal cells (c-oncogene) are responsible for the initiation of cancer. The c-oncogenes (proto-oncogenes) perform a normal function in animal cells but may cause abnormal

proliferation by activation or amplification or promoter/enhancer fusion (translocation), mutation, deletion or inactivation. The transforming genes of DNA viruses do not have cellular counterparts and they induce tumors by interacting with tumor suppressor genes. An allelic form of an oncogene represents such a gain-of-function that favors cancerous transformation. The primary target of the majority of oncogenes is the cell cycle and they deregulate the function of genes that normally control the initiation or progression of the cell cycle. The human genome contains about 30 recessive and over 100 known oncogenes. For details see ►**ABL**, ►**AKT1**, ►**AMV**, ►**ARAF**, ►**ARG**, ►**BLYM**, ►**BMYC**, ►**CBL**, ►**DBL**, ►**ELK**, ►**EPH**, ►**ERBB**, ►**ERG**, ►**ETS**, ►**EVI**, ►**FES**, ►**FGR**, ►**FLT**, ►**FMS**, ►**FOS**, ►**GLI**, ►**HIS**, ►**HKR**, ►**HLM**, ►**HST**, ►**INT**, ►**JUN**, ►**KIT**, ►**LCA**, ►**LCK**, ►**LYT**, ►**MAS**, ►**MCF**, ►**MEL**, ►**MET**, ►**MIL**, ►**MYB**, ►**MYC**, ►**NGL**, ►**NMYC**, ►**OVC**, ►**PIM**, ►**PKS**, ►**PVT**, ►**RAF**, ►**RAS**, ►**REL**, ►**RET**, ►**RHO**, ►**RIG**, ►**ROS**, ►**SPI1**, ►**SEA**, ►**SIS**, ►**SK**, ►**SNO**, ►**SRC**, ►**TRK**, ►**VAV**, ►**YES**, ►**YUASA**. Many of the oncogenic transformations are caused by cis-activation of proto-oncogenes by non-oncogenic viruses. ►**cancer**, ►**carcinogens**, ►**retroviruses**, ►**non-productive infection**, ►**proto-oncogene**, ►**CATR1**, ►**tumor suppressor**, ►**amplification**, ►**gene fusion**, ►**protein tyrosine kinases**; Kung HJ et al 1991 *Curr Top Microbiol Immunol* 171:1; Liu D, Wang LH 1994 *J Biomed Sci* 1:65; Dua K et al 2001 *Proteomics* 1:1191; <http://cgap.nci.nih.gov/>; <http://oncodb.hcc.ibms.sinica.edu.tw>.

Oncogenic Transformation: This refers to the development of a cancerous state. It may begin by the loss or suppression of tumor suppressor genes. ►**oncogenes**, ►**oncoproteins**, ►**oncogenic viruses**; Di Croce L et al 2002 *Science* 295:1079.

Oncogenic Viruses: These can integrate into mammalian cells and rather than destroying the host, they can induce cancerous proliferation of the target tissues by inhibiting the cellular tumor suppressor genes. Oncogenic viruses may have double-stranded DNA genetic material such as adenoviruses (genome size ca. 37-kbp), Epstein-Barr virus (ca. 160-kbp), human papilloma virus (ca. 8-kbp), polyoma virus (ca. 5–6-kbp) and the single-strand RNA viruses (retroviruses, 6–9-kb). ►**adenoviruses**, ►**SV40**, ►**papilloma virus**, ►**Epstein-Barr Virus**, ►**papova viruses**, ►**hepatitis B**, ►**retroviruses**, ►**acquired immunodeficiency**, ►**tumor viruses**, ►**Kaposi sarcoma**, ►**Moloney**, ►**Kirsten**, ►**Rous sarcoma**, ►**avian**

Oncolytic Viruses: Herpes simplex-1, Newcastle disease virus, reovirus and adenovirus may selectively

replicate and destroy tumor cells without the causing disease itself. Selectively targeting tumor cells may be accomplished by fusing antibody fragments or erythropoietin or heregulin to the viral envelope protein. Erythropoietin recognizes its receptor on erythroid precursor cells. Heregulin is a nerve growth factor required specifically for breast cancer and fibrosarcoma cells. Engineering tumor-specific promoter to the viral genes may enhance tumor-specific viral gene expression. The herpes simplex (HSV) or adenovirus may directly lyse the tumor cells. Cyclophosphamide enhances glioma therapy in rats by HSV by inhibiting immune responses (Fulci G et al 2006 *Proc Natl Acad Sci USA* 103:12873). Newcastle disease virus may increase sensitivity to tumor necrosis factor (TNF). The parvovirus may promote apoptosis of the cancer cells. The viral antigens bound to cellular MHC class I proteins may become targets for cytotoxic T lymphocytes (CTL). ►**cancer gene therapy**, ►**herpes**, ►**Newcastle disease**, ►**parvovirus**, ►**reovirus**, ►**adenovirus**, ►**heregulin**, ►**TNF**, ►**apoptosis**, ►**CTL**, ►**ONYX-015**, ►**cyclophosphamide**; Wildner O 2001 *Annals Med* 33 (5):291; Smith ER et al 2000 *J Neuro-Onc* 46(3):268.

Oncomine: This is a cancer microarray database and integrated data mining platform. (See <http://www.oncomine.org/>).

Oncomouse: This is the trade name for a mouse strain prone to breast cancer and suitable for this type of research. ►**breast cancer**; Kerbel RS 1998–99 *Cancer Metastasis Rev* 17(2):301.

Onconase: This is an anti-tumor protein with ribonuclease activity to tRNA. ►**tRNA**, ►**ribonuclease**; Notomista E et al 2001 *Biochemistry* 40:9097.

Oncoprotein: A product of an oncogene which is responsible for the initiation and/or maintenance of hyperplasia and malignant cell proliferation. ►**oncogenes**

Onco-Retroviral Vectors: These are engineered from onco-retroviruses such as murine leukemia virus and Rous sarcoma virus. The viral protein genes required for disease are removed and replaced by transgenes. Infectious particles are generated through packaging cells. ►**retroviruses**, ►**viral vectors**, ►**transgene**, ►**packaging cell lines**

Oncostatin M: ►**APRF**; Radtke S et al 2002 *J Biol Chem* 277:11297.

Index: Facilitates data acquisition from linked, integrated and visualized bases by graph analysis techniques. It can handle many hundreds of thousands of data and examine their potential relationships by identifying equivalent concepts and

filtering out unattached nodes. (See <http://ondex.sourceforge.net/>).

One Gene-One Enzyme Theorem: This theorem recognizes that one gene is generally responsible for one particular biosynthetic step, mediated through an enzyme. More precisely stated is the one gene (cistron)-one polypeptide rule because some enzymatically active protein aggregates may be encoded by more than a single gene. There are some other apparent exceptions, e.g., one mutation blocking the synthesis of homoserine may also prevent the synthesis of threonine and methionine because homoserine is a common precursor of these amino acids (see Fig. O11). Further, in the branched-chain amino acid (isoleucine-valine) pathway, ketoacid decarboxylase and ketoacid transaminase enzymes control the pathways leading to both isoleucine and valine. As data on genomics accumulate it becomes increasingly evident that the one nucleotide sequence (depending on the multiple promoters and processing of the transcript) may carry out different (pleiotropic) functions. Sequencing and proteomic information of the human genome indicates that the same gene (DNA tract) is spliced in three alternate ways and this may be construed as one gene—three functions. ▶homoserine, ▶isoleucine-valine biosynthetic pathway, ▶bifunctional enzymes, ▶overlapping genes, ▶contiguous gene syndrome, ▶pleiotropy, ▶genetic network; Beadle GW 1945 *Chem Rev* 37:15; Boguski MS 1999 *Science* 286:543; Venter JC et al 2001 *Science* 291:1304; Chen J et al 2002 *J Biol Chem* 277:22053; Kondrashov FA 2005 *Nature Genet* 37:9.

Figure O11. Block in homoserine biosynthesis generates requirements for threonine and methionine

One Gene-One Polypeptide: ▶one gene-one enzyme theorem

One-Hybrid Binding Assay: This is basically a gene fusion assay where a transcriptional activation domain is attached to a particular gene. The function of such a “hybrid” may be assessed by the expression of an easily monitored reporter gene (e.g., luciferase), depending on the signal received from the particular gene. ▶two-hybrid assay, ▶gene fusion, ▶luciferase, ▶split-hybrid system, ▶three-hybrid system; Wilhelm JE, Vale RD 1996 *Genes Cells* 1(3):317; Murakami A et al 2001 *Nucleic Acids Res* 29:3347.

One-Step Growth: Bacteriophages multiply within the bacterial cell and in one step, within less than 10 min, during the “rise” period, all the particles are released. The temperate phages may have a longer period preceding the rise after infection because the phage DNA may be integrated into the bacterial chromosome and then replicates synchronously with the bacterial genes (see Fig. O12). Upon induction the phage may switch to a lytic cycle, which begins with autonomous replication followed by liberation of the phage particles. The number of phage particles released is called the burst size. See Fig O12, ▶bacteriophages, ▶phage lifecycles; Hayes W 1965 *The Genetics of Bacteria and Their Viruses*. Wiley, New York.

Figure O12. One-step growth

Onion (*Allium* spp.): The *Alloideae* subfamily of lilies has 600 species. *A. cepa*, $2n = 2x = 16$. Most of the North American species have $x = 8$ (see Fig. O13). Polyploid species occur in different parts of the world with somatic chromosome numbers 24, 32, 40, 48. The eye-irritating lachrymatory factor (propanal S-oxide) is generated from 1-propenyl-L-cysteine sulfoxide by the enzyme lachrymatory factor synthase. It may be possible to develop a variety of onion that retains its full flavor without the pungent characteristics [Imai S et al 2002 *Nature [Lond]* 419:685]. ▶garlic

Figure O13. *Allium* $x = 8$

One-Tailed Test: The deviation is measured in one direction of the null hypothesis.

Onozuka R-10: ►cellulase

Onset: Denotes stage (time) of expression of a genetically determined trait.

Onto Tools: Function analysis of protein-coding genes from microarray data. <http://vortex.cs.wayne.edu/Projects.html>.

Ontogeny: Describes the developmental course of an organism. ►phylogeny

Ontology, Genetic: This seeks out the function and meaning of genes and genetic elements; e.g., the gene is a functional unit that can be either a DNA or a RNA but it is not a protein or other macromolecule. ►gene ontology; <http://bcl.med.harvard.edu/proj/gopart>.

Ontos: Refers to *E. coli* computer data sets organized into object-oriented database management system.

Onyx-015: This is a genetically modified adenoviral vector which lacks E1B-55K. It was earlier believed that the absence inactivates p53 tumor suppressor protein and facilitates oncolytic viral replication and selectively destroys cancer cells. However, it now known that the loss of E1B-55K leads to the induction rather than the inactivation of p53 by selective RNA export function (O'Shea CC et al 2004 Cancer Cell 6:611). ►adenovirus, ►oncolytic viruses, ►p53; Galanis E et al 2001 Crit Rev Oncol Hematol 38 (3):177.

Oocyte Donation: This is a means to overcome infertility in women who for some reason (older age, genetic risks, etc.) do not want or cannot conceive in the normal manner but can serve as a recipient of either their own ovum obtained earlier and preserved or of an ovum from a donor. These women can thus carry to term a normal baby. From a genetic viewpoint it is important that the ovum implanted is carefully analyzed to ensure that there is no risk involved. ►artificial insemination, ►surrogate mother, ►ART, ►micromanipulation of the oocyte; Noyes N et al 2001 Fertil Steril 76:92.

Oocyte, Primary: This has the same chromosome number as other common body cells (2n, 4C) but upon meiotic division each gives rise to two haploid *secondary oocytes* (n, 2C). The smaller of the two is called the 1st polar body. By another division the egg and three polar bodies (n, 1C) are formed. The egg may become fertilized but the polar bodies do not contribute to the progeny and fade away. In human females meiosis begins in the four month old fetus and proceeds to the diakinesis (dictyotene) stage until sexual maturity. After puberty in each four-week cycle one oocyte reaches the stage of the secondary oocyte and after completing the equational phase of meiosis (meiosis II), an egg is released during

ovulation. Each of the two human ovaries contains about 200,000 primary oocytes (see Fig. O14). On an average around 400 eggs are produced during the entire fertile period of the human female, spanning a period of 30 to 40 years, i.e., beginning at puberty and terminating with the onset of menopause. Apoptosis leads to the loss of oocytes. The exhaustion of oocytes nutrients and the inability to generate NADPH may be contributing factors. It has been observed that pentose-phosphate-mediated inhibition of cell death is due to inhibitory phosphorylation of caspase 2 by calcium-dependent protein kinase II (Nutt LK et al 2005 Cell 123:89). In vitro differentiation of oocytes from embryonic stem cells can be studied experimentally. According to some reports, bone marrow and peripheral blood stem cells can repopulate the ovaries and can reinitiate the ovulation of oocytes after the loss of this capacity due to radiation injury or disease (Johnson J et al 2005 Cell 122:303). These findings have significance for post-menopausal women or those who suffered from cured ovarian cancer. A recent study did not confirm these observations and concluded that parabiosis, allowing efficient circulation of humoral and cellular factors, did not contribute to ovulated oocytes in mice but only to previously committed blood cells (Eggen K et al 2006 Nature [Lond] 441:1109).

Figure O14. Human oocyte with about 1,500 spermatozoa (Courtesy of Dr. Mia Tegner)

In the human metaphase II oocytes, compared with reference samples from other tissues, 5,331 transcripts were significantly upregulated and 7,074 transcripts significantly down regulated. Of the oocyte upregulated probe sets, 1,430 had unknown function. A core group of 66 transcripts was identified by intersecting significantly upregulated genes of the human oocyte with those from the mouse oocyte and from human and mouse embryonic stem cells. GeneChip array results were validated using RT-PCR in a selected set of oocyte-specific genes. Within the upregulated probe sets, the top overrepresented categories were related to RNA and protein metabolism, followed by DNA metabolism and chromatin modification (Kocabas AM et al 2006 Proc Natl Acad Sci USA 103:14027).

Mouse embryonic stem cells in culture can develop into oögonia that enter meiosis, recruit adjacent cells to form follicle-like structures, and later develop into blastocysts (Hübner K et al 2003 Science 300:1251). Stem cells isolated from the skin of porcine fetuses have the intrinsic ability to differentiate into oocyte-like cells. When differentiation was induced, a subpopulation of these cells expressed markers such as Oct4, growth differentiation factor 9b (GDF9b), the Deleted in Azoospermia-like (*DAZL*) gene and Vasa (a germ line-specific protein) — all consistent with germ cell formation. On further differentiation, these cells formed follicle-like aggregates that secreted estradiol and progesterone and responded to gonadotropin stimulation. Some of these aggregates extruded large oocyte-like cells that expressed oocyte markers, such as zona pellucida, and the meiosis marker, synaptonemal complex protein 3 (SCP3). Some of these oocyte-like cells spontaneously developed into parthenogenetic embryo-like structures (Dyce PW et al 2006 Nature Cell Biol 8:384). These developments may eventually obviate the need for embryonic stem cells in therapeutic cloning. ▶egg, ▶spermatocyte, ▶meiosis, ▶C amount of DNA, ▶menopause, ▶gametogenesis, ▶*Xenopus* oocyte culture, ▶oögonium, ▶oospore, ▶oocyte translation system, ▶nurse cell, ▶fertilization, ▶spermatozoon, ▶stem cells, ▶NADP, ▶protein kinase, ▶caspase, ▶parabiosis, ▶azoospermia, ▶therapeutic cloning; Johnstone O Lasko P 2001 Annu Rev Genet 35:365.

0

Oocyte, Secondary: ▶oocyte primary

Oocyte Translation System: mRNAs injected into the amphibian oocyte (*Xenopus*) nucleus (germinal vesicle) may be transcribed, and in the cytoplasm these exogenous messengers are translated, the proteins may be correctly processed, assembled, glycosylated, phosphorylated, and delivered (targeted) to the proper location, etc. Similarly, injections of foreign DNA into the fertilized embryos may be replicated and inserted into the chromosomes. ▶translation in vitro; Skerrett IM et al 2001 Methods Mol Biol 154:225.

Oogamy: Refers to the fertilization of a (generally) larger egg with a (smaller) sperm. ▶oocyte.

Oögenesis: Refers to the formation of the egg. Meiosis in the mammalian oocyte begins much before fertilization but it is arrested at late prophase (dictyotene stage). The G_s protein-linked receptor (GPR3) maintains the pause (Mehlmann LM et al 2004 Science 306:1947). Shortly before ovulation meiosis is resumed. In vertebrates, the luteinizing hormone of the pituitary acts on the surrounding somatic cells and the continuation of meiosis is

mediated by CDK1. ▶gametogenesis, ▶dictyotene stage, ▶ G_s protein, ▶luteinizing hormone, ▶CDK1; Navarro C et al 2001 Curr Biol 11:R162; Matzuk MM et al 2002 Science 296:2178; Schmitt A, Nebreda AR 2002 J Cell Sci 115:2457.

Oögonium: This is the female sex organ of fungi fertilized by the male gametes. It is also called a zygote.

Oögonium in Animals: Refers to the primordial female germ cell that is enclosed in a follicle by the term of birth of the individual and becomes the oocyte. ▶gametangium, ▶gametogenesis

Ookinete: This is the protozoan zygote at a motile stage within the malaria host mosquito.

Oophorectomy: The surgical removal of the ovary is also known ovariectomy, neutering, or spaying. ▶castration

Ooplasm: This is an egg cytoplasm. The transfer of 5–15% of ooplasm from a donor may facilitate pregnancy in certain cases of in vitro fertilization. The transfer involves mitochondria and mRNA. ▶ART; Brenner CA et al 2000 FertilSteril 74:573.

Oospore: A fertilized egg in (fungi) which is either dikaryotic or diploid and is frequently covered by a thick wall (see Fig. O15). ▶oögonium

Figure O15. Oospore

Oözing: The binding of a protein at one site facilitates the adjacent binding of additional proteins until the resulting multimeric protein complex extends to the site of transcription initiation (Talbert PB, Henikoff S 2006 Nature Rev Genet 7:793).

Opal: This is the chain-terminator codon (UGA). ▶code genetic

Opaque (o): Refers to genes in maize (several loci); *o-2* in particular attracted attention because its presence reduces the levels of prolamins and zein type proteins and increases the lysine content of the kernels. This improves the nutritional value significantly which is of concern to people in some parts of the world where corn is the main staple food. ▶floury, ▶kwashiorkor

Open-Label Trial: In contrast to the double-blind tests both subjects and experimenters are aware of the prospective medicine tested and the dose used.
▶ [double-blind trial](#)

Open Promoter Complex: Refers to a partially unwound promoter (the DNA strands separated) to facilitate the operation of the RNA polymerase. This separation is thought to be the result of the attachment of the transcriptase to the promoter. The TATA box of the promoter is a logical place for the attachment of the pol enzyme because there are only two hydrogen bonds between A and T in contrast to the three bonds between G and C and thus the separation of the double helix is easier. This is followed by initiation of transcription. After the attachment of the RNA elongation proteins, the σ subunit of the bacterial pol enzyme is evicted and transcription proceeds. Transcription factor TFIIB has a 7-bp recognition element immediately upstream of the TATA box and TFIIB and TBP are required for the formation of the preinitiation complex for RNA polymerase II. Several protein elements are important for forming an open complex. ▶ [closed promoter complex](#), ▶ [promoter melting](#), ▶ [PIC](#), ▶ [pol](#), ▶ [Pribnow box](#), ▶ [Hogness box](#), ▶ [TBP](#), ▶ [TAF](#), ▶ [transcription factors](#), ▶ [RAD25](#), ▶ [regulation of gene activity](#), ▶ [nucleosome](#), ▶ [reinitiation](#), ▶ [PSE](#), ▶ [IHF](#), ▶ [FIS](#), ▶ [CAP](#); Uptain SM et al 1997 Annu Rev Biochem 66:117; Ranish JA et al 1999 Genes Dev 13:49; Davis C A et al 2005 Proc Natl Acad Sci USA 102:285.

Open Reading Frame (ORF): This is a nucleotide sequence between an initiation and a terminator codon. In higher organisms one of the two DNA strands is usually transcribed into functional products although there are open reading frames in both strands. ▶ [initiation codon](#), ▶ [nonsense codon](#), ▶ [coding sequence](#), human and mouse ORF database: <http://orf.invitrogen.com/>.

Open System: This system exchanges material and energy within its environment.

Operand: Refers to what is supposed to be operated (worked) on.

Operational Concepts: These concepts were frequently used in genetics for providing an explanation when the underlying mechanism was not fully understood but from the manifest behavior a conceptualization was possible in agreement with what was known. For example: T.H. Morgan defined the gene as the unit of function, mutation and recombination before the nature of the genetic material was discovered. F.H.C. Crick concluded on the basis of frameshift mutagenesis—before the genetic code was experimentally determined—that the genetic code probably used nucleotide triplets.

Operational RNA Code: This is a sequence/structure-dependent aminoacylation of RNA oligonucleotides that are devoid of an anticodon. The specificity and efficiency is determined by a few nucleotides near the amino acid acceptor arm. ▶ [aminoacylation](#), ▶ [aminoacyl-tRNA synthetase](#), ▶ [transfer RNA](#), ▶ [mini-helix of tRNA](#); Schimmel P et al 1993 Proc Natl Acad Sci USA 90:8763; de Pouplana LR, Schimmel P 2001 J Biol Chem 276:6881.

Operational Taxonomic Unit (OTU): ▶ [character matrix](#)

Operator: This is the recognition site of the regulatory protein in an operon or possibly in other systems such as suggested for controlling elements (transposable elements) of maize. ▶ [transposable elements](#), ▶ [operon](#), ▶ [Lac operon](#), ▶ [Ara operon](#)

Operon: This is a functionally coordinated group of genes producing polycistronic transcripts (co-transcription). Operons have been discovered in prokaryotes but are exceptional in eukaryotes. Similar organization occurs in the homeotic gene complexes of eukaryotic organisms, such as *ANTP-C* and *BX-C* of *Drosophila*. Many genes of the nematode (ca. 15%), *Caenorhabditis* seem to be coordinately regulated and transcribed into polycistronic RNA that is processed into monocistronic mRNA by transsplicing (Blumenthal T et al 2002 Nature [Lond] 417:851). ▶ [Lac operon](#), ▶ [Arabinoase operon](#), ▶ [Tryptophan operon](#), ▶ [His operon](#), ▶ [dual-gene operons](#), ▶ [supraoperon](#), ▶ [morphogenesis in Drosophila](#), ▶ [homeotic genes](#), ▶ [coordinate regulation](#), ▶ [überoperon](#), ▶ [transsplicing](#), ▶ [SL1](#), ▶ [SL2](#); Hodgman TC 2000 Bioinformatics 16:10; Blumenthal T, Seggerson Gleason K 2003 Nature Rev Genet 4:119; Ben-Shahar Y et al 2007 Proc Natl Acad Sci USA 104:222; <http://regulondb.ccg.unam.mx:80/index.html>; operon database: <http://odb.kuicr.kyoto-u.ac.jp/>.

Operon, Selfish: Clustered genes are more likely to be transmitted as a group. This is a selfish evolutionary feature because the clustering itself may not have any physiological benefit for the host, except the joint transmission. ▶ [lateral transmission](#); Lawrence JG, Roth JR 1996 Genetics 143:1843; Lawrence J 1999 Curr Opin Genet Dev 9:642.

Ophthalmoplegia: Autosomal dominant phenotypes (incidence $\sim 1 \times 10^{-5}$, encoded at 10q23.3-q24.3, 3p14.1-p21.2, 4q34-q35) involve defects in moving the eyes and the head as well as some other variable symptoms. The 4q locus encodes a tissue-specific adenine nucleotide (ADP/ATP) translocator (ANT) and also controls mtDNA integrity. The autosomal recessive ophthalmoplegic sphingomyelin lipidosis appears to be allelic to the Niemann–Pick syndrome gene and it is associated with mitochondrial DNA

mutations. ▶mitochondrial diseases in humans, ▶neurogastrointestinal encephalomyopathy, ▶Kearns–Sayre syndrome, ▶Niemann–Pick syndrome, ▶eye disease, ▶myopathy, ▶inclusion body myopathy, ▶horizontal gaze palsy

Opiate: An opium-like substance which regulates pain perception and pain signaling pathways and mood (see Fig. O16). *Endogenous opiates*, enkephalins and endorphins, were isolated from the brain and the pituitary gland, respectively. They contain a common 4-amino acid sequence and bind to the same cell surface receptors as morphine (and similar alkaloids). Nociceptins (orphanin) are 17 amino acid antagonists of the opioid receptor-like receptor. Opioids are opiate-like, but they are not derived from opium. Nocistatin with an evolutionarily conserved C-terminal hexapeptide blocks pain transmission in mammals. Opioids activate the expression of FAS which upon binding its ligand (FasL) promotes apoptosis of lymphocytes and thereby the immune system. Opioids may affect the immune system by suppressing cytokine synthesis. Opioids modulate stress responses, learning and memory, metabolism, and may lead to addiction, etc. A region of chromosome 14q with a non-parametric lod 3.3 is responsible for opioid addiction (Lachman HM et al 2007 Human Mol Genet 16:1327). The major types of opiates are plant alkaloids. ▶enkephalin, ▶endorphin, ▶dynorphin, ▶morphine, ▶FAS, ▶apoptosis, ▶immune system, ▶cytokines, ▶nociceptor; formula after Massotte D, Kieffer BL 1998 Essays Biochem 33:65.

Morphine: $R^1 = R^2 = H$
 Codeine: $R^1 = CH_3$, $R^2 = H$
 Heroin: $R^1 = R^2 = CH_3 - CO$

Figure O16. Opiates

Figure O17. Pro-opiocortin

Opines: These are synthesized in crown-gall tumors of dicotyledonous plants under the direction of agrobacterial plasmid genes. The bacteria use these opines as carbon and nitrogen sources. The octopine family of opines comprises octopine, lysopine, histopine, methiopine and octopinic acid. The nopaline group includes nopaline and nopalinic acid. Agropines are agropine, agropinic acid, mannopine, mannopinic acid and agrocinosines. ▶*Agrobacteria*, ▶T-DNA octopine, ▶nopaline; Petit A et al 1970 Physiol Vég 8:205.

Opiocortin: This is a prohormone (pro-opiocortin) translated as a precursor of several corticoid hormones and cut by proteases and processed into corticotropin, β -lipotropin, γ -lipotropin, α -MSH (melanin-stimulating hormone), β -MSH and β -endorphin as shown here (see Fig. O17) ▶animal hormones, ▶POMC, ▶individual peptide hormones under separate entries, ▶pigmentation of animals; Lowry PJ 1984 Biosci Rep 4(6):467; De Wied D, Jolles J 1982 Physiol Rev 62:976; Challis BG et al 2002 Hum Mol Genet 11:1997.

Opisthotonus: A motor protein (myosin) dysfunction resulting in spasms and backward pulling of the head and heels while the body seems to move forward. ▶Usher syndrome

Opitz Syndrome (G syndrome, BBB syndrome, 22q11.2): An apparently autosomal dominant anomaly with complex features such as hypertelorism (the distance between paired organs is abnormally increased), defects in the esophagus (the passageway from the throat to the stomach), hypospadias (the urinary channel opens in the underside of the penis in the vicinity of the scrotum), etc. In an autosomal recessive form it is characterized by polydactyly, heart anomaly, triangular head, failure of the testes to descend into the scrotum and suspected deficiency of the mineralocorticoid receptor. An Xp22 gene encodes the 667-amino acid Mid1 (midline) Ring finger protein and its mutant forms may interfere with microtubule function. ▶corticosteroid, ▶head/face/brain defects, ▶Opitz-Kaveggia syndrome; Liu J et al 2001 Proc Natl Acad Sci USA 98:6650.

Opitz-Kaveggia Syndrome: This is a Xp22-linked phenotype characterized by a large head, short stature, imperforate anus, heart defect, muscle weakness, defect in the white matter of the brain (corpus callosum) and mental retardation. A recent report noted that *MED12* (Xq13) encodes a subunit of the macromolecular complex of Mediator, which is required for thyroid hormone-dependent activation and repression of transcription by RNA polymerase II. The MED12 protein is not part of the Mediator core complex but is a member of a Mediator module that may act as an adaptor for specific transcription factors and a defect in it leads to the syndrome (Risheg H et al 2007 Nature Genet 39:451). ▶stature in humans, ▶heart disease, ▶mental retardation, ▶head/face/brain defects, ▶Opitz syndrome

Opossum (Metatherians/Marsupials): *Caluromys derbianus* 2n = 14, *Chironectes panamensis* 2n = 22, *Monodelphis domestica* 2n = 18. The latter is a South American species, closely related to the North American Virginia opossum. A draft sequence of its genome is available which contains 3,475 Mb comprising about 18,000 to 20,000 protein-coding genes. The autosomes of opossum are extremely large whereas the X chromosome is much smaller than in most eutherians. The average rate of autosomal recombination is lower ($0.2\text{--}0.3\text{ cM Mb}^{-1}$) compared to other amniotes ($0.5\text{--}3\text{ cM Mb}^{-1}$) but in the X chromosome it is larger than in the autosomes. The G + C content is about 2% lower than in other amniotes. Segmental duplications are much shorter and lower in frequency than the sequenced amniotes and shorter sequences separate them. The stability of the genome is greater. Conserved non-coding elements in opossum evolved from transposons. The eutherian protein-coding sequences are largely conserved in this species (Mikkelsen TS et al 2007 Nature [Lond] 447:167; Goodstadt L et al 2007 Genome Res 17:969; Belov K et al 2007 Genome Res 17:982; Gentles AJ et al 2007 Genome Res 17:992).

Opsins: These are photoreceptor proteins of the retina but non-visual photoinduction opsin is found in the pineal gland. The chromophore of opsins is either 11-cis-retinal or 3-dehydroretinal. Red-green color vision depends on these molecules. The red- and green-sensitive pigments differ mainly in amino acids at sites 180, 277 and 28 respectively. In red sensitives alanine and phenylalanine, and in green sensitives serine, tyrosine and threonine, respectively are most common. In hominids and Old World monkeys two X chromosomal genes encode these pigments. In all mammals (with the exception of the New World monkeys) there is only one locus encoding either red or green opsins. In humans, additional sites have minor effects. In pigeons five retinal opsin genes have

been distinguished. ▶pineal gland, ▶rhodopsin, ▶retinoic acid, ▶color vision, ▶color blindness, ▶navigation; Yokoyama S, Radlwimmer FB 1999 Genetics 153:919.

Opsonins: These trigger phagocytosis by the scavenger macrophages and neutrophils. These substances bind to antigens associated with immunoglobulins IgG and IgM and facilitate the recognition of the antigen-antibody complexes by the defensive scavenger cells. Also, they may bind to the activated complement of the antibody and assist in the recognition of the cell surface antigens and thus mediate their destruction. ▶antibody, ▶complement, ▶immunoglobulins, ▶macrophage, ▶neutrophil; Moghimi SM, Patel HM 1988 FEBS Lett 233:143.

Opsonization: Foreign invaders of the cells are coated by opsonins to facilitate their destruction by phagocytosis. ▶opsonin, ▶phagocytosis; Mevorach D 2000 Ann NY Acad Sci 926:226.

Optic Atrophy: This is determined either by autosomal dominant, recessive (early onset types) or X-linked or mitochondrial defects of the eye, the ear and other peripheral nerve anomalies. OPA1 gene in 28 exons encodes a dominant optic atrophy at human chromosome 3q28-q29. Its product is a 960-amino acid dynamin-like protein localized in the mitochondria. The prevalence of OPA1 is 5×10^{-4} . ▶Behr's syndrome, ▶night blindness, ▶Leber optic atrophy, ▶Kearn-Sayre syndrome, ▶Wolfram syndrome, ▶mitochondrial disease in humans, ▶myoclonic dystrophy, ▶eye diseases, ▶color blindness, ▶dynammin, ▶methylglutaconic aciduria; Pesch UEA et al 2001 Hum Mol Genet 10:1359.

Optical Density: ▶O.D.

Optical Mapping: This may be used for ordering restriction fragments of single DNA molecules. The fragments are stained by fluorochrome(s) and the restriction enzyme-generated gaps can be visualized. The contigs are assembled automatically by using the Gent algorithm. Most of the optical mapping procedures are useful only for mapping small genomes. An adaptation of these principles for the assembly of very large genomes is also available (Valuev A et al 2006 Proc Natl Acad Sci USA 103:15770). ▶physical mapping, ▶mapping genetic, ▶FISH, ▶Gent algorithm; Lin J et al 1999 Science 285:1558; Aston C et al 1999 Trends Biotechnol 17:297.

Optical Rotatory Dispersion: Denotes a variation of optical rotation by the wavelength of polarized light; it depends on the difference in refractive index between left-handed and right-handed polarized light. The rotation is measured as an angle. It is similar to circular dichroism. ▶base stacking, ▶circular dichroism

Optical Scanner: A device that generates signals from texts, diagrams, pictures, electrophoretic patterns, autoradiograms, etc. that can be then read or printed out with the assistance of a computer.

Optical Tweezer: This consists of a special laser beam linked to a microscope system. It facilitates the manipulation of cell membranes, protein folding, DNA condensation, structure of chromosomes, etc. ▶ [scanning force spectroscopy](#); Hayes JJ, Hansen JC 2002 Proc Natl Acad Sci USA 99:1752; Grier DG 2003 Nature [Lond] 424:810.

Optimon: This DNA unit avoids recombination and is preserved as such during evolution.

Opus: ▶ [copia](#)

OR: ▶ [odds ratio](#), ▶ [lod score](#)

Oral Bacterial Films: The human oral cavity and the gut may be inhabited by more than 500 different taxa. These microorganisms cause tooth decay, gingival bleeding and other health problems. ▶ [microbiome](#), ▶ [gut](#), ▶ [Helicobacter](#); Kolenbrander PE 2000 Annu Rev Microbiol 54:413; Hooper LV, Gordon J I 2001 Science 292:1115.

Oral-Facial-Digital Syndrome: ▶ [orofacial-digital syndrome](#)

Orange (*Citrus aurantium*, $2n = 18$): This is a common fruit tree. Botanically, the peel of the fruit is the pericarp, containing at the lower face the fragrant oil glands. The juice sacs are enclosed by the carpels, containing the seeds. ▶ [navel orange](#)

ORC (origin recognition complex): This six subunit complex (including Rap1 and Abf1 silencers) is required before DNA replication can begin in the eukaryotic cell. The N-terminal domain of Orc1 protein (the largest subunit) interacts with Sir1 and Sir1 mediates the recruitment of the other Sir proteins. Sir2 is a NAD-dependent histone deacetylase and Sir3 and Sir4 play structural roles. Sir3 and Sir4 interact with Rap1 and bind the N-terminal ends of histones H3 and H4 and control the epigenetic mechanism of sex determination in yeast and chromatin remodeling (Hsu H-C et al 2005 Proc Natl Acad Sci USA 102:8519). In yeast the ORC binds to the autonomously replicating sequence (ARS). During a cell cycle replication can be initiated only once but hundreds of sites of replicational origin exist. The ORC may place the nucleosomes at the DNA replication initiation site to facilitate the process. The ORC also mediates sister chromatid cohesion in yeast (Shimada K, Gasser SM 2007 Cell 128:85). In budding yeast the ORC complex and Cdc6 in the presence of a tandem array of GAL4 binding site in a plasmid is sufficient for the initiation of replication

from this artificial construct (Takeda DY et al 2005 Genes Dev 19:2827).

The replication cannot begin before the *origin of licensing* is created in the M phase with the participation of the MCM protein(s). This is followed by the *origin of activation* in the S phase. Both these steps are controlled by the ORC. Protein subunit ORC2 (Orp2 in fission yeast) apparently interacts with Cdc2, Cdc6 and Cdc18 proteins that regulate replication. The ORC is required for silencing the *HMRa* and *HMLa* loci of yeast, involved in mating type determination. The ORC homolog of *Drosophila* is DmORC2. Budding yeast genome appears to have ~429 replication origins. The replication origins in *Schizosaccharomyces pombe* are quite different from the same functional elements in budding yeast. They are mainly in intergenic regions, rich in AT (~70%) sequences (Dai J et al 2005 Proc Natl Acad Sci USA 102:337). ▶ [replication](#), ▶ [Cdc2](#), ▶ [Cdc18](#), ▶ [mating type determination in yeast](#), ▶ [HML](#), ▶ [HMR](#), ▶ [ARS](#), ▶ [MCM](#), ▶ [replication licensing factor](#), ▶ [ARS](#), ▶ [cell cycle](#), ▶ [Rap1](#), ▶ [Abf1](#), ▶ [histone deacetylase](#), ▶ [nucleosomes](#), ▶ [cohesin](#), ▶ [sister chromatid cohesion](#); Lipford JR, Bell SP 2001 Mol Cell 7:21; Vashee S et al 2001 J Biol Chem 276: 26666; Dhar SK et al 2001 J Biol Chem 276:29067; Gilbert DM 2001 Science 294:96; Wyrick JJ et al 2001 Science 294:2357; Fujita M et al 2002 J Biol Chem 277:10345.

Orchard Grass (*Dactylis glomerata*): A shade and drought-tolerant forage crop, $2n = 28$.

Orchids (*Orchideaceae*, $2n = 20, 22, 34, 40$): These are monocotyledonous tropical ornamentals.

Ord: 55-kDa chromosomal protein with a role in chromatid cohesion. ▶ [sister chromatid cohesion](#); Bickel SE et al 1998 Genetics 150:1467.

Order: A taxonomic category above *family* and below *class*, e.g., order of primates within the class of mammals.

Ordered Tetrad: The spores in the ascus represent the first and second meiotic divisions in a linear sequence such as A A a a . ▶ [tetrad analysis](#)

Figure O18. Ordered tetrad

Orestes: Contraction of the words open reading frames + EST (expressed sequence tags). The procedure is aimed at sequencing mid-portions of the genes in contrast to ESTs which deal with either 5' or 3' ends. ORESTES may help in the annotation of the genomes. By 2001 700,000 ORF tags were available for the definition of the human proteome. ▶ [ORF](#),

►EST, ►proteome; de Souza SJ et al 2000 Proc Natl Acad Sci USA 97:12690; Camargo AA et al 2001 Proc Natl Acad Sci USA 98:12103.

Orexin A and B (hypocretin): Appetite-boosting peptides synthesized in the lateral hypothalamus area of the brain. Their aberrant splicing (caused by insertional mutation) may lead to narcolepsy. Their G-protein coupled receptors are Hcrtr-1 and -2. Hcrtr-2 was assigned to human chromosome 17q21. Orexins also regulate the sleep-wake cycles in neurodegenerative diseases, and drug (e.g., cocaine) and food reward. ►leptin, ►obesity, ►narcolepsy; Scammell TE 2001 Curr Biol 11:R769; Petersen A et al 2005 Hum Mol Genet 14:39; Harris GC et al 2005 Nature [Lond] 437:556.

ORF: Denotes open reading frame, i.e., the nucleotide sequences between the translation initiator and the translation terminator codons, e.g., AUG →→→→→→→→ UAG. ►cORF, ►hORF, ►kORF, ►qORF, ►sORF, ►tORF, ►OST, ►Gateway cloning; Snyder M Gerstein M 2003 Science 300:248.

Orfome (ORFeome): The collection of all defined open reading frames of an organism (Harrison PM et al 2002 Nucleic Acids Res 30:1083). ►Gateway cloning

Organ: A body structure destined to a function.

Organ Culture: Refers to growing organs in vitro to gain insight into function, differentiation and development. Plant organ cultures, such as propagating roots, stem tips and embryos under axenic conditions on synthetic media are known for decades. More recently, research has focused on generating human tissues and organs as replacements in case of injury or disease. The organs generated from the patients' own tissues avoid some of the problems of graft rejection. Since 1997 the US Food and Drug Administration has approved the clinical use of cultured cartilage. Laboratory production of blood vessels, bladder, cardiovascular tissues and even kidneys and livers is expected. Usually, researchers employ biodegradable polymer scaffolds (polyglycolic acid, polylactide) to permit the development of thicker cell layers permeable to nutrients. ►tissue culture, ►grafting in medicine, ►stem cells

Organelle: Refers to intracellular bodies, such as the nucleus, mitochondria and plastids. The division of plastids requires – among other proteins – FtsZ and DRP. The division of the mitochondria does not require an ancestral prokaryotic system but relies on DRP and other proteins. Both these organelles universally require dynamin-related guanosine triphosphatases for division (Osteryoung KW, Nunnari J 2003 Science 302:1698).

The term organelle is also used for specialized protein complexes. Earlier no bacterial organelles were detected. Recently, membrane-enclosed acidocalcisomes have been identified in *Agrobacterium tumefaciens* (Seufferheld M et al 2003 J Biol Chem 278:29971) that are similar to the acidic calcium storage compartments of some unicellular eukaryotes (trypanosomas, apicomplexan parasites, algae and slime molds). In *Arabidopsis* the number of proteins localized in different organisms was as follows: endoplasmic reticulum 182, Golgi apparatus 89, plasma membrane 92, vacuoles 24, mitochondria and plastids 140 and 162 to unknown sites (Dunkley TPJ et al 2006 Proc Natl Acad Sci USA 103:6518). These numbers are probably much lower than the actually figures. A map of the mouse liver reveals 10 subcellular locations of 1,404 proteins (Foster LJ et al 2006 Cell 125:187). ►nucleus, ►mitochondria, ►chloroplast, ►apicoplast, ►FtsZ, ►DRP, ►dynamin, ►*Agrobacterium*, ►*Trypanosoma*, ►slime mold, ►evolution of organelles, ►tissue-specificity; origin of organelles: Dyall SD et al 2004 Science 304:253; genomes: <http://megasun.bch.umontreal.ca/gobase/>; protein database: <http://organelledb.lsi.umich.edu/>; protein map in organelles: <http://proteome.biochem.mpg.de/ormd.htm>; mitochondrial and chloroplast genome database: <http://gobase.bcm.umontreal.ca/>.

Organelle Genetics: ►mitochondrial genetics, ►chloroplast genetics, ►sorting out, ►Golgi, ►gobase

Organelle Sequence Transfers: During evolution sequences homologous among the major organelles were transferred in the direction shown (see Fig. O19). In budding yeast mtDNA sequences may be regularly transferred to the nucleus during double-strand break repair. In the 2nd chromosome of *Arabidopsis* 135 genes appear to be of chloroplast origin. In the centromeric region of the same chromosome of one *Arabidopsis* ecotype ~618-kb appears identical to part of the mitochondrial genome (Stupar RM et al 2001 Proc Natl Acad Sci USA 98:5099). The organelle genomes (mitochondrial, plastidic) are adopted by initial symbiosis. The complete genomes of the originally free-living organisms were not retained during evolution, some were lost and others were redistributed among the organelles. Some of the genes were apparently sequestered into the organelles in order to assure a homeostatic balance in the redox potential. Approximately 18% of the nuclear protein-coding genes of *Arabidopsis* appear to be acquired from the cyanobacterial ancestors of the plastids (Martin W et al 2002 Proc Natl Acad Sci USA 99:12246). Enhanced production of reactive oxygen—by metabolic accident—may kill the sensitive cells unless the damage is readily corrected at the origin. A survey

277 genera of angiosperm plants indicated that the ribosomal protein gene, *rps10*, has been transferred from the mitochondrion to the nucleus at a very high rate during evolution and this probably still continues in plants but not in animals. The transfer of functional genes from the mitochondria to the nucleus seems to be more common in selfing or clonal plants than in outcrossing plants. It has been suggested that selfing and vegetative reproduction conserve adaptive mitochondrial – nuclear gene combinations, allowing functional transfer, whereas outcrossing prevents transfer by breaking up these combinations (Brandwain Y et al 2007 Science 315:1685).

Figure O19. Organelle sequence transfer

Nuclear mutations in yeast control the escape of mitochondrial DNA into the nucleus (Thorsness PE Fox TD 1993 Genetics 134:21). The process is mediated by zinc-dependent mitochondrial protease (Weber ER et al 1996 Mol Biol Cell 7:307). There are interactions between organellar and nuclear functions without the actual transfer of genetic material (Traven A et al 2001 J Biol Chem 276:4020). Microarray hybridization revealed that in the petite strains of yeast (devoid of mitochondrial DNA), the expression of several nuclear genes (citrate synthase, lactate dehydrogenase, etc.) is altered. The petite strains exhibited increased resistance to heatshock and pleiotropic drug resistance. The rate of transfer of genes from the mitochondria to the nucleus appears to be within the range of 2×10^{-5} and from the plastid to the nucleus is about 6×10^{-5} per cell generations. The potential expression of organellar genes within the nucleus depends of the nature of the promoters. Prokaryotic type organelle promoters may not function at nuclear locations. Some of the aminoacyl-tRNA synthases (24 known) can be shared between mitochondria and chloroplasts (~15) and 5 are shared between the cytosol and mitochondria and one also present in the chloroplasts (Duchène A-M et al 2005 Proc Natl Acad Sci USA 102:16484). The phototrophic unicellular ciliate protozoan *Myrionecta rubra*/*Mesodinium rubrum* can intake chloroplasts, mitochondria and nuclei from the cryptomonad alga *Geminigera cryophila* and these organelles can

survive and function up to 30 days within the predator (Johnson MD et al 2007 Nature [Lond] 455:426). ▶mobile genetic elements, ▶chloroplasts, ▶mtDNA, ▶double-strand break, ▶nupt, ▶numts; Race HL et al 1999 Trends Genet 15:364; Adams KL et al 2000 Nature [Lond] 408:354; Blanchard JL, Lynch M 2000 Trends Genet 16:315; Hedtke B et al 1999 Plant J 19:635; Adams KL et al 2002 Plant Cell 14:931; Huang CY et al 2003 Nature [Lond] 422:72; Martin W 2003 Proc Natl Acad Sci USA 100:8612; Timmis JN et al 2004 Nature Rev Genet 5:123; <http://megasun.bch.umontreal.ca/gobase/gobase.html>.

Organelles: These are membrane-enclosed cytoplasmic bodies such as the nucleus, mitochondrion, plastid, Golgi and lysosome. See under separate entries, ▶organelle, ▶organelle sequence transfer; organelle protein database of several eukaryotes: <http://organelledb.lsi.umich.edu/>.

Organic: A carbon containing compound or something associated with a metabolic function.

Organic Evolution: Refers to the historical development of living beings in the past and present times. ▶geological time periods

Organismal Genetics: Studies inheritance in complete animals and plants by biological means and does not employ molecular methods or the tools of reversed genetics. ▶reversed genetics, ▶inter-organismal genetics

Organizer (Spemann organizer): The dorsal lip of the blastopore (an invagination that encircles the vegetal pole of the embryo) becomes a signaling center for differentiation (see Fig. O20). The formation of the organizer is preceded by induction of the mesoderm cell layer, resulting in the expression of organizer-specific homeobox genes and transcription of genes coding for signal molecules. This is followed by recruitment of the neighboring cells into the axial mesoderm and neural tissues. Several of the nuclear genes responsible for the component of the organizer have been identified by genetic and molecular means. The organization is controlled by proteins such as Wnt that determine the body axis and anterior posterior development. Activin and fibroblast growth factor (FGF) involve signal reception to organize the formation of the mesoderm or by noggin that controls dorsal/ventral differentiation. Chordin affects the development of the notochord, and follistatin is an antagonist of activin, etc. Chordin and noggin are also required for the development of the forebrain. These proteins apparently bind to and antagonize the BMP protein of vertebrates (homologous to decapentaplegic of *Drosophila*). The organizer may show some

Figure O20. Organizer

additional variations in different species. It is diagrammatically not possible to represent correctly the complexity of the embryonal differentiation, which involves thousands of genes directly and indirectly. The discovery of the organizer by Hans Spemann and co-workers in the 1920s is considered a major milestone in experimental embryology and in recognition of his work Spemann was awarded the Nobel Prize in 1935. This line of research initiated a new series of inquiries in “chemical embryology” and became the focus of contemporary molecular biology. Many of the genes involved in embryonic induction, regulation of differentiation and development have now been cloned. The discovery of new techniques based on genetics, immunology, radioactive tracers, fluorochromes, microarray hybridization, scanning electron microscopy, etc., coupled with genetic transformation will provide the answer to the most basic problems of development and the nature of disease, cancer, etc. The *Gooseoid* homeobox transcription factor of the organizer promotes tumor cell malignancy and indicates that other conserved organizer genes may function similarly in metastasis of human cancer (Hartwell KA et al 2006 Proc Natl Acad Sci USA 103:18969). ▶vegetal pole, ▶animal pole, ▶morphogenesis, ▶gastrula, ▶epiblast, ▶homeobox, ▶homeotic genes, ▶signal transduction, ▶LIM, ▶BMP, ▶FGF, ▶decapentaplegic, ▶activin, ▶follistatin, ▶bone morphogenetic protein, ▶noggin, ▶pattern formation, ▶induction, ▶signal transduction, ▶primitive streak, ▶left-right asymmetry, ▶Spemann organizer, ▶self-regulation, ▶metastasis; Harland R Gerhart J 1997 Annu Rev Cell Dev Biol 13:611; De Robertis EM et al 2000 Nature Revs Genet 1:171; Shilo B-Z 2001 Cell 106:17; Lee HX et al 2006 Cell 124:147; Yu J-K et al 2007 Nature [Lond]445:613.

Organogenesis: The development of organs from cells differentiated for special purposes.

Organophosphates: These are common ingredients of insecticides and biological warfare agents such as sarin, soman and paraoxon. Their acute toxicity is due to irreversible inhibition of acetylcholinesterase, an enzyme that inactivates the neurotransmitter acetylcholine. Galanthamine (see Fig. O21), a reversible inhibitor, when administered in combination with atropin to guinea pigs provides effective protection soon after exposure to organophosphates (Albuquerque EX et al 2006 Proc Natl Acad Sci USA 103:13220). Goats transgenic for recombinant butyrylcholinesterase produced active rBChE in milk, sufficient for prophylaxis of humans at risk for exposure to organophosphate agents (Huang Y-J et al 2007 Proc Natl Acad Sci USA 104:13603). ▶acetylcholinesterase, ▶acetylcholine, ▶sarin, ▶insecticide resistance

Figure O21. Galanthamine

ori: Refers to origin of replication. ▶DNA replication, ▶replication, ▶plasmid ori_T, ▶ori_V

oriC: This gene controls the origin of replication in *E. coli* and binds the replication proteins DnaA and

DnaB. ►DNA replication in prokaryotes, ►DnaA, ►DnaB; Margulies C, Kaguni JM 1996 J Biol Chem 271:17035.

Orientation, Magnetic: Determines the light-dependent migration of birds during autumn and spring. Photon absorption leads to the formation of radical pairs and the avian compass responds to the intensity of light. However, the fixed direction in migratory orientation depends on another mechanism (Wiltschko R et al 2005 Current Biol 15:1518)

Orientation Selectivity: The majority of transposases work well only in one orientation. Accessory proteins associated with the transposases choose this orientation. It is synonymous with the directionality of transposons. ►transposable elements, ►transposons

Origin of Life: The prebiotic evolution laid down the foundations for the origin of life ►evolution prebiotic, ►evolution of the genetic code. The following steps may have been involved in this process: 1. generation of organic molecules, 2. polymerization of RNA, capable of self-replication and heterocatalysis (cf. ribozymes), 3. peptide synthesis with the assistance of RNA, 4. the evolution of translation and polypeptide assisted replication and transcription, 5. reverse transcription of RNA into DNA, 6. the development of DNA-RNA-Protein auto- and heterocatalytic systems, 7. the sequestration of this complex into organic micellae formed by fatty acid - protein membrane-like structures, 8. the appearance of the first cellular organisms about 3–4 billion years ago, and 9. the development of photosynthesis and autonomous metabolism. According to some estimates, the starter functions of life may have been carried out by as few as 20–100 proteins. The extensive duplications in all genomes may be an indication that the early enzymes did not have strong substrate specificity. The minimal cellular genome size may have been comparable to that of *Mycoplasma genitalium*, 580-kb long and coding 482 genes. The time required to develop from the 100-kb genome to a primitive heterotroph cyanobacterium with 7,000 genes may have taken about 7 million years. Life originated on earth about 3.2 billion years ago (Nofke N et al 2006 Geology 34:253). ►spontaneous generation unique or repeated, ►exobiology, ►geological time periods, ►evolution of the genetic code; Nisbet EG, Sleep NH 2001 Nature [Lond] 409:1083; Rotschild LJ, Mancinelli RL 2001 ibid:1092; Carroll SB 2001 ibid. 1102; Hanczyc MM et al 2003 Science 302:618.

Origin of Replication: This is the starting point of replication during cell proliferation. ►replication

Origin of Species: This is the title of a book by Charles Darwin, first published in 1859. The book is one of the most influential works on human cultural history. Darwin recognized the role of natural selection in evolution. Although he did not understand the principles of heredity (this book was published 7 years prior to the paper of Mendel). With the development of modern concepts of heredity, cytogenetics, population genetics and molecular biology, the seminal role of this book became generally recognized and appreciated even from a sesquicentennial distance. ►Darwinism, ►evolution

Origin Recognition Element (ORE): This is the DNA site where proteins that initiate replication bind. ►replication fork

Origins: These are the processors of environmental perturbations in transcriptional networks. Origins are sub-networks originating in a single transcription regulatory network. A pleiotropic regulator controls all nodes in *modulons*. *Simulons* include all nodes affected by an environmental signal and are composed of all origins rooted in transcription factors sensitive to the signal. ►networks, ►genetic networks, ►modulon; Balázs G et al 2005 Proc Natl Acad Sci USA 102:7841.

ori_T: This refers to the origin of transfer of the bacterial plasmid. Its A=T content is higher than the surrounding DNA. It has recognition sites for a number of conjugation proteins. It contains promoters for the *tra* genes that are localized in such a way that only after the complete transfer of the plasmid can all of them be transferred. The transfer of the single strand proceeds in 5'→3' direction in all known cases, including the transfer of T-DNA to plant chromosomes. The 3' end can accept added nucleotides. After the transfer has terminated, the plasmid re-circularizes. All these processes require specific proteins. ►bom, ►conjugation, ►T-DNA

Ori_v: Refers to the origin of vegetative replication that is used during cell proliferation of bacteria.

Ornithine (NH₂[CH₂]₃CH[NH₂]COOH): A non-essential amino acid for mammals. It is synthesized through the urea cycle. ►urea cycle

Ornithine Aminotransferase Deficiency (hyperornithinemia, OAT): Ornithine is derived either from arginine or *N*-acetyl glutamic semialdehyde or glutamic semialdehyde, and carbamoylphosphate synthetase converts it to citrulline. The decarboxylation of ornithine (a pyridoxalphosphate [vitamin B₆] requiring reaction) yields polyamines such as spermine and spermidine. OAT deficiency causes ornithinemia, 10–20 times increase of ornithine in blood plasma, urine and other body fluids. It also leads to

the degeneration of eye tissue and tunnel vision and night blindness by late childhood. Restricted ornithine diet may prevent eye defects due to deficiency of the γ -chain. The OAT locus (21-kb, 11 exons) is in human chromosome 10q23qter and its mutation blocks the metabolic path between pyrroline-5-carboxylate and ornithine. Pseudogenes are at Xp11.3-p11.23 and at Xp11.22-p11.21. ▶amino acid metabolism, ▶urea cycle, ▶ornithine transcarbamylase deficiency, ▶ornithine decarboxylase, ▶ornithine transcarbamylase deficiency, ▶pseudogene, ▶hyperornithinemia, ▶nicotine

Ornithine Decarboxylase (ODC): The dominant allele (human chromosome 2p25, mouse chromosome 12, in *E. coli* 63 min) controls the ornithine→putrescine reaction and its activity is very sensitive to hormone levels. There is a second ODC locus in human chromosome 7 but the latter has a reduced function. Elevated levels of ODC may be indicative of skin tumorigenesis. ▶amino acid metabolism, ▶ornithine aminotransferase deficiency, ▶antizyme

Ornithine Transcarbamylase Deficiency (OTC): This X-linked (Xp21.1) enzyme normally expressed primarily in the liver mitochondria, catalyzes the transfer of a carbamoyl group from carbamoyl phosphate to citrulline and ornithine is made while inorganic phosphate is released (see Fig. O22). The defect may lead to an accumulation of ammonia (hyperammonemia) because carbamoyl phosphate is generated from NH_4^{4+} and HCO_3^- (in the presence of 2 ATP). The high level of ammonia may cause emotional problems, irritability, lethargy, periodic vomiting, protein avoidance and other anomalies. Na-benzoate, Na-phenylacetate and arginine may mediate the plasma ammonium level. The incidence of OTC deficiency in Japan was found to be about 1.3×10^{-3} . In mice an OTC deficiency mutation is responsible for the *spf* (sparse fur) phenotype. This single gene metabolic defect may be corrected by somatic gene therapy. Unfortunately, one of the initial attempts using a very high dose of adenoviral vector (6×10^{14} particles/kg) ended in an unexpected fatal immune reaction in Jesse Gelsinger in 1999. ▶amino acid metabolism, ▶ornithine aminotransferase, ▶ornithine decarboxylase, ▶channeling, ▶hyperammonemia

Figure O22. Carbamoyl phosphate

Ornithine Transporter: ▶urea cycle

Orofacial-Digital Syndrome (OFD): OFD I is a dominant Xp22-linked or a recessive autosomal syndrome. The

dominant form is lethal in males. OFD I is characterized by loss of hearing and polydactyly of the great toe, mental retardation, face and skull malformation, cleft palate, brachydactyly (short fingers and toes), defective kidney cysts, etc. (Ferrante MI et al 2006 Nature Genet 38:112). OFD II (Mohr syndrome) is characterized by polysyndactyly, brachydactyly [short digits] and lobate tongue. OFD III and OFD IV include mental retardation, eye defects, teeth anomalies, incomplete cleft palate, hexadactyly, hunchback features, etc. OFD IV is distinguished on the basis of tibial dysplasia (shinbone defects). OFD V (Váradí-Papp syndrome) also includes a nodule on the tongue and neural defects, etc. ▶polydactyly, ▶limb defects, ▶mental retardation, ▶Majewski syndrome; Ferrante MI et al 2001 Am J Hum Genet 58:569.

Orosomucoid: There are two orosomucoid (serum glycoprotein) genes in humans, ORM1 and ORM2 in 9q31-q32. (See Yuasa I et al 2001 J Hum Genet 46(10):572).

Orotic Acid:

Figure O23. Orotic acid monohydrate

0

Oroticaciduria: This is a recessive deficiency of the enzyme orotidylate decarboxylase, encoded at human chromosome 3q13 or a deficiency of orotate phosphoribosyl transferase. Rare human diseases have their counterparts in other higher eukaryotes. The clinical symptoms include anemia with large immature erythrocytes and urinary excretion of orotic acid (see Fig. O24). The administration of uridylate and cytidylate alleviates the symptoms. Homologous mutations have been detected in cattle. ▶orotic acid

Figure O24. Orotate in the pyrimidine pathway

Orphan Genes: These are open reading frames in yeast (about 1/3 of the ORFs) that cannot be associated with known functions (FUN genes) and do not seem to have homologs in other organisms. With advancing information their number is expected to decline. ▶ORF, ▶*Saccharomyces*, ▶fun genes; Enmark E Gustafsson JA 1996 Mol Endocrinol 10:1293; Brenner S 1999 Trends Genet 15:132.

Orphan Receptor: This has either no known ligand or it has the ligand-binding domain but lacks the conserved DNA binding site. ▶nuclear receptors, ▶receptor; Xie W Evans RM 2001 J Biol Chem 276:37739.

Orphanin: ▶opiate

Orphon: This is a former member of a multigene family, but at a site separate from the cluster, and contains one coding region or they are pseudogenes. ▶gene family, ▶pseudogene

Orthogenesis: Evolution follows a straight line toward a goal or proceeds along a predetermined path rather than being influenced by Darwinian selection.

Orthogonal-Field Alternation Gel Electrophoresis: ▶OFAGE

Orthogonal Functions: These can be employed for comparisons between observed data which have not affected each other.

Orthogonal mRNAs: The suppressor tRNA is not a substrate for endogenous aminoacyl-tRNA synthetases, and the mutant aminoacyl-tRNA synthetase aminoacylates only the suppressor tRNA with an unnatural amino acid but no other tRNA. Such a system facilitates the incorporation of unnatural amino acids into peptides. ▶unnatural amino acids

Orthologous Loci: These genes are in the direct line of evolutionary descent from an ancestral locus, e.g., 1,000 genes in *Bacillus subtilis* are similar to those in *Escherichia coli*, indicating the common ancestry. Among the eukaryotes, *Saccharomyces cerevisiae* and *Caenorhabditis elegans* ~57% of the protein pairs of the two organisms are represented by just one from each of these organisms. Intermediary metabolism (in 28%), DNA and RNA synthesis and function (in 18%), protein folding and degradation (in 13%), transport and secretion (in 11%) and signal transduction (in 11%) are carried out by genes preserved through evolution from a common origin in these two eukaryotes. ▶paralogous loci, ▶duplications, ▶evolution of proteins, ▶non-orthologous gene displacement, ▶xenology, ▶homolog, ▶orthologous proteins, ▶genome projects, ▶comparative genomics, ▶constrained elements; Koonin EV 2005 Annu Rev Genet 39:309; <http://www.ncbi.nlm.nih.gov/COG>; orthologous groups of 17 eukaryotes: <http://inparanoid.cgb.ki.se/>; human-mouse orthologous miRNA gene homologies <ftp://ftp.ncbi.nih.gov/pub/HomoloGene/>; http://www.informatics.jax.org/searches/homology_form.shtml; orthologs in 9 eukaryotes: http://www.sanger.ac.uk/PostGenomics/S_pombe/YOGY/; ortholog server: <http://oxytricha.princeton.edu/BlastO/>.

Orthology: Refers to common ancestry in evolution. ▶orthologous loci, ▶paralogy

Orthostitchies: ▶phyllotaxis

Orthotopic: This means in normal position. ▶ectopic

Oscillator: This molecular mechanism generates the circadian rhythm, heart, neuronal and other cellular functions. The bursts of cell divisions oscillate between pauses and transcription of genes within the entire genome displays temporal clusters. In baker's yeast cell suspensions with billions of cells show synchronized metabolic oscillations in NADH fluorescence with a period of duration around one half minute (see Fig. O25). Acetaldehyde and glucose (if the glucose transporters are open) are oscillators. The oscillation indicates that the cells are in communication (Danø S et al 2007 Proc Natl Acad Sci USA 104:12732). ▶circadian rhythm, ▶quantized, ▶repressilator, ▶entrainment, ▶gene-switch cassette, ▶gene circuits; Goldbeter A 2002 Nature [Lond] 420:238; Klevecz RR et al 2004 Proc Natl Acad Sci USA 101:1200, Farré EM et al 2005 Current Biol 15:47; Fung E et al 2005 Nature [Lond] 435:118.

Figure O25. Schematic representation of metabolic oscillations. Enzymes E1 and E2, respectively turned on (arrow) or off (bar). The substrates and products are represented by shaded ovals

Oscillin: This is a protein formed in the egg after penetration by the sperm, and it is involved with the oscillation of the level of Ca^{2+} . It is apparently involved in triggering the early development of the embryo. (See Nakamura Y et al 2000 Genomics 68(2):179).

Osha: This is the acronym for Occupational Safety and Health Administration which is based in the USA. It provides information about and protects against potential hazards involved in laboratory and industrial operations.

Oskar (*osk*, 3–48): *Drosophila* homozygous females and males are normally viable and fertile. The embryos produced by the homozygous females lack pole plasm, the abdominal segments do not form and the embryos die (see Fig. O26). The *osk* mRNA appears in the posterior of the embryo. Kinesin I facilitates the transport of *oskar* and *Staufen* mRNAs along the microtubules and the Mago Nashi (Kataoka N et al 2001 EMBO J 20:6424) and Y14 proteins (Hachet O, Ephrussi A 2001 Curr Biol 11:1666) are involved in the splicing of the pre-mRNA (Palacios IM 2002 Curr Biol 12:R50). Translation initiation factor eIF4E-binding protein Cup interacts with silencing protein Bruno and inhibits translation. The large (50S-80S) silencing particle involving the oligomerized mRNA cannot be accessed by the ribosomes although it may be advantageous for mRNA transport (Chekuleava M et al 2006 Cell 124:521). ▶eIF-4E

Figure O26. Oskar

Osler-Rendu-Weber Syndrome: ▶telangiectasia hereditary hemorrhagic

Osmiophilic: This readily stains by osmium or osmium tetroxide.

Osmium Tetroxide (OsO_4): This is a fixative for electron microscopic specimens. ▶fixatives, ▶microscopy

Osmolarity: Refers to the osmotic pressure of a solution as the molarity of dissociated particles.

Osmosis: This is a process by which water passes through a semipermeable membrane toward another compartment (cell) where the concentration of solutes is higher. The osmo-sensing signal seems to be mediated by the Jnk protein kinase, a member of the mitogen-activated large family of proteins in mammals. In bacteria, a histidine kinase sensor (EnvZ) and a transcriptional regulator (OmpR) are involved. In yeast a similar mechanism is implicated, also involving HOG-1. ▶HOG-1, ▶histidine kinase, ▶HSP

Osmotic Pressure: In two compartments separated by a semipermeable membrane the solvent molecules pass toward the higher concentration of solutes. This

flow may be prevented by applying high pressure to the compartment toward which the flow is directed. Osmotic stress may regulate the expression of genes as a homeostatic control. (See Xiong L et al 2002 J Biol Chem 277:8588)

Osmotin: Refers to protein in plants that may accumulate at high concentrations of salts. It is a homolog of mammalian adiponectin, which regulates lipid and sugar metabolism. ▶adiponectin; Narasimhan M L et al 2005 Mol Cell 17:171.

O-Some: A nucleosome-like structure of lambda phage involved in DNA replication. It is formed from dimeric λO (lambda origin) protein-coding sequences and four inverted repeats. During the beginning of replication the dimer of λP (λ promoter) and a hexamer of DnaB forms $\text{ori}\lambda\sim\lambda\text{O}\sim(\lambda\text{P}\sim\text{DnaB})_2$ which gives rise to the pre-primosomal complex. ▶lambda phage, ▶nucleosome, ▶DNA replication prokaryotes, ▶primosome; Zyllicz M et al 1998 Proc Natl Acad Sci USA 95:15259.

OSP: ▶allele-specific probe for mutation

OSP94: ▶HSP

Ossification of the Longitudinal Filaments of the Spine:

This common disorder in humans (over 3% above the age of 50) is caused by ectopic bony development of the spinal muscles. In mice, defects in the nucleotide pyrophosphatase (*Npps*, chromosome 10), which regulates soft tissue calcification and bone mineralization by producing inorganic phosphate, seem to be a major factor.

OST: This is an open reading frame tagged by EST. ▶EST, ▶Gateway cloning

Osteoarthritis: A common human affliction involving degeneration of the cartilage, caused by the replacement of the $[\alpha 1(\text{II})]$ collagen by αII chains with reduced glycosylation. Several gene loci at 4q26, 7p15, 2q12, 11q and others are involved. More than 70% of the US population over 65 years of age may be afflicted to varying degrees. GDF5 (growth and differentiation factor) or CDMP1 (cartilage-derived morphogenetic protein 1) is a member of the transforming growth factor (TGF) superfamily and is closely related to bone morphogenetic proteins (BMPs). GDF5 is expressed in the regions of future joints during early development, and mutations in both mouse and human *GDF5* cause abnormal joint development and is a factor in the development of osteoarthritis (Myamoto Y et al 2007 Nature Genet 39:529). ▶collagen, ▶arthritis; Stefánson SE et al 2003 Am J Hum Genet 72:1448.

Osteoblast: This is a cell involved in bone production from mesenchymal progenitor and is positively

controlled in the mouse mainly by genes CBFA-1. Gene Hoxa-2 and leptin are negative regulators. Osteoblast and skeletal differentiation are mediated by Runx2 and ATF4 transcription factors, controlled by SATB2 (Dobrev G et al 2006 Cell 125: 971). ▶osteoclast, ▶ATF, ▶RUNX, ▶mesenchyma, ▶ITAM; Olsen BR et al 2000 Annu Rev Cell Dev Biol 16:191; Science 2000 Vol. 289:1501–1514.

Osteocalcin (1q25-q31, three γ -carboxyglutamic acid, 5.9 kDa): This is an abundant, non-collagen type protein in the bones dependent on Ca^{2+} . It is involved in blood coagulation. In Neanderthal relics osteocalcin residues have been found which are similar to that observed in modern humans and modern primates (Nielsen-Marsh CM et al 2005 Proc Natl Acad Sci USA 102:4409).

Osteochondromatosis (dyschondroplasia, osteochondrodysplasia): An inhomogeneous group of autosomal dominant bone and cartilage defects encoded at 8q24 and 11p11-p12 and possibly at other sites. ▶spondyloepimetaphyseal dysplasia, ▶spondyloepiphyseal dysplasia, ▶Dyggve-Melchior-Clausen dysplasia

Osteochondroplasias (osteochondrodysplasias): These cartilage disorders are caused by defects in different collagen genes. ▶collagen, ▶chondrodysplasias

Osteoclastogenesis Inhibitory Factor (OCIF): ▶osteoprotegerin

0

Osteoclasts: These multinucleate cells mediate bone resorption. The osteoclast differentiation factor (ODF) receptor is TRANCE/RANK. The ITAM motif plus RANK ligand and macrophage colony stimulating factor are required for maintenance between bone formation and resorption (Koga T et al 2004 Nature [Lond] 428:758). ▶Paget disease, ▶TRANCE, ▶osteoblast, ▶bone morphogenetic protein, ▶RANK, ▶ITAM, ▶macrophage colony stimulating factor, ▶osteoporosis; Karsenty G 1999 Genes & Development 13:3037; Väänänen KH et al 2000 J Cell Sci 113:377; Motickova G et al 2001 Proc Natl Acad Sci USA 98:5798; Feder ME, Mitchell-Olds T 2003 Nature Rev Genet 4:649.

Osteogenesis Imperfecta (OI, 11q12-q13, [neonatal lethal] 17q21.3, [perinatal] 7q22.1): These are rare (prevalence 1/5,000 – 1/10,000) autosomal dominant or recessive disorders of collagen, resulting in abnormal bone formation due to mutation at numerous loci (ca. 17) that replace, e.g., a glycine residue by a cysteine. Such a substitution disrupts the Gly - X - Pro tripeptide repeats in collagen that assures the helical structure of the molecules. Type I (chromosome 17) is characterized by postnatal bone fragility, blue coloring of the eye white (sclera) and

ear problems. Type II (Vrolik type) generally involves dominant negative lethality at about birth time due to a variety of bone defects. Most of the cases are considered new dominant mutations. Type III may lead to prenatal bone deformities and the survivors are crippled. The symptoms may also include hearing loss. This may be either recessive or dominant. Type IV is characterized by a milder expression (17q21.3) of the similar symptoms than the other classes and may not prevent survival. The four types have defects in collagen genes COL1A1 or COL1A2. OI types V – VII have no mutations in collagen; the *fragilitas osseum* mutation of mouse leads to severe osteogenesis and dentinogenesis imperfecta because of deletion of sphingomyelin phosphodiesterase 3 (Aubin I et al 2005 Nature Genet 37:803). Cartilage associated protein (CRTAP) is required for prolyl 3-hydroxylation and its mutation causes OI (Morello R et al 2006 Cell 127:291). ▶collagen, ▶sphingomyelin, ▶dentinogenesis imperfecta, ▶hydrocephalus, ▶mitral prolapse, ▶connective tissue disorders, ▶dominant negative; Millington-Ward S et al 2002 Hum Mol Genet 11:2201.

Osteolysis: This group of diseases is characterized by bone resorption and osteoporosis controlled by several different loci. ▶bone diseases

Osteolysis, Familial Expansile: ▶Paget disease

Osteomalacia: ▶hypophosphatemia; Feng JQ et al 2006 Nature Genet 38:1310.

Osteonectin (5q31.3-q32): This is a glycine-rich protein involved in bone proliferation, formation of the extracellular cell matrix, repair, morphogenesis, etc.

Osteopenia: This condition is characterized by reduced bone mass. It may be due to defects in zinc transporter, ZNT5 resulting in defective maturation of osteoblasts to osteocytes (Inoue K et al 2002 Hum Mol Genet 11:1775)

Osteopetrosis: This condition is manifested in different forms and is controlled by autosomal dominant or recessive genes in humans. The recessive form at 11q13 may be due to defects in a 3-subunit osteoclast-specific proton pump encoded by ATP6i. Osteopetrosis (increased bone mass) with renal tubular acidosis is based on deficiencies in the carbonic anhydrase B or CA2 enzyme. The disease makes the calcified bones brittle. It generally involves mental retardation, visual problems, reduced growth, elevated serum acid phosphatase levels, and higher pH of the urine because of the excretion of bicarbonates and less acids in the urine. In the recessive Albers-Schönberg disease (16p13.3, 1p21), osteopetrosis causes reduction in the size of the head, deafness, blindness, increased liver size and anemia. Defects in

a colony stimulating factor (CSF) have been inferred from mouse experiments. A mild form of osteopetrosis is also known. A severe lethal form affects the fetus by the 24th week and may cause stillbirth. In mice and humans the loss of chloride ion channel (CIC-7, 16p13.3) leads to dominant osteopetrosis, i.e., Albers-Schönberg disease. ▶carbonic anhydrase, ▶osteoporosis, ▶TRANCE, ▶colony stimulating factor, ▶ion channels, ▶cathepsins; Lazner F et al 1999 Hum Mol Genet 8:1839; Kornak U et al 2001 Cell 104:205; Bénichou O et al 2001 Am J Hum Genet 69:647; Sobachi C et al 2001 Hum Mol Genet 10:1767; Lange PF et al 2006 Nature [Lond] 440:220.

Osteopoikilosis (BOS, Buschke–Ollendorf syndrome, 12q14): Refers to dominant, spotty (sclerotic) areas at the ends of bones and skin, as well as connective tissue lesions. (See Hellemans J et al 2004 Nature Genet 36:1213)

Osteopontin: This glycoprotein is produced by osteoblasts and is encoded in human chromosome 4q21–q25 at the SPP1 locus. Its expression is repressed by Hoxc-8 but Smad1 prevents Hoxc-8 from binding to the osteopontin promoter and facilitates its transcription. Osteopontin is also called Eta-1 (early T lymphocyte activation factor 1) because it is a ligand of CD44 and plays a role in cell-mediated immunity. Its deficiency severely impairs the immunity of mice to Herpes simplex virus 1 and bacterial (*Listeria monocytogenes*) infection. Osteopontin deficiency interacting with CD44 reduces the expression of IL-10. A phosphorylation-dependent interaction of Eta-1 and its integrin receptor stimulates IL-12. Osteopontin normally affects cell migration, calcification, immunity and tumor cell phenotype. Milk production in cattle is affected by six quantitative trait locus (QTL) scattered in the genome. BTA6 QTL controls the milk protein level. The osteopontin gene aids in the characterization of the neighboring QTL (Schnabel RD et al 2005 Proc Natl Acad Sci USA 102:6896). ▶osteoblast, ▶homeotic genes, ▶Smad, ▶integrin, ▶CD44, ▶L-10, ▶IL-12, ▶Herpes, ▶QTL; Agnihotri R et al 2001 J Biol Chem 276:28261.

Osteoporosis (17q21.31–q22.05, 7q22.1, 7q21.3): This condition is characterized by abnormal thinning of the bone structure because of reduced activity of the osteoblasts to manufacture bone matrix from calcium and phosphates. The frequency of fracture of the vertebrae may increase up to ~30 times in post-menopausal women. Steroids and other hormones and vitamin D can regulate this condition. The autosomal recessive juvenile form (IJO) may be caused by defects in bone formation and the symptoms may be alleviated spontaneously by adolescence or may be treated successfully with steroid hormones. Another

autosomal recessive form in infancy involves eye defects (pseudoglioma) and possibly problems of the nervous system. The collagen genes COL1A1 and COL1A2 have been implicated. An extracellular non-collagen proteoglycan (biglycan) deficiency in mice may lead to an osteoporosis-like phenotype. A vegetable rich diet may retard bone resorption. Osteoporosis is caused by bone resorption mediated through the osteoclasts. Inactivation of the cannabinoid type 1 receptors results in increased bone mass and protects ovariectomized rodents from bone loss. Also, cannabinoid receptor antagonists protect against bone loss after ovariectomy (Idris AI et al 2005 Nature Med 11:774). Osteoclasts mediating bone resorption in osteoporosis when inhibited by the antibiotic reveromycin A (see Fig. 027) caused apoptosis of these cells and thus attenuated osteoporosis (Woo J-T et al 2006 Proc Natl Acad Sci USA 103:4729). ▶aging, ▶LDL, ▶hormone-receptor elements, ▶estradiol, ▶Cbl, ▶Src, ▶collagen, ▶ABL oncogene, ▶osteoblast, ▶osteoclasts, ▶apoptosis, ▶ovariectomy, ▶TNF, ▶Paget disease

Figure 027. Reveromycin A (from Woo, JT et al 2006)

0

Osteoprotegrin (osteoclastogenesis inhibitory factor, OPG/OCIF): This is a receptor of the TNF family of proteins. The ~29-kb human gene encodes an inhibitor of TRAIL and other TNF ligands. It regulates bone formation and the mutant form may lead to the early onset of osteoporosis and arterial calcification, i.e., calcium deposits in the veins. ▶TNF, ▶TRAIL, ▶osteoporosis; Bucay N et al 1998 Genes Dev 12:1260.

Osteosarcoma: This autosomal recessive, usually malignant bone tumor has an onset in early adulthood. It is normally part of a complex disease. People affected by bilateral (but not those afflicted by unilateral) retinoblastoma are at a high risk to develop bone cancer. Circulating monocytes mediate the inflammation in osteosarcoma. These cells can be used as reporters for the disease by the genetic markers carried (Patino WD et al 2005 Proc Natl Acad Sci USA 102:3423). ▶retinoblastoma, ▶sarcoma

Osteosclerosis: This condition is characterized by abnormal hardening of the bones. ▶cathepsins, ▶osteopetrosis

Ostiole (ostium): This is a small (mouth-like) opening on various structures such as fungal fruiting bodies or internal organs.

Ostrich (*Struthio camelus*): The zoological name reflects the ancient belief that this huge bird descended from a misalliance between the sparrow and the camel. It differs from other birds because it has only two toes. Also, while other birds copulate by bringing together their cloacas (the combined opening for urine, faeces and reproductive cells), the male ostrich everts a penis-like structure from the cloaca during the process.

OTC: The expanded form of this acronym is over-the-counter drug, i.e., available without prescription.

OTF-1, OTF-2: These binding proteins recognize the consensus octamer 5'-ATGCAAAT-3' and facilitate transcription in several eukaryotic genes. OTF-1 is identical to NF-3 replication factor of adenovirus. ▶[NF](#), ▶[binding proteins](#)

Otopalatodigital Syndrome (OPD): This condition involves human chromosome Xq28, semidominant, variable expression deafness, cleft palate, broad thumbs and big toes. ▶[cranioorodigital syndrome](#), ▶[deafness](#), ▶[cleft palate](#)

Otosclerosis: This is an autosomal dominant hardening of the bony labyrinth of the ear resulting in lack of mobility of the structures and thus conductive hearing defect. It may be a progressive disease starting in childhood and fully expressed in adults. The incidence of otosclerosis leading to loss of hearing is about 0.003 among US whites and among blacks its frequency is of a lower magnitude. OTSC1 is at 15q25-q26 and OTSC2 at 7q34-q36. ▶[deafness](#)

Otter: *Amblonyx cinerea*, 2n = 38; *Enhydra lutris*, 2n = 38 (see Fig. [O28](#)).

Figure O28. Otter

Otto: This is a gene predictor program based on integrated multiple evidence such as homology, EST, mRNA, and RefSeq. ▶[EST](#), ▶[mRNA](#), ▶[RefSeq](#)

OTU (operational taxonomic unit): Refers to an entity such as a particular population or a species which is used in evolutionary tree construction. ▶[evolutionary tree](#), ▶[character matrix](#)

Ötzi: ▶[ice man](#) (named after the Ötztal where the mummy was found)

Ouabain (3[6-deoxy- α -L-mannopyranosyl]oxy]1,5,11 α , 11,19-pentahydroxy-card-20(22)-enolide): A cardiotonic steroid capable of blocking potassium and sodium transport through the cell membranes; a selective agent for animal cell cultures. Ouabain regulates cell adhesion, differentiation, migration and metastasis through hormone-like action (Larre I et al 2006 Proc Natl Acad Sci USA 103:10911). ▶[steroids](#); Aizman O et al 2001 Proc Natl Acad Sci USA 98:13420.

Ouchterlony Assay: ▶[antibody detection](#)

Outbreeding: This is the opposite of inbreeding; mating is between unrelated individuals (crossbreeding, allogamy). ▶[allogamy](#), ▶[autogamy](#), ▶[inbreeding](#), ▶[protogyny](#), ▶[protandry](#)

Outbreeding Depression: Co-adapted and different subpopulations can no longer interbreed successfully because of divergence. ▶[speciation](#), ▶[co-adapted genes](#)

Outcome Space: Denotes all possible genotypic constitutions in a specific pedigree compatible with Mendelian inheritance and parental genotypes.

Outcrossing: Refers to pollination of an autogamous plant by a different individual or strain or mating between animals of different genetic constitution. ▶[protandry](#), ▶[protogyny](#), ▶[incross](#)

Outgroup: This means that at least two species can be used to distinguish an ancestral from a derived species and for the rooting of phylogenetic trees. Characters (physical or molecular) shared between the ingroup and the outgroup are considered to be ancestral. ▶[evolutionary tree](#), ▶[PAUP](#)

Outlier: Refers to a gene or genes which is/are more divergent from the typical members of a gene family than expected. These represent highly specialized function(s). In statistical treatment of data, the extreme values that appear inconsistent with the bulk of the data are called outliers. ▶[gene family](#)

Out-of-Africa: A hypothesis proposes that the origins of the human race are in Africa. The human race diverged from chimpanzee-like ancestors 4.5 million years ago according to DNA information (Takahata N, Satta Y 1977 Proc Natl Acad Sci USA 94:4811). The first human fossil records date back to ~3.6 million years and 2.5 million years ago humans were found only in Africa (Stringer C 2003 Philos Trans Roy Soc London

B 357:563). The African origin thesis is supported by mtDNA composition showing that more differences exist in this respect in Africa than other parts of the world, supposedly because a few founders (highly conserved mtDNA) emigrated, spread and evolved relatively recently into the majority of the existing human racial groups. However, insufficient number and quality of archeological and paleontological relics plague the current concepts of hominine dispersion. It is also difficult to distinguish between the various early species such as *Homo erectus* (*Pithecanthropus erectus*) and *Homo ergaster* and the many other primitive taxonomic categories (Dennell R, Roebroeks W 2005 Nature [Lond] 438:1099).

At the niche of origin longer evolutionary period permitted greater divergence. This hypothesis has been further substantiated by linkage disequilibrium between an Alu deletion at the CD4 locus in chromosome 12 and short tandem repeat polymorphisms (STRP) used as nuclear chromosomal markers. The two markers are separated by only 9.8 kb. The mapping data indicate that 1 cM of the human genome corresponds to about 800 kb. The Alu deletion was mainly associated with a single STRP in Northeast Africa and non-African populations sampled from 1,600 individuals from European, Asian, Pacific and the Amerindian groups. In contrast in the sub-Saharan Africa a wide range of STRP markers were with the Alu deletion. These data also indicate that migration from Africa took place relatively recently, i.e., an estimated 102,000 to 313,000 years

ago. This estimate is in relatively close agreement with the age of the first human fossil records in the Middle East (90,000–120,000 years old). Other information has indicated that dispersion from Africa began about 1.7 million years ago (Gabunia L et al 2000 Science 288:1019). Recent information based primarily on mitochondrial DNA evidence of the oldest isolated human populations, e.g., the Andaman people in the island between India and Burma and the Orang Asli people of Malaysia, has revealed other possible routes of migration as shown on the map (see Forster P Matsumura S 2005 Science 308:965). *Homo sapiens* diverged from *H. erectus* around 800,000 or more years ago. The European continent was settled from the Levant nearly 40,000 years ago in several waves during the paleolithic, mesolithic and neolithic eras. In 2005, Paleolithic flint artifacts dated to about 750,000 (700 kyr) years ago were found in the Suffolk area of England, indicating very old human activity in northern Europe (Parfitt SA et al 2005 Nature [Lond] 438:1008). An analysis of the mtDNA of Paleolithic central European human remains (7500 years old) revealed that mtDNA sequences that were present in 25% of the ancient populations were present in only 0.2% of the present populations (see Fig. O29). This finding suggests that the Paleolithic people made a minimal contribution to the current gene pool (Haak W et al 2005 Science 310:1016). More recent analysis of mtDNA suggests that the Levant area was populated by a migration from Southeast Asia toward the Levant and from the

0

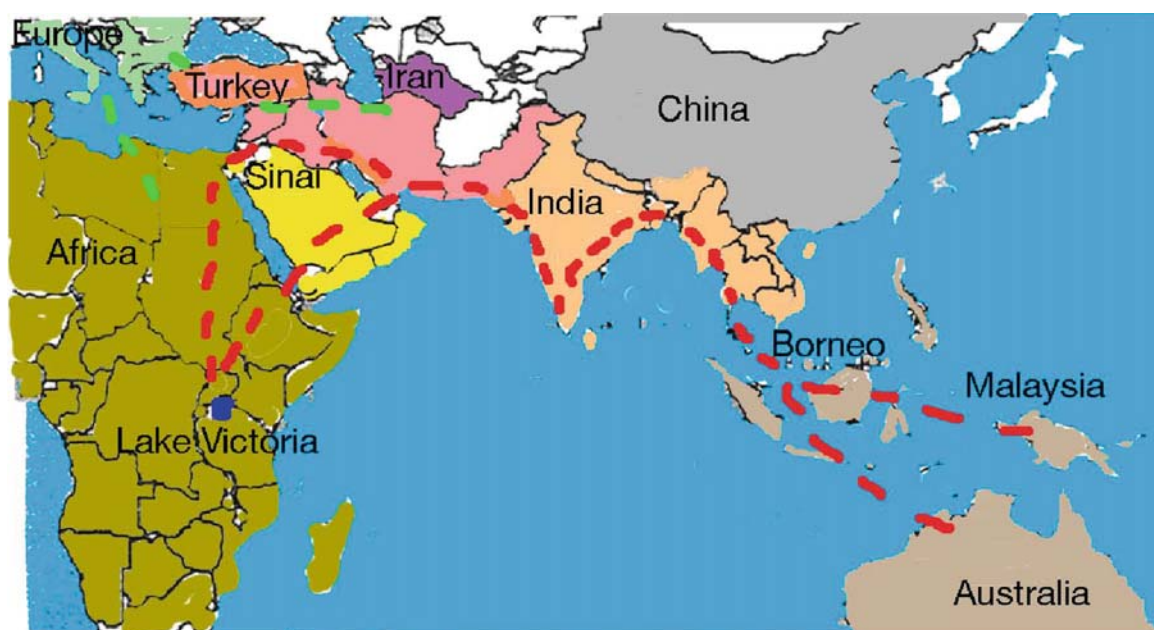

Figure O29. One of the most plausible routes (red path) of human migration from Africa about 85,000 years ago, based on mtDNA and archeological evidence. From Asia Minor and North Africa migration to Europe (green path) also took place

Levant they re-entered North Africa (Olivieri A et al 2006 Science 314:1767). Near the Don River of Russia 45,000–42,000 years old human remains were unearthed (Anikovich MV et al 2007 Science 315:223). In South Africa 36,000–33,000 years old human skulls were found (Grine FE et al 2007 Science 315:226).

The subsequent waves of migration were expected to replace the preceding ones (*replacement theory*). Some anthropologists, however, do not accept this theory of human evolution and have suggested *multiregional origin* of modern humans. An analysis of the human Y chromosome lends support not only to the African origin thesis of male descent, but also to the same general region as proposed by the Eve foremother theory in the case of females. Some genetic variations exist among the major continents and –to a smaller extent – within continents. If appropriate and sufficiently large number of loci are selected, the majority of human groups exhibit differences, especially in regions of limited migration. Even such small differences may be of significance from a medical point of view and for social policy (e.g., lactose intolerance and school lunch programs). Some of the European populations migrated to that continent from Asia as the gradient of gene flow from the Mid-East toward Northern and Western Europe decreased. Patterns of gene differences among the groups indicate population expansion and demography (Harpending HC et al 1998 Proc Natl Acad Sci USA 95:1961). The effective population sizes of males appeared to be lower than those of females indicating polygyny and elimination of males but not females during wars and conquests (Dupaloup I et al 2003 J Mol Evol 57:85). Such studies mandate appropriate case controls in stratification. ▶mtDNA, ▶Eve foremother of mitochondrial DNA, ▶Y chromosome, ▶founder principle, ▶Garden of Eden, ▶CD4, ▶Alu, ▶hominids, ▶ancient DNA, ▶demography, ▶case control, ▶stratification, ▶ethnicity, ▶radiocarbon dating; Quintana-Murci L et al 1999 Nature Genet 23:437; Harpending H Rogers A 2000 Annu Rev Genomics Hum Genet 1:3611; Barbujani G Bertorelle G 2001 Proc Natl Acad Sci USA 98:22; Adcock GJ et al 2001 Proc Natl Acad Sci USA 98:537; Templeton AR 2002 Nature [Lond] 416:45; Tishkoff SA Williams SM 2002 Nature Rev Genet 3:611; Barbujani G Goldstein DB 2004 Annu Rev Genomics Hum Genet 5:119.

Outparalog: This means evolved through ancient duplications. ▶paralogous loci, ▶inparalog

Output Trait: ▶input trait

Outside-in Signaling: ▶inside-out signaling

Ovalbumin: This is a nutritive protein of the egg white of chickens ($M_r \approx 4,500$); each molecule carries a carbohydrate chain. The gene is split by 7 introns into

8 exons and its transcription is induced by estrogen or progesterone. In the presence of the effector hormone the mRNA has a half-life of about a day but in the absence of it, its half-life may be reduced to 20%. The gene is part of a family of 3. ▶oviduct, ▶intron

Ovalocytosis: ▶elliptocytosis, ▶acanthocytosis

Ovarian Cancer: This is probably due to mutation of the OVC oncogene (9p24). In 2004 it accounted for approximately 26,000 new cases and around 16,000 deaths in the USA. The expression of several other genes is altered. The same genes affect a large variety of other cancers too. Ovarian cancer may be associated with breast cancer and may increase following the administration of tamoxifen medication. Mutation in the so-called ovarian cancer cluster region (OCCR, nucleotides 3059–4075 and 6503–6629) of the BRCA2 increases the relative risk of ovarian cancer by 0.46–0.84. Ovarian germ cell cancer involves the germ cells in the ovaries and ~5% of the cases are due to genetic causes. OPCML (opioid binding protein/cell adhesion-like molecule, encoded at 11q25) appears to be a tumor suppressor of ovarian cancer (Sellar GC et al 2003 Nature Genet 34:337). Hormone (estradiol family) replacement therapy of menopausal women may increase the risk. It has been suggested that the use of oral contraceptives may lower the risk. Apparently microarray hybridization profile provides an early diagnosis. Bombesin, somatostatin and luteinizing hormone releasing hormone coupled with 2-pyrrolinodoxorubicin can be targeted to the receptors of these substances in the ovary and may block ovarian cancer (Buchholz S et al 2006 Proc Natl Acad Sci USA 103:1043). ▶breast cancer, ▶tamoxifen, ▶sex hormones, ▶mesothelin, ▶bombesin, ▶somatostatin LRF, ▶doxorubicin; Welsh JB et al 2001 Proc Natl Acad Sci USA 98:1176; Thompson D, Easton D (Breast Cancer Linkage Consortium) 2001 Am J Hum Genet 68:410; Cannistra SA 2004 New Engl J Med 351:2519.

Ovariectomy (oophorectomy): Surgical removal of the ovary. ▶castration, ▶spaying, ▶neutering

Ovariole: ▶ovary

Ovary (ovarium): This contains the ovules of plants, the egg-producing organ of animals, and a female gonad. The ovaries of *Drosophila* contain *ovarioles*, each with 2–3 germ line stem cells at the tip and associated with the *terminal filament cells* with the duty of somatic signaling (see Fig. O30). In the *Caenorhabditis* asymmetric differentiation of the germ cell lineage is not observed rather the distal mitotic stem cells undergo meiosis through adulthood. In humans the pre-implantation development is mediated through the brain-derived neurotrophic factors (BDNF) through TrkB and some low-affinity receptors.

BDNF enhances exclusion of the first polar body and oocytes development (Kawamura K et al 2005 Proc Natl Acad Sci USA 102:9206). Ovary transplantation (in the case of developmental failure) from one monozygotic twin to the other can be successful and can lead to the restoration of fertility (Silber SJ et al 2005 N Engl J Med 353:58). ▶gonad, ▶uterus, ▶gametogenesis, ▶germarium, ▶pole cells, ▶germ line, ▶cytoblast, ▶ovary genes, ▶functions, ▶mutations, ▶TRK, ▶BDNF, ▶polar body, ▶twinning; biomedical relevance: <http://ovary.stanford.edu>.

Figure O30. Ovary of *Drosophila*

OVC Oncogene: This was discovered in an ovarian cancer in a fusion of human chromosomes 8–9. ▶oncogenes

Overdispersion: The empirically observed variance of the data exceeds expectation for a certain model, e.g., the variation is not compatible with the binomial distribution or with the Poisson distribution because of the numbers of outliers encountered or specifications used. ▶binomial distribution, ▶Poisson distribution, ▶outlier

Overdominance: The *Aa* heterozygote surpasses both *AA* and *aa* homozygotes. Deleterious recessive genes may occur in heterozygotes at a higher frequency (at linkage disequilibrium) than expected because of the association with neutral genes; this is called *associative overdominance* (see Fig. O31).

Figure O31. Allelic complementation (= overdominance) of temperature-sensitive pyrimidine mutants of *Arabidopsis*. Top and bottom rows are homozygous mutants, in the middle row: the F_1 hybrids. (From Li, S.L. & Rédei, G.P)

Pseudo-overdominance occurs when two genes are closely linked and the *aB* and *Ab* combinations simulate overdominance whereas the increased performance is actually due to dominance. Polar overdominance characterizes the non-Mendelian inheritance of the callipyge genes in sheep and cattle. Callipyge (*CLPG1*) is expressed as a muscular hypertrophy in the buttock due to a single nucleotide substitution ($A \rightarrow G$) in the heterozygotes but not in the homozygotes in the intergenic region of the imprinted genes *Delta-like (DLK1)* and the maternally *Expressed Gene 3 (MEG3)*. These two genes are at the distal end of bovine chromosome 18. The CLPG gene is expressed biallelically during the prenatal stage but only monoallelically in adults. During prenatal development CpG sites flanking the mutation is normal but postnatally it increases, except when two alleles are present. In the CLPG sheep *DLK1* expression is enhanced because of the reduction in chromatin condensation at the location. Imprinting is not affected by callipyge (Murphy SK et al 2006 Genome Res 16:3430; Takeda H et al 2006 Proc Natl Acad Sci USA 103:8119). ▶hybrid vigor, ▶superdominance, ▶heterosis, ▶overdominance and fitness, ▶polar overdominance

Overdominance and Fitness: It is assumed that in the case of overdominance the selection against the two homozygotes at a locus is 0.05. Thus, instead of the Hardy-Weinberg proportions, the population will be *AA* 95, *Aa* 200 and *aa* 95. The proportion of the surviving zygotes will be $390/400 = 0.975$. This means 2.5% reduction in the size of the population in a single reproductive phase. This may not be very serious in the case of a single locus and large populations, but in the case of 10, 100 and 500 loci it would be $0.975^{10} \cong 0.776$, $0.975^{100} \cong 0.0795$ and $0.975^{500} \cong 0.0000032$, respectively.

It is likely that such a large reduction in population size would not be tolerated. Thus, overdominance may be advantageous only at 1 or very small number of loci. ▶heterosis, ▶fitness, ▶hybrid vigor, ▶allelic complementation, ▶monogenic heterosis; Rédei GP 1982 Cereal Res Commun 10:5.

Overdrive: A consensus of 5'-TAAAPuTPyNCTGT-PuTNTGTTTTGTTTG-3' in the vicinity of the T-DNA right border of some octopine plasmids facilitating the transfer of the T-DNA into the plant chromosomes. The VirC1 protein binds this region. In the *overdrive mode* of the RNA polymerase the system does not respond to protein signals of transcription termination or pause. ▶*Agrobacterium*, ▶T-DNA, ▶virulence genes of *Agrobacterium*, ▶antitermination, ▶terminator, ▶transcription factors, ▶RNA polymerase; DeVos G Zambryski P 1989 Mol Plant-Microbe Interact 2:43.

Overepistasis: This is an archaic term for overdominance.

Overgrowth: Denotes increase of cell size and/or number in the neighboring tissues.

Overhang: A double-stranded nucleic acid has a protruding single strand end (see Fig. O32)

Figure O32. Single-strand overhang

Overlapping Code: This is a historical idea about how neighboring codons may share nucleotides. ▶overlapping genes; Yčas M 1969 The Biological Code. North-Holland, Amsterdam.

Overlapping Genes: These occur in the small genomes of viruses, eukaryotic mitochondria and rarely in eukaryotic nuclear genes. In *Drosophila* 3,152 (~22%), in humans more than 1,000 protein coding (~1,600) and in the mouse 2,481 protein coding and non-protein coding gene pairs appeared overlapping in either a parallel or an antiparallel fashion or in a nested arrangement (Boi S et al 2004 Curr Genomics 5:509). In human chromosome 11 one-quarter of the protein coding genes overlaps other genes (Taylor TD et al 2006 Nature [Lond] 440:497). In *Arabidopsis* 1,340 potential overlapping (cis-natural) gene sequences have been identified and evidence has been obtained for 957 cis-nat-pair transcription (Wang X-J et al 2005 Genome Biol 6(4):r30). Earlier, a multitude of sense and antisense transcripts was detected in rice (Osato N 2003 Genome Biol 5:R5). Sequences of the genetic material may be read in different registers; thus the same sequences may represent two or more genes in a complete or partial overlap because they do not need equal amounts of proteins from the overlapping genes. The means for achieving this goal is either stop codon read-through or translational frame shifting on the ribosome. The murine leukemia virus (MLV) and the feline leukemia virus (FeLV) use the first alternative. In

the HIV virus the RNA transcript makes a small loop and in the sequence 5' UUUUUUA]GGGAAGAU-LOOP-GGAU a one base slippage (framed) takes place. This allows the normally UUA recognizing tRNA^{Leu} to pair with UUA (leucine) and in place of GGG (glycine) an AGG (arginine) was inserted, and thus the stop codon was thrown out of frame which permitted the synthesis of a fusion protein (*gag* + *pol*, i.e., envelop + reverse transcriptase). This frameshift translation is generally stimulated by a pseudoknot located 5–9 nucleotides (3') from the shift site. After the translation the pseudoknot unfolds and the RNA returns to a linear shape. Such a ribosomal frameshifting occurred only in a fraction (11%) of the ribosomes but as a consequence instead of a 10–20 envelope:1 reverse transcriptase protein, the proportion changed to 8 envelope:1 reverse transcriptase (*gag* + *pol*) production. After the completion of sequencing of the genome, of the 879 nested genes found in *Drosophila* 574 were transcribed from the opposite polarity strands (Misra S et al 2002 Genome Biol 3(12):res0083). Within a ~3-Mb region of the long arm of chromosome 2 of *Drosophila* 12/17 were transcribed from the antiparallel strand. Deletions encompassing overlapping genes usually result in sterile or lethal phenotypes. In compact eukaryotes such as cryptomonads (e.g., microsporidia, *Guillardia*) single RNA molecules encode more than one gene but the phenomenon is not due to operons (Williams BAP et al 2005 Proc Natl Acad Sci USA 102:10936). ▶gene, ▶transcription, ▶frameshift, ▶decoding, ▶wobble, ▶recoding, ▶tRNA, ▶deletion, ▶knockout, ▶contiguous gene syndrome, ▶translational hopping, ▶φX174, ▶pseudoknot, ▶fuzzy logic; Pedersen AM, Jensen JL 2001 Mol Biol Evol 18:763; Besemer J et al 2001 Nucleic Acids Res 29:2607; Barrette IH et al 2001 Gene 270:181.

Overlapping Inversions: A part of one chromosomal inversion is included in another inversion (see Fig. O33). ▶inversion, ▶figure, ▶salivary gland chromosomes

Figure O33. Two overlapping inversions in a heterozygous salivary gland cell of *Drosophila*. The salivary gland chromosomes display somatic pairing. (From Dobzhansky T and Sturtevant AH 1938. Genetics 23:28)

Overlay Binding Assay: This is used to determine interactions between protein subunits (on a membrane) after labeling of the SDS-PAGE separated proteins still retaining the critical conformation. ▶[SDS-polyacrylamide gels](#); Kumar R et al 2001 J Biosci 26(3):325.

Overproduction Inhibition: A highly active promoter of a transposase may actually reduce the rate of transposition of a transposable element. ▶[transposable elements](#)

Overwinding: This generates supercoiling in the DNA. ▶[supercoil](#)

Oviduct: This is the passageway through which externally laid eggs are released (e.g., in birds), the channel through which the egg travels from the ovary to the uterus (e.g., mammals). In mammals fertilization takes place in the oviduct. ▶[ovary](#), ▶[uterus](#), ▶[ovalbumin](#), ▶[morula](#)

Ovis aries (sheep, 2n = 54): This forms a fertile hybrid with the wild mouflons but the sheep x goat (*Capra hircus*, 2n = 60) embryos rarely develop in a normal way although some hybrid animals have been produced. ▶[nuclear transplantation](#)

Ovist: ▶[preformation](#)

Ovotestis: Refers to a gonad that abnormally contains both testicular and ovarian functions. ▶[hermaphrodite](#); Sato A et al 2002 Genetics 162:1791.

Ovulation: This involves the release of the secondary oocyte from the follicle of the ovary that is eventually followed by the formation of the egg and the second polar body. Bone morphogenetic protein 15 (BMP15, Xp11.2-p11.4), a member of the TGFβ family of proteins, is expressed specifically in the oocytes and is essential for normal follicular development and ovulation. Heterozygosity for a mutation (in sheep) in the gene may lead to twinning but homozygosity for the mutation impairs follicular growth beyond the primary stage and results in female sterility. The number of oocytes released in a cycle is called the ovulation quota that varies among multiparous and monoparous species. ▶[gametogenesis](#), ▶[twinning](#), ▶[fertility](#), ▶[luteinizing hormone-releasing factor](#), ▶[multiparous](#); Richards JS et al 2002 Annu Rev Physiol 64:69.

Ovule: This is the megasporangium of plants in which a seed develops; the animal egg enclosed within the Graafian follicle. ▶[Graafian follicle](#), ▶[nucellus](#)

Ovulin: A seminal fluid protein which stimulates egg laying and the release of oocytes.

Ovum (plural ova): This is an egg(s) ready for fertilization under normal conditions.

Ox (plural oxen): Refers to a castrated male cattle. ▶[cattle](#)

Ox40: This is a member of the tumor necrosis factor receptor family. ▶[TNF](#); Rogers PR et al 2001 Immunity 15:445.

Oxalosis (hyperoxaluria): Autosomal recessive forms involve the excretion of large amounts of oxalate and/or glycolate through the urine caused either by a deficiency of 2-oxoglutarate (α-ketoglutarate): glyoxylate carboligase or a failure of alanine:glyoxylate aminotransferase or serine:pyruvate aminotransferase. The accumulated crystals may cause disease of the kidney and liver. The glycerate dehydrogenase defects also increase urinary oxalates and hydroxypyruvate. Hydroxypyruvate accumulates because the dehydrogenase does not convert it to phosphoenolpyruvate. It is also called peroxisomal alanine: glyoxylate aminotransferase deficiency (AGXT) traced to human chromosome 2q36-q37. Hyperoxaluria II (9cen) is a deficiency of glyoxylate reductase/hydroxypyruvate reductase. ▶[glycolysis](#), ▶[peroxisome](#)

oxi3: Denotes the mitochondrial DNA gene responsible for cytochrome oxidase.

Oxidation: Refers to loss of electrons from a molecule.

Oxidation–Reduction: This is a reaction transferring electrons from a donor to a recipient.

Oxidative Burst: In plants resistance to microbial infection may be mediated by the production of reactive oxygen species (ROS) such as superoxide anion (O^{•−}), OH[−], H₂O₂. The oxidative burst may induce the transcription of defense genes in the plant tissue infected by even avirulent or non-pathogenic agents. The reactive oxygen may kill the cells along with the invader and may modify the cell wall proteins, which then reinforce the barrier to the infectious microbes. Several genes encoding proteins with functional similarity to RAC, a RAS family of proteins involved in signal transduction, mediate these reactions. ▶[host–pathogen relations](#), ▶[RAC](#), ▶[ROS](#); Martinez C et al 2001 Plant Physiol 127:334; Siddiqi M et al 2001 Cytometry 46(4):243.

Oxidative Deamination: For example, O replaces a NH₂ group of cytosine (C) resulting in the conversion of C → Uracil. ▶[nitrous acid mutagenesis](#), ▶[chemical mutagens II](#)

Oxidative Decarboxylation: ▶[pyruvate decarboxylation complex](#)

Oxidative DNA Damages: These occur when ionizing radiation or oxidative compounds hit cells. The major class of damages includes the formation of thymine

glycol (isomers of 5,6-dihydroxy-5,6-dihydrothymine), 5-hydroxymethyluracil, 5,6-hydrated cytosine, 8-oxo-7,8-di-hydroguanine, 2,2-diamino-4-[(2-deoxy- β -D-erythripenofuranosyl)amino]5(2H)-oxazolone and its precursor, cross-linking between the DNA and protein, elimination of the ribose. 8-oxoguanine represents about 10^{-5} of the mammalian guanine in the DNA. A minor oxidative damage product is 2-hydroxyadenine, which can also pair with guanine. These two purines are regularly generated within the cells and cause mutation or death unless repaired by glycosylases (Ushijima Y et al 2005 Nucleic Acids Res 33:672). 8-oxoguanine can be incorporated and paired in the DNA with A and C residues. DNA polymerases λ and η with the assistance of proliferating cell nuclear antigen (PCNA) and replication protein-A (RP-A) permit the correct incorporation of dCTP (compared to the incorrect dATP) opposite an 8-oxo-G template 1,200-fold and 68-fold better, respectively (Maga G et al 2007 Nature [Lond] 447:606). If 8-oxoguanine is not repaired A \rightarrow T \rightarrow G \rightarrow C transitions or G \rightarrow C \rightarrow T = A transversions occur. The oxidative damages are usually repaired by exonucleases, endonucleases, glycosylases and other repair enzymes in prokaryotes and eukaryotes (Fromme JC et al 2004 Nature [Lond] 427:652). 8-oxoguanine-DNA glycosylase OGG1 excises 8-oxoguanine from the DNA. Defects in OGG1 have been associated with cancer in humans; enhanced mutagenesis and accelerated senescence have been observed in a mouse strain with thermolabile OGG1 (Kuznetsov NA et al 2007 J Biol Chem 282:1029). OGG1 initiates age-dependent CAG trinucleotide expansions in somatic cells resulting in Huntington's chorea (Kovtun IV et al 2007 Nature [Lond] 447:447). In mice mutation of the MMH (MutM homolog) repair enzyme results in a threefold to sevenfold increase in 8-hydroxyguanine. In prokaryotes MutY and in humans hMYH glycosylases normally remove oxoguanine from the DNA. MutY oxidation mediated by guanine radicals with the aid of charge transport of the DNA duplex is the first step in signaling to DNA repair upon oxidative damage (Yavin E et al 2005 Proc Natl Acad Sci USA 102:3546). Oxidation of mRNA leads to premature termination of the translation process and the proteolytic degradation of the modified full length polypeptide resulting from translation errors induced by oxidation (Tanaka M et al 2007 Proc Natl Acad Sci USA 104:66).

A method has been developed for the genome-wide identification of functional polymorphisms in the antioxidant response element (ARE), a *cis*-acting enhancer sequence found in the promoter region of many genes that encode antioxidant and detoxification enzymes/proteins. In response to oxidative stress, transcription factor NRF2 (nuclear factor erythroid-derived 2-like 2) binds to AREs, mediating transcriptional activation of its responsive genes and

modulating in vivo defense mechanisms against oxidative damage (Wang X et al 2007 Hum Mol Genet 16:1188). [▶DNA repair](#), [▶oxidative deamination](#), [▶ROS](#), [▶abasic site](#), [▶photosensitizer](#), [▶transition mutation](#), [▶transversion mutation](#), [▶MtODE](#), [▶MtGendo](#), [▶glycosylases](#), [▶deoxyoxoguanine](#); Nunez ME et al 2001 Biochemistry 40:12465; Kaneko T et al 2001 Mutat Res 487:19; Vance JR Wilson TE 2001 Mol Cell Biol 21:7191; Aitken RJ, Krausz C 2001 Reproduction 122(4):497; Sartori AA et al 2004 Nucleic Acids Res 32:6531; Banerjee A et al 2005 Nature [Lond] 434:612; David SS et al 2007 Nature [Lond] 447:941.

Oxidative Phosphorylation (OXPHOS): ATP is formed from ADP as electrons are transferred from NADH or FADH₂ to O₂ by a series of electron carriers. Such processes take place in the inner membrane of the mitochondria with the assistance of cytochromes as electron carriers. This is the main mechanism of ATP formation. OXPHOS minus yeast mutants are petite and fail to grow on a non-fermentable carbon source and cannot convert into a red pigment, an intermediate of the adenine (*ade*⁻) biosynthetic path. Nearly 20 different mutations in nuclear genes are now known, which control various functions of the mtDNA. Also, 82 structural subunits of mitochondrial genes are encoded in the nucleus versus the 13 coded by the mtDNA. mtDNA haplotypes from NIH3T3 and NZB/B1NJ mice induce significantly different OXPHOS performance as compared with those from C57BL/6J, BALB/cJ and CBA/J mice. In addition, a single nucleotide polymorphism (SNP) in the *mt-Tr* gene (mitochondrial tRNA^{Arg}) is the sequence variation responsible for the phenotypes observed. The differences in OXPHOS performance are masked by a specific upregulation in mitochondrial biogenesis, triggered by an increase in the generation of reactive oxygen species (ROS) in cells carrying NIH3T3 or NZB/B1NJ mtDNA (Moreno-Loshuertos R et al 2006 Nature Genet 38:1261). [▶mitochondria](#), [▶mitochondrial DNA depletion syndromes](#), [▶ATP](#), [▶NADH](#), [▶FAD](#), [▶petite colony mutants](#), [▶mitochondrial diseases in humans](#); ROS, Saraste M 1999 Science 283:1428; Shoubridge EA 2001 Hum Mol Genet 10:2277.

Oxidative Stress: Such stress is exerted by free radicals (reactive oxygen species, ROS, singlet oxygen, nitric oxide) and peroxides and hydroxyl species through the action of enzymes involved in mixed-function oxidation and auto-oxidation (P450 cytochrome complex, xanthine oxidase, phospholipase A₂). These reactions play an important role in mutagenesis, aging, mitochondrial functions, signal transduction, etc., and are thought to affect neuronal degeneration in Alzheimer's and Parkinson's diseases

and in amyotrophic lateral sclerosis. The transcription of protooncogenes may be regulated by redox systems. Glutathione and thioredoxin-dependent enzymes provide some protection. See diseases mentioned under separate entries, ►ROS, ►superoxide dismutase, ►catalase, ►redox reaction, ►glutathione, ►thioredoxins, ►peroxidase, ►Yap1, ►vitellogenin, ►FOX; Carmel-Harel O, Storz G 2000 *Annu Rev Microbiol* 54:439; Rabilloud T et al 2002 *J Biol Chem* 277:19396.

Oxidizing Agent: Refers to an acceptor of electrons.

Oxindoles: These are protein tyrosine kinase inhibitors. They inhibit the fibroblast growth factor and other receptor tyrosine kinases. For example, chemically they are 3-[4-(formylpiperazine-4-yl)benzyl-idenyl]-2-indolinone and 3-[(3-(carboxyethyl)-4-methylpyrrol-2-yl)methylene]-2-indolinone. (See Cane A et al 2000 *Biochem Biophys Res Commun* 276:379).

8-Oxodeoxyguanine: ►oxidative DNA damage, ►abasic site

Oxoguanine: ►8-oxodeoxyguanine (see Fig. O34).

Figure O34. 8-Oxoguanine

Oxoprolinuria: ►glutathione synthetase deficiency

Oxphos (oxidative phosphorylation): A mitochondrial process by which molecular oxygen is combined with the electron carriers NADH and FADH₂ by the enzymes of the respiratory chain and mediate the ADP + P_i → ATP conversion. ►oxidative phosphorylation

Oxygen Effect: In the presence of air or oxygen the frequency of chromosomal aberrations induced by ionizing radiation increases in comparison to conditions of anoxia (lack of air in the atmosphere). Bacterial irradiation experiments have indicated that oxygen must be present before or at the radiation pulse for reducing survival but after the pulse its effect rapidly decreases. Glutathione level in the cells protects against oxygen effect. Exogenous thiols (cysteine, cysteamine, WR2721, Amifostil, [2-(3-amino propyl)aminoethyl-phosphorothioic acid])

also have a protective role. Nitroaromatic compounds (e.g., antiprotozoan metronizadol) and 5'-halogen-substituted pyrimidines (bromouracil) are sensitizers under anoxia. The higher mutability of the mtDNA relative to that of the nucleus is attributed to the presence of reactive oxygen in this organelle. The ambient atmospheric oxygen level has almost doubled during the last 205 million years (beginning in early Jurassic and Eocene periods) and has contributed to the evolution of large placental mammals (Falkowski PG et al 2005 *Science* 309:2202). Deprivation of oxygen may lead to human death within seconds. ►physical mutagens, ►radiation effects, ►mtDNA; Thoday JM, Read JM 1947 *Nature [Lond]* 160:608; Schulte-Frohlinde D 1986 *Adv Space Res* 6(11):89; Hsieh MM et al 2001 *Nucleic Acids Res* 29:3116; Ragu S et al 2007 *Proc Natl Acad Sci USA* 104:9747.

Oxygenases: ►mixed function oxidases

Oxyntic Cells: These cells secrete HCl acid in the lining of the stomach.

Oxyntomodulin: The small intestine secretes oxyntomodulin which reduces appetite and body weight; it suppresses ghrelin. ►ghrelin, ►obesity

Oxysterols: These are derivatives of cholesterol with extra hydroxyl or keto groups, usually at the 7 position on the B ring or at the 24, 25, or 27 positions on the side chain. Oxysterols are synthesized in various tissues by specific hydroxylases and play a role in the export of excess cholesterol from the brain, lung and other organs. They are intermediates in bile acid synthesis. Oxysterols are potent feedback regulators of cholesterol homeostasis despite the fact that their concentration is lower by several orders of magnitude (Rhadhakrishnan A et al 2007 *Proc Natl Acad Sci USA* 104:6511). ►sterol, ►SREBP, ►cholesterol, ►statins

Oxytocin: This is an octapeptide stored in the pituitary that regulates uterine contraction and lactation. During delivery in rats, oxytocin triggers an inhibitory switch in GBA signaling in the brain (Tyzio R et al 2006 *Science* 324:1788). It is synthesized in the hypothalamus with other associated proteins. They are assembled in the neurosecretory vesicles and transported to the nerve ends in the neurohypophysis (posterior lobe of the pituitary) and may eventually be secreted into the bloodstream. Vasopressin and oxytocin (12-kb between them) and neurophysin genes are linked within the arm of human chromosome 20pterp12.21. They are transcribed from the opposite strands of the DNA. It appears that pre-proarginine - vasopressin - neurophysin are transcribed jointly and

post-translationally separated by proteolysis. Oxytocin favorably affects the social behavior of animals and humans (Kosfeld M et al 2005 Nature [Lond] 435:673).
 ▶ vasopressin [antidiuretic hormone], ▶ neurophysin, ▶ animal hormones, ▶ memory, ▶ behavior genetics, ▶ microsatellite, ▶ GABA; Breton C et al 2001 J Biol Chem 276:26931.

Oxytricha: This is a group of ciliate protozoa with a germ line micronucleus and a somatic macronucleus (see Fig. O35). During conversion of the micronucleus to macronucleus about 150,000 internal DNA segments are routinely eliminated by recombinational events. The processes permit shuffling of the ca. 30,000 genes at reconstitution and high rates of mutation. ▶ protozoa; Prescott DM 1999 Nucleic Acids Res 27:1243; <http://oxytricha.princeton.edu/dimorphism/database.htm>.

Figure O35. *Oxytricha*. (Courtesy of National Human Genome Research Institute)

Ozone (O₃): This is a bluish, highly reactive form of oxygen. It is a disinfectant and its presence in the atmosphere acts as a screen protecting the earth from excessive ultraviolet radiation coming from the sun.

Historical vignettes

“First your opponents say it can’t be true. Next they say if it is true it can’t be very important. Finally they say well, we’ve known it all along.”

Jeffrey Kluger (2004) citing Jonas Salk in his book *Splendid Solution. Jonas Salk and the Conquest Polio*. Putnam, New York.

On July 9, 1909 (more than two decades earlier than the Neurospora work), FA Janssens, Professor at the University of Louvain, presented his theory of chiasmotypy in the journal *La Cellule* (25:389–411):

“In the spermatocytes II, we have in the nuclei chromosomes which show one segment of two clearly parallel filaments, whereas the two distal parts diverge... The first division is therefore reductional for segment A and a and it is equational for segment B and b ... The 4 spermatids contain chromosomes 1st AB, 2nd Ab, 3rd ab, and 4th aB. The four gametes of a tetrad will thus be different...

“The reason behind the two divisions of maturation is thus explained... The field is opened up for a much wider application of cytology to the theory of Mendel.”

P

P: Parental generation.

P: ►probability

P (Polyoma): A regulatory DNA element in the viral basal promoter. ►Simian virus 40, ►polyoma

³²**P:** Phosphorus isotope. ►isotopes

P1: Double-stranded DNA, temperate *E. coli* phage. It is also a vector used DNA sequencing with a load capacity of ~80 kb.

P₁, P₂: Designations of the parents, homozygous for different alleles, at the critical locus (loci) in a Mendelian cross. ►Mendelian laws, ►gametic arrays, ►genotypic segregation, ►allelic combinations

p (petit): Short arm of chromosomes, also denote frequencies. ►q

π: ►diversity

π: $22/7 \approx 3.132857$, Ludolf number, indicates the ratio of the circumference to the diameter of a circle.

Φ (phi): The symbol of some phages.

ψ (psi): ►pseudouridine (see Fig. P1), formula. Also, packaging signal for virions. The packaging signal is located at the 5' LTR repeat and reaches over into the upstream end of the gag gene. It is not translated. ►retroviruses

Figure P1. Pseudouridine

p13suc1: The yeast cell cycle activating enzyme binding to the cyclosome. ►cyclosome, ►cell cycle; Simeoni F et al 2001 Biochemistry 40:8030.

p14: ►ARF

p15^{INK4B}: An inhibitor of CDK4 (encoded in human chromosome 9p21) appears to be an effector of TGF-β, a protein known to control the progression

from G1 phase of the cell cycle to S phase. ►cell cycle, ►TGF, ►p16^{INK4}, ►p18, ►p19, ►cancer; Seoane J et al 2001 Nature Cell Biol 3:400.

p16 (*MTS1* [multiple tumor suppressor], CDKN2): A cell cycle gene (in human chromosome 9p21) that has a major role in tumorigenesis. In 50% of the melanoma cells, it is deleted and in 25%, it is mutated. Over 70% of the bladder cancer cases are associated with deletions of 9p21 in both homologous chromosomes, in head and neck tumors 33%, in renal and other cells usually this tumor suppressor gene is lost. It normally restrains CDK4 and CDK6. ►melanoma, ►pancreatic adenocarcinoma, ►CDK4, ►CDK6, ►cell cycle, ►ARF; Serrano M et al 1993 Nature [Lond] 366:704.

p16: A weak ATPase and a packaging protein of φ29 bacteriophage. It interacts with the viral packaging RNA (pRNA) and the phage portal protein and assists in pumping the double-stranded DNA into the phage head. p16 and other packaging components are not found within the head. ►packaging of DNA; Ibarra B et al 2001 Nucleic Acids Res 29:4264.

p16^{INK4} (CDKN2A): A protein inhibitory to CDK4/CDK6 and thus appears to be a tumor suppressor because it inhibits the progression of the cell cycle from G¹ to S. Thus, it may also direct the cell toward senescence rather than neoplasia. p16^{INK4a} induces age-dependent decline in cell regenerative capacity (Krishnamurthy J et al 2006 Nature [Lond] 443:453). Absence of p16^{INK4a} may reduce aging of hematopoietic stem cells and acts similarly to ARF in tumor suppression. The two proteins share coding sequences but ARF does not seem to affect stem cell aging (Janzen V et al 2006 Nature [Lond] 443:421). Both p16^{INK4} and p19^{INK4} are transcribed from the same 9p21 locus but from alternative alleles. ►CDK4, ►tumor suppressor, ►PHO81, ►cell cycle, ►cancer, ►p18, ►p19, ►Ets oncogene, ►Id protein, ►senescence, ►mole, ►centrosome; Quelle DE et al 1995 Cell 83:993; Wang W et al 2001 J Biol Chem 276:48655; Reynolds PA et al 2006 J Biol Chem 281:24790.

p18^{INKC}: Cell cycle inhibitors that block cell cycle kinases CDK4 and CDK6. ►cell cycle, ►cancer, ►p15, ►p16, ►p19; Blais A et al 2002 J Biol Chem 277:31679.

p19^{INK4d}: Cell cycle inhibitor of CDKs. ►p15, ►p16, ►p18, ►cell cycle, ►cancer, ►ARF

p21: A transforming protein of the Harvey murine sarcoma virus. A Ras-gene encoded 21 kDa protein binds GDP/GTP and hydrolyzes bound nucleotides

and inorganic phosphate. This protein is involved in signal transduction, cell proliferation and differentiation and p21 controls the cyclin-dependent kinases (Cdk4, Cdk6, Cdk2), and binds to DNA polymerase δ processivity factor and it inhibits in vitro PCNA-dependent DNA replication but not DNA repair. In the absence of p21, cells with damaged DNA are arrested temporarily at the G2 phase and that is followed by S phases without mitoses. Consequently hyperploidy arises and apoptosis follows. Gene *p21* is under the control of p53 protein and the retinoblastoma tumor suppressor gene RB. MyoD regulates expression of the p21 Cdk inhibitors (p21^{Cip/Waf1}, 6p21.2) during differentiation of muscle cells and non-muscle cells, and then withdrawal from the cell cycle does not require the participation of p53. Experimental evidence indicates that telomere dysfunction induces p21-dependent checkpoints in vivo that can limit longevity at the organismal level (Choudhury AR et al 2007 Nature Genet 39:99). RAF and RHO activate protein p21^{Cip/Waf}, leading to inhibition of the transition of the cell cycle into the S phase. Actually, RAS activates the serine/threonine kinase Raf that may facilitate the transition to the S phase but upon excessive stimulation by RAF and RHO, p21^{Cip/Waf} has the opposite effect. Also, p53 is an independent activator of p21^{Cip/Waf}. After mitosis, p21 is expressed at the onset of differentiation but it may again be down-regulated at later stages of differentiation due to proteasome activity. In addition, p21 may not have an absolute requirement for induction by MyoD. The N terminal domains of p27 and p57 provide other antimitogenic signals. P21^{SNFT} is a 21 kDa nuclear factor of T lymphocytes. Its overexpression represses transcription from the interleukin-2 and AP1-driven promoters. [▶cell cycle](#), [▶Cdk](#), [▶mitosis](#), [▶cancer](#), [▶hyperploidy](#), [▶apoptosis](#), [▶p53](#), [▶PCNA](#), [▶p27](#), [▶p57](#), [▶MyoD](#), [▶cell cycle](#), [▶RAS](#), [▶RASA](#), [▶proteasome](#), [▶interleukin](#), [▶AP1](#), [▶NF-AT](#), [▶epigenesis](#); Prall OWJ et al 2001 J Biol Chem 276:45433; Wu Q et al 2002 J Biol Chem 277:36329; Bower KE et al 2002 J Biol Chem 277:34967.

p24: A family of evolutionarily conserved small integral membrane proteins, which form parts of the COP transport vesicles or regulate the entry of cargo into the vesicles. It also mediates viral infection. [▶protein sorting](#), [▶COP transport vesicles](#); Blum R et al 1999 J Cell Sci 112(pt 4):537; Hernandez M et al 2001 Biochem Biophys Res Commun 282:1.

p27 (p27^{Kip1}): A haplo insufficient tumor suppressor protein, which inactivates cyclin-dependent protein kinase 2. Its mutation (homo- or heterozygous) results in increased body and organ size and neoplasia in mouse. p27 in cooperation with RAS controls metastasis (Bessom A et al 2004 Genes Dev 18:862). The wild type allele as a transgene may retard cancerous proliferation. Germ-line mutations in p27^{Kip1} can predispose to the development of multiple endocrine tumors in both rats and humans (Pellegata NS et al 2006 Proc Natl Acad Sci USA 103:15558). Inactivation of p27^{Kip1} is triggered by phosphorylation and mediated by the proteasome complex. Non-receptor tyrosine kinases phosphorylate p27^{Kip1} and decrease its stability leading to entry into the cell cycle (Kaldis P 2007 Cell 128:241). p34^{cdc2-2}: The gene coding for the catalytic subunit of MPF in *Schizosaccharomyces pombe* (counterparts, *CDC28* in *Saccharomyces cerevisiae*, *CDCHs* in humans have 63% identity with *cdc2*; these genes are present in all eukaryotes). The gene product is a serine/tyrosine kinase and its function is required for the entry into M phase of the cell cycle. If prematurely activated, it may cause apoptosis. [▶cell cycle](#), [▶MPF](#); Shimada M et al 2001 Biol Reprod 65:442; Nigg EA 2001 Nature Rev Mol Cell Biol 2:21.

p35 (Cdk5 regulatory subunit): A homolog of the baculoviral (survival) protein and cyclin-dependent regulator of neural migration and growth and which blocks apoptosis in a variety of eukaryotic cells. It colocalizes in the cells with RAC and Pac-1. Truncation of p35 results in a very stable p25 protein that is present in Alzheimer disease tangles. [▶baculoviruses](#), [▶RAC](#), [▶Pac-1](#), [▶Alzheimer disease](#), [▶CDK](#); Tarricone C et al 2001 Mol Cell 8:657; Lin G et al 2001 In Vitro Cell Dev Biol Anim 37(5):293.

p38 (MPK2/CSBP/HOG1): A stress-activated protein kinase of the MEK family. It accelerates the degradation of p27^{Kip1}, and it phosphorylates H3 histone. p38 is one of the factors required for the initiation of G2/M checkpoint after UV radiation. The down-regulation of E-cadherin during mouse gastrulation requires p38 and a p38-interacting protein (Zohn IE et al 2006 Cell 125:957). The p38-activated protein (PRAK) is essential for RAS-induced senescence and tumor suppression (Sun P et al 2007 Cell 128:295). The mitogen-activated protein kinase

(MAPK) p38 controls inflammatory responses and cell proliferation. Using mice carrying conditional *Mapk14* (also known as *p38α*) alleles, when specifically deleted in the mouse embryo, fetuses developed to term but died shortly after birth, probably owing to lung dysfunction. Fetal hematopoietic cells and embryonic fibroblasts deficient in p38 showed increased proliferation resulting from sustained activation of the c-Jun N-terminal kinase (JNK) pathway (Hui L et al 2007 Nat Genet 39:741). p38 is a lung tumor suppressor (Ventura JJ et al 2007 Nat Genet 39:750). ►MEK, ►MEF, ►MAP kinase, ►JNK, ►cadherins, ►gastrula, ►checkpoint, ►UV; Schrantz N et al 2001 Mol Biol Cell 12:3139; Bulavin DV et al 2002 Curr Opin Genet Dev 12:92.

p40: A tumor suppressor encoded in human chromosome 3q, produced by alternative splicing of p51. Also an L1 RNA transcript (of ORF II) binding protein required of retrotransposon movement. ►p51, ►p53, ►L1, ►retrotransposon, ►ORF; Hess SD et al 2001 Cancer Gene Ther 8(5):371; Henning D, Valdez BC 2001 Biochem Biophys Res Commun 283:430.

p42: ►MAPK

p50: The N-terminus of the p105 light chain of NF-κB encoded at 4q23-q24. ►NF-κB; Yamada H et al 2001 Infect Immun 69:7100.

p51: A cell proliferation inhibitor protein related to p73 and encoded at 3q28. p51A is 50.9 kDa and p51B is 71.9 kDa. ►p73, ►p40, ►p53; Guttieri MC, Buran JP 2001 Virus Genes 23:17.

p52^{SHC}: A RAS G-protein regulator protein; it is regulated through CTLA-4–SYP associated phosphatase. ►CTLA-4, ►SYP, ►RAS; Joyce D et al 2001 Cytokine Growth Factor Rev 12:73.

p53 (TP3, 17p13.1): A tumor suppressor gene when the wild type allele is present but single base substitutions may eliminate suppressor activity and the tumorigenesis process may be initiated.

p53 is a tetramer with separate domains for DNA binding, transactivation and tetramerization (see Fig. P2).

The transcriptional coactivator p300 binds to and mediates the transcriptional functions of the tetrameric tumor suppressor p53. In the four domains of

the complex between tetrameric p53 and p300, the latter wraps around the four transactivation domains of p53 (see Fig. P3) (Teufel DP et al 2007 Proc Natl Acad Sci USA 104:7009). Protein p53 as tetramers of tetramers binds to different DNA sites and in case of stress activates the expression of genes involved in apoptosis. Wild type alleles of oncogenes and DNA damage, both activate tumor suppressor activities of p53 although through separate metabolic routes (Efeyan A et al 2006 Nature [Lond] 443:159; Christophorou MA et al 2006 Nature [Lond] 443:214). New information is available for the structural framework in interpreting mechanisms of specificity, affinity and cooperativity of DNA binding as well as regulation by regions outside the sequence-specific DNA-binding domain (Kitayner M et al 2006 Mol Cell 22:741). Protein p53 recognizes specific DNA sequences, activates transcription from promoters with p53 protein binding sites and represses transcription from promoters lacking p53-binding sites; p53 regulates more than 160 genes. Recent data based on chromatin immunoprecipitation and paired end ditag sequencing identified 542 binding sites for p53 (Wei CL et al 2006 Cell 124:207). After DNA damage, the level of p53 increases by new translation and increased half-life of its mRNA. Ribosomal protein L26 binds to the 5'-untranslated region of mRNA and enhances its translation. Protein nucleolin binds to the same region and decreases translation (Takagi M et al 2005 Cell 123:49). Tumor suppressors p53, p63 and p73 express multiple splice variants and can use different promoters, thereby determine tissue-specificity of their expression (Bourdon J-C et al 2005 Genes Dev 9:2122; Murray-Zmijewski F et al 2006 Cell Death Differ 13:962). It promotes annealing of DNAs, inhibits replication, controls G1 and G2 phase checkpoints, leads to apoptosis or just blocks cytokinesis if the DNA is damaged, interferes with tumorous growth, maintains genetic stability, reduces radiation hazards by its regulatory role in the cell cycle. For the maintenance of G2 arrest after DNA damage it also requires the presence of p21. Protein p53 binds to a somewhat conserved consensus and it is phosphorylated at serine 315 residues by CDK proteins during S, G2 and M phases of the cell cycle but not at G1 although p53 controls an important G1

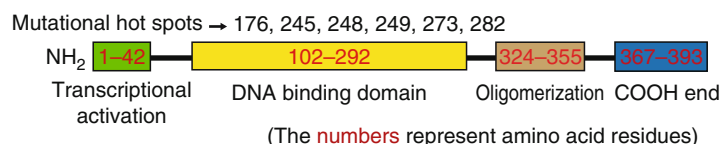

Figure P2. Structure of the p53 protein

Figure P3. Ribbon diagram of the four core domains of p53 (light blue, green, yellow, maroon) interacting with DNA (dark blue). The Van der Waals surface is shown in gray; the four Zn ions are represented by magenta spheres. (Courtesy of Professor Z. Shakked, Weizmann Institute of Science)

checkpoint. Binding subunits may have ubiquitin-conjugating role. Histone H3, methylated at lysine 79, targets 53BP1 to DNA double-strand breaks (Huyen Y et al 2004 Nature [Lond] 432:406). p53 also controls proteins p21, p27 and p57. The p53 protein binds to the four copies of its consensus in DNA (5'-PuPuPuGA/T-3'). The C-terminal domain controls tetramerization and the N-terminal domain is responsible for transcriptional activation and for the regulation of down-stream genes. Small-angle x-ray scattering information in solution defined its shape, and NMR identified the core domain interfaces and showed that the folded domains had the same structure in the intact protein as in fragments. The combined solution data with electron microscopy on immobilized samples provided medium resolution 3D maps (Tidow H et al 2007 Proc Natl Acad Sci USA 104:12324).

One study indicated that at least 34 different transcripts were induced by p53 more than ten-fold although there was heterogeneity in the response. Co-activators TAFII40, TAFII 60 and other TATA box binding factors mediate its transcriptional activation. When the first six exons of the gene are deleted, the mRNA is still translated into a C-terminal protein fragment. Such a mutation enhances tumor suppression but leads to premature aging in mice (Tyner SD et al 2002 Nature [Lond] 415:45). p53 is encoded in human chromosome 17p13.105-p12; in about half of the human tumors the normal allele is altered. p53 regulates mitochondrial respiration through cytochrome oxidase c (SCO2) and may account for glycolysis in cancer cells and aging versus the

respiratory pathway in normal cells (Matoba S et al 2006 Science 312:1650). Protein 53 plays a central role in cellular metabolism and its expression is induced by many factors such as oncogene expression, chemotherapy, oxidative stress, hypoxia, etc. Topoisomerase I is a p53-dependent protein. A p53-induced apoptosis may require transcriptional activation or it may occur in the absence of RNA or protein synthesis. The activation of p53 may be followed by FAS transport from Golgi intracellular stores without a need for synthesis of FAS. Tumor suppressor p53 product in the nucleus regulates pro-apoptotic genes such as *FAS*, *BAX*, *Bid*, *Noxa* and *PUMA*. In the cytoplasm, the p53 protein activates Bcl-2 and facilitates the permeability of the mitochondria for the release of pro-apoptotic molecules such as cytochrome c. In the cytoplasm, p53 is dislodged from Bcl-2 by PUMA to act on the mitochondrial permeability and apoptosis; thus PUMA interconnects the nuclear and cytoplasmic functions of p53 (Chipuk JE et al 2005 Science 309:1732).

The activity of p53 is also regulated by methylation of lysine 4 residues of histone-3 by Set9 methyltransferase and thereby the protein is better stabilized (Chuikov S et al 2004 Nature [Lond] 432:353). The Smyd2 protein mediates methylation of Lys370 in p53 and represses its activity; Set9 mediated methylation at Lys372 reduces methylation at Lys370 (Huang J et al 2006 Nature [Lond] 444:629). Acetylation of lysines 373 and 382 increases its DNA binding (Luo J et al 2004 Proc Natl Acad Sci 101:2259). Single nucleotide polymorphism in the promoter of MDM2 increases the affinity of the Sp21 transcriptional activator and attenuation of the p53 resulting in accelerated tumorigenesis (Bond GL et al 2004 Cell 119:591).

The ASPP family member regulatory proteins bind to the proline-rich region of p53, which contains the most common p53 polymorphism at codon 72. iASPP (inhibitory ASPP) binds to and regulates the activity of p53Pro72 more efficiently than the alternative amino codon p53Arg72. Hence, escape from negative regulation by iASPP is a newly identified mechanism by which p53Arg72 activates apoptosis more efficiently than p53Pro72 (Bergamaschi D et al 2006 Nature Genet 38:1133).

The calcium-binding proteins S100B and S100A4 bind preferentially to the tetramerization domain at lower oligomerization states, disrupt tetramerization and control intracellular movement of the p53 protein (Fernandez-Fernandez, M.R. et al. 2005 Proc Natl Acad Sci USA 102:4735).

Protein p73 has functions similar to those of p53. p33^{ING1}, encoded at human chromosome 13q34, cooperates with p53 by protein-protein interaction in

repressing cellular proliferation and the promotion of apoptosis.

The DNA-dependent protein kinase (DNA-PK) activates p53 in case the DNA is damaged. When amino acid site 376 is dephosphorylated by ionizing radiation protein 14-3-3 binds to p53 and increases its ability for DNA binding (see Fig. P4). Still other proteins such as IRF may be involved with p53 and other cooperating proteins. p53 activity may also be affected by oncoproteins RAS and MYC. Chemotherapeutic agents, UV light and protein kinase inhibitors may also activate p53. p53 is reversibly blocked by pifithrin- α (2[2-imino-4,5,6,7-tetrahydro-benzothiazol-3-yl]-1-polyethanone) and may protect from the undesirable side effect of anticancer therapy without causing new tumors in the absence of p53 function. When 33,615 human unique genes were tested by cDNA microarrays, 1,501 genes responded one way or another to p53 (Wang L et al 2001 J Biol Chem 276:43604).

Figure P4. Some of the circuits of p53. Ionizing radiation damage to the ataxia telangiectasia protein results in the phosphorylation of the serine 15 residue of p53 and checkpoint 2 (CHK2), which in turn phosphorylates residue 20. The latter point is normally occupied by Mdm2/HDM2 a negative regulator of p53 that is now dislodged by the phosphorylation of site 20. The p53 ser20-p protein is now stabilized, despite the radiation and can induce BAX (a porin with anti-apoptosis function) and p21, a suppressor of mitosis. The blocking of CHK2 then prevents its inhibition of cell division cycle proteins (Cdc25 and Cdc2). The process to mitosis is then facilitated

Pharmacological compounds (CP-31398, CP-257042, etc.) have been selected by large-scale screening that could stabilize the DNA-binding domain of mutant p53 and activate its transcription as well as to slow tumor development in mice. In some cancers, p53 may increase sensitivity to chemotherapeutic agents but in others, it does not affect them.

NADH quinone oxidoreductase may stabilize the p53 protein. Synthetic siRNA with single base difference may suppress the expression of mutation in p53 and may selectively block tumorigenesis by restoring wild type function (Martinez LA et al 2002 Proc Natl Acad Sci USA 99:14849). Using RNAi technology p53 function can be reactivated in murine liver carcinomas by triggering cellular senescence and innate immunity and consequently leading to tumor clearance (Xue W et al 2007 Nature [Lond] 445:656). Blocking p53 expression by introducing a stop cassette into the gene or removing it by the use of the Cre/loxP system, lymphomas and sarcomas of mice could be induced and then regressed after restoration of p53 function (Ventura A et al 2007 Nature [Lond] 455:661). The antiviral and anticancer effects of p53 is mediated by interferons (α and β), which boost the response to stress signals and thus promote apoptosis (Takaoka A et al 2003 Nature [Lond] 424:516).

Germline mutations occur in about 1×10^3 of the Caucasian populations but in about half of the sporadic cancers, it is somatically mutated. (Science magazine declared p53 the molecule of year 1993). **p53** tumor suppressor gene, **p53** annealing, **p53** apoptosis, **p53** PUMA, **p53** BCL, **p53** TAF, **p53** TBP, **p53** transactivator, **p53** nucleolin, **p53** cancer, **p53** Sp1, **p53** cell cycle, **p53** p21, **p53** p27, **p53** p40, **p53** p51, **p53** p57, **p53** p63, **p53** p73 substitution mutation, **p53** DAP kinase, **p53** MDM2, **p53** lactacystin, **p53** ARF, **p53** IRF, **p53** papilloma virus, **p53** DNA-PK, **p53** protein 14-3-3, **p53** E2F, **p53** ribonucleotide reductase, **p53** ataxia telangiectasia, **p53** CHK, **p53** Cdc, **p53** porin, **p53** p21, **p53** GADD45, **p53** RNAi, **p53** interferon, **p53** paired-end diTAG; Vogelstein B et al 2000 Nature [Lond] 408:307; Vousden KH 2000 Cell 103:691; Asher G et al 2001 Proc Natl Acad Sci USA 98:1183; Johnson RA et al 2001 J Biol Chem 276:27716; Olivier M et al 2002 Hum Mut 19:607; minireview: Kastan MB 2007 Cell 128:837; p53 mutation database: <http://www-p53.iarc.fr/index.html>; <http://p53.free.fr>.

p55 (TNFR1): A tumor necrosis factor receptor of Fas. **p55** Fas, **p55** TNF; Dybedal I et al 2001 Blood 98:1782; Longley MJ et al 2001 J Biol Chem 276:38555.

p56^{chk1}: A protein kinase and a checkpoint for mitotic arrest after mutagenic damage inflicted by UV, ionizing radiation or alkylating agents. The DNA damage results then in the phosphorylation of this protein in yeasts. The phosphorylation may prevent the mitotic arrest yet the cells may die later; p56 is not involved in DNA repair. Phosphorylation is required so that other checkpoint genes become/stay functional. **p56^{chk1}** cell cycle, **p56^{chk1}** DNA repair; Feigelson SW et al 2001 J Biol Chem 276:13891.

- p57** (p57^{Kip2}): An antimitogenic protein; its carboxyl end assures nuclear localization and the amino end is involved in the inhibition of CDK proteins. ►**CDK**, ►**p21**, ►**p27**, ►**cell cycle**, ►**KIP**; Thomas M et al 2001 *Exp Cell Res* 266:103.
- p58^{IPK}**: A heatshock protein 40 family member that inhibits interferon-induced, double-stranded RNA-activated eukaryotic translation initiation factor eIF2 α protein kinase, PERK. Stress in the endoplasmic reticulum (ER) caused by unfolded proteins activates the translation of the gene and thereby reduces protein overload in the ER. ►**heat-shock proteins**, ►**eIF2**; Yan W et al 2002 *Proc Natl Acad Sci USA* 99:15920.
- p60**: Binds to Hsp70 and Hsp90 and chaperones the assembly of the progesterone complex. ►**Hsp70**, ►**Hsp**, ►**progesterone**, ►**animal hormones**, ►**chaperone**; Mukhopadhyay A et al 2001 *J Biol Chem* 276:31906.
- p63**: A member of the p53 tumor suppressor gene family, encoded at 3q27-q29. The gene expresses at least 6 transcripts, involved with transactivation of p53 and p73, DNA binding and oligomerization. It controls ectodermal (limb, craniofacial and epithelial) differentiation. Protein p63 regulates also the commitment to prostate cell lineage development (Signoretti S et al 2005 *Proc Natl Acad Sci USA* 102:11355). The first direct target of p63 appears to be the Perp protein localized in the desmosomes. Absence of Perp leads to post-natal death in mice (Ihrie RA et al 2005 *Cell* 120:843). Although p63 belongs to the p53 tumor suppressor family, its function seems to be different. Mouse heterozygotes for p63 were not prone chemically induced tumorigenesis (Keyes WM et al 2006 *Proc Natl Acad Sci USA* 103:8435). p63 protects female germ line—by apoptosis—during meiotic arrest (Suh E-K et al 2006 *Nature [Lond]* 444:624). Epithelial stem cells require p63 for proliferation (Senoo M et al 2007 *Cell* 129:523). ►**p53**, ►**p73**, ►**desmosome**, ►**EEC syndrome**, ►**Hay-Wells syndrome**; van Bokhoven H et al 2001 *Am J Hum Genet* 69:481; van Bokhoven, Brunner HG 2002 *Am J Hum Genet* 71:1.
- p65**: A component of the NF- κ B complex. It can be exploited advantageously for gene activation in a chimeric construct with a mutant progesterone-receptor-ligand binding domain of gene GAL4. ►**NF- κ B**, ►**GAL4**, ►**gene-switch**, Burcin MM et al 1999 *Proc Natl Acad Sci USA* 97:355.
- p70/p86**: The Ku autoantigen. ►**DNA-PK**, ►**Ku**
- p70^{S6k}**: Phosphorylates S6 ribosomal protein at serine/threonine residues before translation. Also called S6 kinase. ►**translation initiation**, ►**p85^{S6k}**, ►**S6 kinase**, ►**signaling to translation**; Harada H et al 2001 *Proc Natl Acad Sci USA* 98:9666.
- p73**: It has homology in amino acid sequence to p53 protein and is encoded in human chromosome 1p36.3. Similarly to p53, it regulates apoptosis and anti-tumor activity (upon E2F1 induction), hippocampal dysgenesis, hydrocephalus, immune reactions and pheromone sensory pathways. It affects proliferation, although in a somewhat different manner, but its loss does not lead to tumorigenesis in mice. p73 may compete with p53. This protein may have antiapoptotic effect in neurons. ►**p53**, ►**apoptosis**, ►**p63**, ►**E2F**; Sasaki Y et al 2001 *Gene Ther* 8:1401; Stiewe T, Putzer BM 2001 *Apoptosis* 6:447; Melino G et al 2002 *Nature Rev Cancer* 2:605.
- p75**: A non-tyrosine kinase receptor protein, TNFR 2 (tumor necrosis factor receptor 2). It is a Fas receptor. ►**Fas**, ►**TNF**; Hutson LD, Bothwell M 2001 *J Neurobiol* 49(2):79; Wang X et al 2001 *J Biol Chem* 276:33812.
- p80^{Sdc25}**: A protein phosphatase that activates p34^{cdc2}-cyclin protein kinase complex by dephosphorylating Thr¹⁴ and Tyr¹⁵. ►**cell cycle**, ►**Ku**; McNally KP et al 2000 *J Cell Sci* 113[pt 9]:1623.
- p85^{S6k}**: Phosphorylates S6 ribosomal protein before translation at serine/threonine sites; also called S6 kinase. p85 protein is also involved in a p53-dependent apoptotic response to oxidative damage and activation of natural killer. p85 phosphoinositide 3-kinase also mediates developmental and metabolic functions. ►**translation initiation**, ►**p70^{S6k}**, ►**S6 kinase**, ►**phosphoinositides**; Fruman DA et al 2000 *Nat Genet* 26:379.
- p95**: is Fas and is involved in apoptosis; its mutation leads to the Nijmegen breakage syndrome and other double breakage of the chromosomes. ►**acrosomal process**, ►**Fas**, ►**APO**, ►**Nijmegen breakage syndrome**, ►**apoptosis**
- p97** (Cdc48): About M_r 600 ATPase and mediates membrane fusion. ►**endoplasmic reticulum-associated degradation**; Hirabayashi M et al 2001 *Cell Death Differ* 8(10):977.
- p105**: ►**p50**
- p107**: A retinoblastoma protein-like regulator of the G1 restriction point of the cell cycle. ►**restriction point**, ►**tumor suppressor**, ►**retinoblastoma**, ►**cell cycle**, ►**pocket**; Charles A et al 2001 *J Cell Biochem* 83:414.
- p110 α** : The catalytic subunit of PIK. It has a critical role in insulin signaling and with TOR it controls the

development of gliomas. ►PIK/PI(3)K, ►insulin, ►glioma

p110^{Rb}: The protein encoded by the retinoblastoma (Rb) gene. When not fully phosphorylated it interferes with the G₀ and G₁ phases of the cell cycle by inhibition of the E2F transcription factor. ►retinoblastoma, ►cell cycle, ►tumor suppressor, ►E2F, ►killer cells; DeCaprio JA et al 1988 Cell 54:275.

p115: A monomeric GTPase with a specific guanine exchange factor (GEF) for RHO (p115 Rho GEF). ►GTPase, ►RHO, ►GEF; Wells CD et al 2001 J Biol Chem 276:28897.

p125^{FAK} (focal adhesion kinase): A non-receptor tyrosine kinase. ►CAM; Yurko MA et al 2001 J Cell Physiol 188:24.

p130: A retinoblastoma protein-like regulator of the G1 restriction point of the cell cycle. p130^{Cas} is involved in the organization of myofibrils, actin fibers, anchorage-dependence of cultured cells. ►restriction point, ►tumor suppressor, ►retinoblastoma, ►CAS, ►pocket; Tanaka N et al 2001 Cancer 92:2117.

p160: A family of transcriptional co-activators such as SRC-1, GRIP1/TIF2 and pCIP. They modify chromatin structure by methylating some of the histones. ►chromatin remodeling, ►nuclear receptors, ►pCIP; Mak HY 2001 Mol Cell Biol 21:4379.

p300 (CBP): A cellular adaptor protein preventing the G₀/G₁ transition of the cell cycle, it may activate some enhancers and stimulate differentiation. It is also a target of the adenoviral E1A oncoprotein. Its amino acid sequences are related to CBP, a CREB-binding protein. Nuclear hormone-receptors interact with CBP/p300 and participate in gene transactivation. PCAF is a p300/CBP-associated factor in mammals, and it is the equivalent of the yeast Gcn5p (general controlled nonrepressed protein), an acetyltransferase working on histones 3, 4 (HAT A) and thus regulating gene expression. p300 functions also as a co-activator of NF-κB. p300 also binds PCNA. In several human cancers, p300 mutations were identified indicating that the protein is a tumor suppressor. p300 may show ubiquitin ligase activity for p53. ►adenovirus, ►CREB, ►NF-κB, ►PCNA, ►histone acetyl-transferase, ►E1A, ►bromodomain, ►chromatin remodeling, ►histone methyltransferases, ►p53; Lin CH et al 2001 Mol Cell 8:581; ►CARM

p350: A DNA-dependent kinase, it is a likely basic factor in severe combined immunodeficiency and it may also be responsible for DNA double-strand repair, radiosensitivity and the immunoglobulin V(D)J rearrangements. In association with the KU protein,

it forms a DNA-dependent protein kinase. ►severe combined immunodeficiency, ►kinase, ►KU, ►DNA-dependent protein kinase, ►immunoglobulins; Chan DW 1996 Biochem Cell Biol 74:67.

P450 (CYP): A family of genes coding for cytochrome enzymes involved in oxidative metabolism. They are widely present in eukaryotes and scattered around several chromosomes. All mammalian species have at least eight subfamilies. The homologies among the subfamilies are over 30% whereas the homologies among members of a subfamily may approach 70%. These cytochromes possess monooxygenase, oxidative deaminase, hydroxylation, sulfoxide forming, etc., activities. *Aspergillus oryzae* has ~149 cytochrome P450 genes in multiple copies. The proteins are generally attached to the microsomal components of homogenized cells (endoplasmic reticulum [fragments]), often called S9 fraction. Some of these enzymes (subfamily IIB) are inducible by phenobarbital. Their expression may be tissue-specific, predominant in the liver, kidney or intestinal cells. Mammalian P450 cytochrome fraction is generally added to the *Salmonella* assay media of the Ames test in order to activate promutagens. The pregnane X receptor (PXR) is activated by a variety of compounds and is thus responsible for the activation of different drugs involved in mutation, cancer and interaction with other drugs. One member of the P450 series is involved in the regulation of the synthesis of the 6th class of plant hormones, brassinosteroids. P450 enzymes require the cofactor NAD or NADPH and their activity is favored by the presence of peroxides as oxygen donors. By mutagenesis, industrially more useful P450 variants are being produced. The P-450 (CYP1A1) dioxin and aromatic compound-inducible P450 maps to human chromosome 15q22-qter. CYP1A2 is phenacetin O-deethylase. Phenacetin is an analgesic and antipyretic carcinogen. CYP2D (22q13.1) is a debrisoquin 4-hydroxylase. Debrisoquine is a toxic anti-hypertensive drug. CYP51 (7q21.2-q21.3) is lanosterol 14-α-demethylase is a sterol biosynthetic protein. ►Ames test, ►cytochromes, ►hypoaldosteronism, ►steroid hormones, ►brassinosteroids, ►peroxide, ►NAD, ►analgesic, ►antipyretic, ►cyclophilin; Fujita K, Kamataki T 2001 Mutat Res 483:35; Ingelman-Sundberg M 2001 Mutat Res 482:11; crystal structure of p450 3A4: Williams PA et al 2004 Science 305:683.

P Blood Group: Controlled by two non-allelic loci. The non-polymorphic P blood group is located in human chromosome 6 and it is encoding globoside whereas the polymorphic P1 locus in human chromosome 22 encodes paragloboside. The frequency of the P gene in Sweden was found to be 0.5401 and that of P1 0.4599. According to other studies, the frequency of

P among caucasoids is about 0.75. The P1 blood type facilitates bacterial attachment to the epithelial cells of the urinary tract and kidney. Therefore, infections are more common. Some P alleles raise the risk of abortions, and others may increase the chances of stomach carcinomas. Some of the literature calls P as P1 and P1 as P2. ►blood groups, ►globoside; Stroud MR 1998 *Biochemistry* 37:17420.

P Body (processing bodies, cytoplasmic body): A small number of specific sites in the cytoplasm involved in the decapping of mRNA after deadenylation of the polyA tail. At this location, mRNAs occur at various stages of degradation mediated by several proteins. Argonaute 2 of the RISC complex of RNAi is also localized in the P bodies (Sen GL, Blau HM 2005 *Nat Cell Biol* 7:633). The mammalian protein elongation factor eIF4E, its transporter (eIF4E-T) as well as the DEAD-box helicase rck/p54 are also located at these cytoplasmic sites (Andrei MA et al 2005 *RNA* 11:717). P bodies can recycle to the polysomes and when conditions are favorable can be translated (Brenques M et al 2005 *Science* 310:486). ►decapping, ►mRNA, ►RNAi, ►microRNA, ►eIF-4E, ►DEAD-box, ►RNA surveillance; Sheth U, Parker R 2003 *Science* 300:805; review: Parker R, Sheth U 2007 *Mol Cell* 25:635.

P1 Cloning Vectors: They have a carrying capacity up 100 kbp DNA; thus they fall between Lambda and YAC vectors. ►vectors, Park K, Chatteraj DK 2001 *J Mol Biol* 310:69; Grez M, Melchner H 1998 *Stem Cells* 16(Suppl. 1):235.

P

P Cytotype: ►hybrid dysgenesis

P Element: ►hybrid dysgenesis

P Element Vector: Constructed from the 2.9 kb transposable element P of *Drosophila* equipped with 31 bp inverted terminal repeats. The gene to be transferred is inserted into the element but in order to generate stable transformants the transposase function located in the terminal repeats is disabled. Functional transposase is provided in a separate helper plasmid (p π 25.7wc). Such a binary system permits the separation of the two plasmids and the screening of the permanent transgenes if a selectable marker is included. Both plasmids are mixed in an injection buffer and delivered into pre-blastoderm embryos. The various P vectors have been widely used in for gene tagging, induction of insertional mutation and for exploration of functional genetic elements in *Drosophila* and in some other insects. A newer type of vector, Pacman contains the P transposase and the phage ϕ C31 integration site. The ϕ C31 integrase mediates recombination between the engineered phage *attP* in the *Drosophila* genome

and a bacterial *attB* site in an injected plasmid. Such a system permits integration of large tracts of DNA (up to 133 kb) at specific sites. Such a targeted transgenesis can rescue much larger lethal mutations than it would be possible with only P element (Venken KJT et al 2006 *Science* 314:1744). ►hybrid dysgenesis, ►transposon vector, ►att sites; Sullivan W et al 2000 *Drosophila* Protocols, Cold Spring Harbor Laboratory Press, Cold Spring Harbor, New York.

P Granule: Serologically definable elements in the cytoplasm of animal cells at fertilization that segregate to the posterior part of the embryo where stem cell determination takes place. During embryogenesis, the P granules (RNA) may segregate asymmetrically into the blastomeres that produce the germline. (See Harris AN, Macdonald PM 2001 *Development* 128:2823).

P Nucleotides: ►immunoglobulins

P1 Phage: An *E. coli* transducing phage and vector with near 100 kb carrying capacity. (See Lehnher H et al 2001 *J Bacteriol* 183:4105).

P22 Phage: The temperate bacteriophage of *Salmonella typhimurium*; its genome is about 41,800 bp. (See Vander Byl C, Kropinski AM 2000 *J Bacteriol* 182:6472).

P1 Plasmid: A cloning vector with a carrying capacity of about 100 kb. ►vectors, ►P1 phage; Bogan JA et al 2001 *Plasmid* 45(3):200.

P Region of GTP-Binding Proteins: Shares the G-X-X-X-X-G-K-(S/T) motif (►amino acid symbols) and is suspected to involve the hydrolytic process of GTP-binding and several nucleotide triphosphate-utilizing proteins. ►GTP binding protein superfamily

P Site: The peptidyl site on the ribosome where the first aminoacylated tRNA moves before the second charged tRNA lands at the A site as the translation moves on. The binding of the tRNA to the 30S ribosomal subunit appears to be controlled by guanine residues at the 966, 1401 and 926 positions in the 16S rRNA. ►A site, ►protein synthesis, ►ribosome; Feinberg JS, Joseph S 2001 *Proc Natl Acad Sci USA* 98:11120; Schäfer MA et al 2002 *J Biol Chem* 277:19095.

PABp: The poly(A) binding protein (~72 kDa) is the major protein that binds to the poly A tail of eukaryotic mRNA and converts it to mRNAP. Pab1p connects the mRNA end to the eIF-4H subunit of the eukaryotic peptide initiation factors eIF-4G and eIF-4F. It contains four RRM motifs. PABp also interacts with PAIP a translational co-activator protein in mammals. ►binding proteins, ►mRNAP, ►mRNA

tail, ►polyadenylation signal, ►mRNA decay, ►eIF-4F, ►eIF-4G, ►Xrn1p, ►ribosome scanning, ►translation initiation, ►translational termination, ►RRM, ►mRNA circularization; Kozlov G et al 2001 Proc Natl Acad Sci USA 98:4409.

PAC (phage artificial chromosome): P1 phage PAC carries about 100–300 kb DNA segments. Most PAC vectors lack selectable markers suitable for mammalian cell selection but can be retrofitted by employing the Cre/loxP site-specific recombination system. ►BAC, ►YAC; Poorkaj P et al 2000 Genomics 68:106.

pac: A site in the phage genome where terminases bind and cut during maturation of the DNA before packing it into the capsid. ►terminase, ►packaging of the DNA

PAC-1: Dephosphorylates Thr¹⁸³ and Tyr¹⁸⁵ residues and thus regulates mitogen-activated MAP protein kinase involved in signal transduction. The Pac1 nuclease removes the 3' external transcribed spacers from the nascent rRNAs in cooperation with RAC. PAC1 is activated by p53 protein during apoptosis and suppresses carcinogenesis. ►MAP, ►MKP-1, ►apoptosis, ►p53; Boschert U et al 1997 Neuroreport 8:3077; Spasov K et al 2002 Mol Cell 9:433.

PACAP (pituitary adenylyl cyclase-activating polypeptide-like neuropeptide): A neurotransmitter at the body-wall neuromuscular junction of *Drosophila* larvae. It mediates the cAMP-RAS signal transduction path. ►signal transduction, ►RAS, ►RAF; Kopp MD et al 2001 J Neurochem 79:161.

Pacemaker: Maintains rhythmic balance like the pulse of the heart or circadian rhythm.

Pachynema: Literally “thick thread” of chromosomes at early meiosis when the double-stranded structure of the chromosomes is not distinguishable by light microscopy because the chromatids are tightly appositioned (see Fig. P5). Also, the two homologous chromosomes are closely associated, unless structural differences prevent perfect synapsis. If a pair of chromosome is not completely synapsed by pachytene, they will not pair later either. In pachytene the chromosomal knobs and chromomeric structure is visible and can be used for identification of individual chromosomes. After pachytene, the synaptonemal complex is dismantled and the chromosomes progressively condense. In case the chromosomes are defective at this stage the Red1 (required for chromosome segregation) and Mek1 proteins serve as checkpoint control by preventing further progress of meiosis. Normally MEK kinase phosphorylates Red. Phosphatase Glc7 dephosphorylates Red. More than two dozens of other proteins (named differently in

different organisms) are also involved in pachytene controls. ►meiosis, ►pachytene analysis, ►synapsis, ►chiasma, ►chromomere, ►MEK; Bailis JM, Roeder GS 2000 Cell 101:211; Roeder GS, Bailis JM 2000 Trends Genet 16:395.

Figure P5. Naturalistic drawing of the 10 pachytene chromosome pair of a teosinte x maize hybrid. Note (←) unpaired ends of chromosomes V, VII. And some terminal and near-terminal knobs (Courtesy of Dr. A. E. Longley, see also 1937 J Agric Res 54:835)

Pachyonychia: A rare autosomal dominant keratosis of the nails and skin. ►keratosis

Pachytene Analysis: The study of meiotic chromosomes at the pachynema stage when cytological landmarks, chromomeres, and knobs are distinguishable by the light microscope, and chromosomal aberrations (deletions, duplications, inversions, translocations, etc.) can cytologically be identified and correlated with genetic segregation information. The pachytene analysis of plants is analogous to the study of giant chromosomes in dipteran flies and other lower animals. The bands of the (somatic) salivary chromosomes are tightly appositioned chromomeres in these endomitotic chromosomes. ►meiosis, ►salivary gland, ►chromomere, ►endomitosis, ►recombination nodule; McClintock B 1931 Missouri Agric Exp Sta Bull 163; Carlson WR 1988 In: Corn and Corn Improvement, Agricultural Monograph 18, ASA-CS-SSA, Madison, Wisconsin, p 259.

Pachytene Stage: The chromosomes form pachynema. pachynema.

Packaging Cell Lines (For Retroviral Vectors): For the replication of the vector the viral proteins gag, pol, env are required but these are deleted from the vectors to prevent the production of disease-causing virions. The packaging signal ψ is however retained in the vector. Another solution is to insert these viral genes

into host chromosomes or remove from the helper virus the packaging signal (Ψ [psi]) and delete the 3'-LTR. In neither case could the production (by two recombinations) of replication-competent virions be completely eliminated. Thus, the nucleic acid (with the transgene) can be packaged although the virions are defective. An improved construct removed LTRs from the structural genes and replaced them with heterologous promoters and polyadenylation signals. The *gag* and *pol* genes are placed on a plasmid different from the one that carries the *env* gene. Thus, in the packaging cell lines, these two are inserted at different chromosomal sites. Also, if the number of cell divisions is limited, the chance of recombination between vector and helper is reduced. In an improved packaging system, a stop codon is engineered into *gag* reading frame to prevent the assembly of a fully competent virus. In the packaging cell lines, the appropriate envelope protein for the intended target (ecotropic or amphotropic) should be present in the helper virus (pseudotyping) to insure optimal transfection. The envelope protein may need modification in order to ensure the proper targeting to the intended types of cells. Antibodies, specific for certain cell surface antigens or against particular receptors may be employed. Although some of these procedures appear very attractive, they may not always be equally efficient. These technical problems are obviously attracting serious research efforts. ▶retroviral vectors, ▶ecotropic retrovirus, ▶amphotropic retrovirus, ▶pseudotyping, ▶viral vectors; Thaler S, Schnierle BS 2001 Mol Ther 4(3):273.

P

Packaging of Phage DNA: λ phage gene A recognizes the cos sites, gene D assists in filling the head (capsid) and genes W, F, V ILK and GMH assemble the phage from prefabricated elements and act in the processes shown diagrammatically in Fig. P6.

The DNA that first enters the phage capsid has the Nu end and the opposite end (the last) is the R end. The organization of the DNA in the phage head is not random; the geometry of the arrangement is determined by writhe of the DNA (Arsuaga J et al 2005 Proc Natl Acad Sci USA 102:9165). ▶lambda phage, ▶p16, ▶development, ▶writhe number, ▶heedful rule; Smith DE et al 2001 Nature [Lond] 413:748, Kindt J et al 2001 Proc Natl Acad Sci USA 98:13671.

Figure P6. Packaging of phage DNA

Packaging Signal (ψ): Allows the stuffing of the viral genome into the viral capsid.

Packing Ratio: The DNA molecule is much-much longer than the most extended chromosomes fibers. The packing ratio was defined as the proportion of the DNA double helix and the length of the chromosome fibers. In the human chromosome complement, the packing ratio was estimated to be more than 100:1 at metaphase. The length of the *Drosophila* genome at meiotic metaphase was estimated to be 7.8 μm and the length of a chain of 3000 nucleotides is approximately 1 μm . The *Drosophila* genome contains about 9×10^7 bp, hence the total length of DNA within the *Drosophila* genome is about 30,000 μm and that would indicate a packing ratio of 3846:1. The packing ratio indicates some of the problems the eukaryotic chromosomes encounter in condensing an enormous length of DNA to a small space and still replicating, transcribing and recombining it in an orderly manner. To illustrate the problems in a trivial way: many eukaryotes have the same packing problem as folding a 2.5 km (1.6 mi) long thread into a 2.5 cm (1") skein. Prokaryotic type DNA—such as without nucleosomal structure—the excessive amount of plasmid DNA forms liquid crystalline molecular supercoils. ▶Mosolov model, ▶supercoiled DNA; see photo of bacterial chromosome at lysis, p. 1,150; DuPrav EJ 1970 DNA and Chromosomes. Holt, Rinehart and Winston, New York; Holmes VF, Cozzarelli NR 2000 Proc Natl Acad Sci USA 97:1322; Cook PR 2002 Nature Genet 32:347.

Pack-MULEs: The abundant (3000/rice genome) transposable elements in different plant species that carry fragments of cellular genes (~ 1000 in rice) derived from all chromosomes. These fragments can have multiple chromosomal origins, and can be functional. During millions of years, the fragments could be rearranged, amplified and contributed to evolution of plant genes. ▶transposable elements plants; Jiang N et al 2004 Nature [Lond] 431:569.

Paclitaxel: ▶taxol

Pac-Man Model: Kinetochores induce depolymerization of the microtubules of the kinetochore at their plus end and that allows the sister-chromatids to move toward the poles during mitosis by, so to say, chewing

up spindle fiber tracks. ►anaphase, ►spindle fibers, ►microtubules, ►kinetochore; Rogers GC et al 2004 Nature [Lond] 327:364; Liu J, Onuchic JN 2006 Proc Natl Acad Sci USA 103:18432.

PACT (p53 associated cellular protein): A negative regulator of p53. ►p53

Pactamycin: An inhibitor of eukaryotic peptide chain initiation (see Fig. P7).

Figure P7. Pactamycin

PAD4: peptidylarginine deiminase. It converts methyl-arginine to citrulline and releases methylamine. It targets also multiple sites in histones H3 and H4. ►arginine, ►citrulline, ►methylation of DNA, ►histones, ►epigenesis; Wang Y et al 2004 Science 306:279.

Padlock Probe: Contains two target-complementary segments connected by linker sequences (see Fig. P8). Hybridization to target sequences brings the two ends close to each other and can be covalently ligated. The so circularized probes are thus catenated to the DNA (\approx) like a padlock (OO). Such probes permit high-specificity detection and distinction among similar target sequences and can be manipulated without alterations or loss. By using circularizable or circularized allele-specific probe, primers and rolling circle, amplification can detect mutations in short genomic sequences (see Fig. P9). The principle of the procedure is shown modified after Lizardi PM et al 1998 Nature Genet 19:225.

Figure P8. Padlock

Alternatively, for the rolling circle amplification two primers were used (see Fig. P10). After the first primer (P1) initiated the replication the second (P2) primer is bound to the tandem repeats and both primers generate repeats in opposite directions \rightarrow or \leftarrow using either the (+) or (−) strands, respectively. In 90 min, at least 10^9 copies of the circles are generated making it possible to detect very rare somatic mutations. Rolling circle amplification can detect gene copy number single base mutations and can quantify the transcribed mRNA (Christian AT et al

Figure P9. The probe at left, interrupted by a 6- to 10-base gap, hybridizes to the target DNA. The gap is filled with an allele-specific or DNA polymerase-generated sequence. After ligation, it generate a closed duplex padlock. A complementary (18-base) primer was then employed with a DNA polymerase. The original target DNA is not shown

Figure P10. Padlock primers

2001 Proc Natl Acad Sci USA 98:14238). The procedure generated replication products, which were hybridized to either fluorescein- or Cy3-labeled deoxyribonucleoprotein-oligonucleotide (DNP) tags, respectively. The tag was anti-DNP immunoglobulin M (IgM). This process of condensation of amplification circles after hybridization of encoding tags is called CACHET. The procedure permits also the identification of single-copy genes by epifluorescence microscopy. ▶[probe](#), ▶[rolling circle](#), ▶[fluorochromes](#), ▶[immuno-globulins](#), ▶[DNA polymerases](#), ▶[microscopy](#), ▶[mutation detection](#); Baner J et al 2001 Curr Opin Biotechnol 12:11; Roulon Tet al 2002 Nucleic Acids Res 30 (3):e12.

Padumnal Allele: Derived from the male. ▶[madumnal allele](#)

PAF (population attributable fraction): PAF represents the fraction of the disease that would be eliminated if the risk factor were removed. High risk alleles generally show PAF > 50% whereas in rare alleles in common diseases it is generally <10%. The common modest-risk alleles account for greater PAF in common diseases than the rare high-risk alleles. This hypothesis is called the common disease/common variant (CDCV). ▶[complex disease](#), ▶[QTL](#), ▶[correlation](#), ▶[association](#), ▶[HapMap](#); Carlson CS et al 2004 Nature [Lond] 429:446.

PAF: A positive and negative regulator of RNA polymerase II mediated transcription (Shi X et al 1996 Mol Cell Biol 16:669). The Paf complex has a role also in polyadenylation of mRNA.

PAF-AH: platelet activating factor acetylhydrolase coupled with dynein affects neural migration in lissencephaly. ▶[lissencephaly](#), ▶[dynein](#); Tarricone C et al 2004 Neuron 44:809.

Page: An acronym for polyacrylamide gel electrophoresis. ▶[gel electrophoresis](#)

Paget Disease: Two autosomal dominant forms have been described involving cancer of the bones or of the anogenital region (the region of the anus and genitalia) or the breast. The disease is an anomaly of osteoclastogenesis. BDB1 gene was located to 6p21.3 and PDB2 (also called familial expansile osteolysis, FEO) to 18q21-q22. Mutations in the tumor necrosis factor receptor, TNFR seem to be involved and affect the signaling by NF-κB (RANK, receptor activator of nuclear factor κB). Additional loci mapped to 5q35-qter (PDB3), to 5q31 (PDB4), to 2q36 (PDB5) and 10p13 (PDB6). ▶[osteoclast](#), ▶[osteoporosis](#), ▶[NF-κB](#), ▶[TNFR](#); Laurin N et al 2001 Am J Hum Genet 69:528.

PAH (polyaromatic hydrocarbon): The majority of PAH are carcinogenic (see Fig. P11).

Figure P11. PAH

PAH (paired amphipathic helix motif): It may mediate protein-protein interactions in regulating enzyme functions. ▶[amphipathic](#)

PAI: plasminogen activation inhibitor. ▶[plasminogen activator](#); Eilers AL et al 1999 J Biol Chem 274:32750.

Pain-Insensitivity: Controlled by defects causing hereditary sensory neuropathies. In the dominant form, the dorsal ganglia are degenerated. In the recessive neuropathy, the loss of myelinated A-fibers cause touch insensitivity. The congenital pain insensitivity with anhidrosis (CIPA, 1q21-q22) involves a defect of the nerve growth factor receptor (TRKA), and in the congenital insensitivity to pain without anhidrosis, the small myelinated A-delta fibers are defective. Mutation in the Na-channel subunit (SCN9A, encoded at 2q24.3) leads to pain-insensitivity (Cox JJ et al 2006 Nature [Lond] 444:894). The apparent insensitivity to the self-torture of the fakirs (Hindu ascetics) may be based on such genetic condition. ▶[neuropathy](#), ▶[Riley-Day syndrome](#), ▶[TRK](#), ▶[sensory neuropathy 1](#), ▶[anhidrosis](#); Mardy S et al 2001 Hum Mol Genet 10:179; Cheng H-YM et al 2002 Cell 108:31.

Pain-Sensitivity: May be traditionally treated with analgesics. Gene therapy by introduction of genes producing analgesic substances (catecholamines, enkephalins) or antinociceptive peptides are potential molecular approaches. The capsaicin or vanilloid receptor (VR1) control heat-gated ion channel with response to low temperature (~43°C) stimuli whereas the VRL-1 receptor responds to about 52°C. The vanilloid channel receptor is induced by protein kinase C. The transcriptional repressor DREAM constitutively suppresses prodynorphin in the neurons of the spinal cord. When DREAM is knocked out, there is still sufficient expression of dynorphin but there is a strong reduction in pain-sensitivity. Single amino acid substitutions (val¹⁵⁸/met) in catechol-O-methyltransferase (COMT) may modulate pain sensitivity/insensitivity. Simultaneous, two synonymous and one

non-synonymous, divergence in the human haplotype of the gene modulate COMT protein expression by altering mRNAs secondary structure (Nackley AG et al 2006 Science 314:1930). Prostaglandin E^2 is a mediator of inflammatory pain-sensitization via glycine receptor $\alpha 3$ (Harvey RJ et al 2004 Science 304:884). Expectation of pain reduced the subjective feeling of pain as well as activation of pain-related areas of the brain (Koyama T et al 2005 Proc Natl Acad Sci USA 102: 12950). Covalent modification of reactive cysteines within TRPA1 (Transient Receptor Potential family of ion channels) by noxious compounds causes channel activation, rapidly signaling potential tissue

Figure P12. Pair rule genes. The banding pattern on the body of the *Drosophila* embryo is under the control of several regulatory genes. In the case of the *even-skipped* gene (chromosome 2.58) the seven stripes in the syncytial blastoderm are under the control of five enhancers. Three of them #1, #2, #3 drive the expression of single stripes and the remaining two control the expression of pairs of stripes (3 + 7 and 4 + 6). The stripes are formed at the boundary of interactions of the suppressor gradients of genes *Hunchback* (encoded at 3.48) and *Knirps* (encoded at 3.46) and the *even-skipped* enhancers. It is assumed that binding-site affinity and distribution on the enhancers determine the sensitivity to the repressors as illustrated on the diagram. The four bands in the middle represent body stripes (not chromosome bands!) brought about by the interactions of the suppressor gradients. (Modified after Clyde DE et al 2003 Nature [Lond] 426:849)

►*RecA*, ►*RecT*, ►*Rad*, ►*Ph* gene; Kagawa W et al 2001 J Biol Chem 276:35201.

Pairing Alkylated Bases: ►alkylation

Pairing Centers: The cis-acting sites required for accurate segregation of homologous chromosomes during meiosis of *Caenorhabditis elegans* (MacQueen AJ et al 2005 Cell 123:1037). The *HIM-8* gene, encoding a zinc-finger protein, concentrates at the pairing centers on the X chromosome mediates chromosome-specific synapsis (Phillips CM et al 2005 Cell 123:1051).

Pairing-Sensitive Repression: Polycomb (PC) proteins bind to Polycomb-response elements (PREs) and thus cause repression. Repression is enhanced when two such elements are present. There are other similar elements like Mcp. ►*Polycomb*

Pair-wise Likelihood Score: Estimates the potential relationship between pairs of individuals on the basis of allele sharing. (See Smith BR et al 2001 Genetics 158:1329).

PAK (p21 activated kinase): The serine/threonine kinases activated by GTPases, Rac and Cdc42. Pak3 regulates Raf-1 by phosphorylating serine 338 in rats. Paks regulate the actin cytoskeleton, cell motility, neurogenesis, angiogenesis, signal transduction, apoptosis, metastasis, etc. A non-syndromic mental retardation (human chromosome Xq22, yeast homolog is *STE20*) prematurely terminates PAK3 transcription. ►*GTPase*, ►*Rac*, ►*raf*, ►*Cdc42*, ►*p21*, ►*p35*, ►*PDK*, ►*actin*, ►*cytoskeleton*, ►*apoptosis*, ►*mental retardation*, ►*non-syndromic*; Xia C et al 2001 Proc Natl Acad Sci USA 98:6174; Bokoch GM 2003 Annu Rev Biochem 72:743.

PAL: Phenylalanine ammonia lyase.

Palea: The inner, frequently translucent, bract around the grass flower (see Fig. P14).

Figure P14. Palea

Paleogenomics: ►ancient DNA

Paleolithic Age (Old Stone Age): More than 20,000 years ago it marked the beginning of human tool formation and cave artistry by the Cro-Magnon

humans. ►*neolithic*, ►*mesolithic*, ►*geological time periods*, ►*Lascaux*, ►*Neanderthal*

Paleologous Loci: Include ancient duplications.

Paleontology: Deals with the relics of past geological periods. Its methods and materials are used for the study of the evolution of biological forms. ►*paleolithic age*, ►*geological time periods*; Eurasian Miocene and Pleistocene land mammals and excavation sites: <http://www.helsinki.fi/science/now/>.

Paleozoic: The geological period between about 225 to 570 million years ago. During the later part of this period land plants, amphibians and reptile appeared. ►*geological time periods*

Palindrome: The region of a DNA strand where complementary bases are in opposite sequence, such as ATGCAC*GTGCAT (see Fig. P15). Palindromes may come about by inverted repeats of sections of the double-stranded DNA where these sequences of the opposite strands read the same forward and backward. Upon folding of these sequences in a single strand, they can assume structures with paired bases.

Figure P15. Palindromic DNA and possible pairing within single strands of it. (From Flavell RB, Smith DB 1975 Stadler Symp 7:47)

Palindromic sequences in the DNA reassociate very rapidly because of the complementary bases are in close vicinity. A simple palindromic word is MADAM, it reads the same from left to right or from right to left. Palindromic sequences are often unstable; recombination within palindromes results in deletions and duplications. The restriction enzyme recognition sites are palindromic. Palindromes are common in cancer cells and provide a platform for gene amplification and chromosomal aberrations (Tanaka H et al 2005 Nature Genet 37:320). ►*stem and loop*, ►*inverted repeats*, ►*insertion elements*, ►*restriction enzyme*, ►*RecA independent recombination*; Leach DR 1994 Bioessays 16:893; Nasar F et al 2000 Mol Cell Biol 20:3449; Zhu Z-H et al 2001 Proc Natl Acad Sci USA 98:8326; short

palindromic repeat detection: <http://crispr.u-psud.fr/Server/CRISPRfinder.php>.

Palingenesis: The regeneration of lost organs and parts or the reappearance of evolutionarily ancestral traits during ontogeny. According to Ernst Haeckel (1834–1914) the ontogeny recapitulates the phylogeny. ▶ontogeny, ▶phylogeny

Palisade Cells: Oblong cells and arranged in a row; the large palisade parenchyma cells are below the upper epidermis of plant leaves and loaded with chloroplasts (see Fig. P16).

Figure P16. Palisade cells in a leaf

Pallister-Hall Syndrome: postaxial polysyndactyly (PA-PA1), encoded in human chromosome 7q13, at the same location as the Greig syndrome. The gene is also called GLI3 and its product has a homology to the *Drosophila* Krüppel Zn-finger protein. The clinically distinct phenotypes of the two diseases are due to different allelic mutations of the same gene (Johnston JJ et al 2005 Am J Hum Genet 76:609). A similar syndactyly was recorded by French scientist, Maupertuis, in the Prussian royal court in Berlin in 1756. ▶polydactyly, ▶Greig cephalopolysyndactyly, ▶DNA-binding protein domains, ▶EEC syndrome, ▶Smith-Lemli-Opitz syndrome

Palmitoylation: The covalent attachment of fatty acids (mainly palmitate) to cysteine residues to membrane proteins by creating a thioester link. This process tethers protein reversibly to cellular membrane surfaces. The enzymes involved belong to the protein acetyltransferase (PAT) family (e.g., Akr1, Erf2) and share a common domain of DHHC (aspartate-histidine-histidine-cysteine; see Mitchell DA et al 2006 J Lipid Res 47:1118). Palmitoylated proteins play key roles in cell signaling, membrane traffic, cancer and synaptic transmission, heterotrimeric G proteins and many non-receptor tyrosine kinases (Fyn, Lck, Yes) and the epithelial nitric oxide synthase are palmitoylated. By proteomic analysis, 35 new PAT proteins have been identified in budding yeast (Roth AF et al 2006 Cell 125:1003). ▶fatty acids, ▶G proteins, ▶Fyn, ▶Lck, ▶Yes, ▶nitric oxide

Palmprint: ▶fingerprint, ▶Down's syndrome, ▶simian crease

Palomino: A horse with light tan color fur and flaxen mane and tail. The genetic constitution is *AAbbCCDd* (see Fig. P17).

Figure P17. Palomino

PALS: ▶alternative splicing

Palsy (paralysis): Cerebral palsy may be caused by physical injuries or may be part of the symptoms of diverse genetic syndromes. ▶syndrome, ▶tau

PAM: ▶evolutionary clock

PAMAM (polyamidoamine): The dendrimers can carry chemotherapy compounds (methotrexate) to the cancer cell, especially if connected with folate hooks that attach preferentially to the abundant folate receptors of cancer cells. ▶dendrimer, ▶methotrexate, ▶nanotechnology; Najlah M et al 2007 Bioconjug Chem 18:937.

PAMP: pathogen-associated molecular pattern recognition is an important step in developing reaction in animals and plants against infection. ▶vaccine

PAN: The genus of chimpanzees. ▶primates, ▶hominidae; Gagneux P 2002 Trends Genet 18:327.

PAN Editing: Adding of U residues to the primary transcripts of mtDNA and thus causing extensive post-transcriptional changes in RNA. ▶kinetoplast, ▶RNA editing

Pancreas: A large gland behind the stomach, between the spleen and the duodenum. It secretes insulin, glucagons, and protein-digesting enzymes. ▶spleen, ▶duodenum, ▶insulin, ▶glucagons, ▶diabetes, ▶Langerhans islets, diabetes: <http://www.cbil.upenn.edu/EPConDB>.

Pancreatic Adenocarcinoma: The cancer of the pancreas is frequently associated with loss or defect of DCC, or p53 or MTS1 oncogene suppressors. One study revealed an average of 15 annotated gene alterations (amplifications, deletions, tumor suppressors) in 24 adenocarcinoma lines (Aguirre AJ et al 2004 Proc Natl Acad Sci USA 101:9067). It was also attributed to mutations in codon 12 of the c-K-ras

(Kirsten RAS) gene encoded at human chromosome 12p12. A dominant susceptibility locus was assigned to 4q32-q34. Chromosomal aberrations, telomere shortening, methylation of CpG islands and point mutation may be the underlying cause. Silencing of cancer suppressors by hypermethylation at multiple genes may be involved. HER2/NEU overexpression is also a frequent cause. Tyrosine-kinase growth factor receptors may be involved. It may be associated with the Peutz-Jeghers syndrome (66%) and other syndromes such as hereditary pancreatitis (40%), BRCA2 (5–10%), etc. Its prevalence in the USA is $\sim 3 \times 10^{-5}$, and its prognosis is bad. ▶DCC, ▶p53, ▶p16, ▶Kirsten-Ras, ▶p21, ▶Peutz-Jeghers syndrome, ▶HER2, ▶NEU; Eberle MA et al 2002 Am J Hum Genet 70:1044; Hansel DE et al 2003 Annu Rev Genomics Hum Genet 4:237.

Pancreatitis, Hereditary: Autosomal dominant (7q35) gene (80% penetrance and variable expressivity) has an onset before the teen years, appearing as abdominal pain and other anomalies. The basic defect is in a cationic trypsinogen. ▶trypsin, ▶Johanson-Blizzard syndrome

Pancytopenia: Low blood cell number.

Panda (*Ailurus fulgens*): $2n = 36$.

Pandemic: The infection by a microbe or virus spread over large areas (countries, continents).

Paneth's Cells: The secretory intestinal epithelial cells expressing defensin and other antimicrobial peptides. In the Paneth cells of mice, 149 transcripts expressed 2 to 45-fold by microbial colonization. Among them was very abundant (31-fold increase) a bactericidal lectin (RegIIIγ) that may represent a primitive evolutionary form of innate immunity (Cash HL et al 2006 Science 313:1126). ▶defensin, ▶microbiome; Ghosh D et al 2002 Nature Immunol 3:583.

Pangenesis: An ancient misconception about heredity that originated in the Aristotelian epoch and periodically revived during the centuries. Charles Darwin has also interpreted inheritance as pangenesis. Accordingly, all the information expressed during the life of the individuals is transported to the gametes from all parts of the body. Thus, pangenesis is the means of the inheritance of all, including the acquired characters. ▶lysenkoism, ▶acquired characters

Pangenome: The essential, shared sequences among all representatives of a species (Tettelin H et al 2005 Proc Natl Acad Sci USA 102:13950).

Panic Disorder (PD): Episodic panic attacks involving palpitations, sweating, shortness of breath, feeling of choking, chest pain, false touch sensations usually in the absence of physical contact (such as burning, prickling), nausea, etc. The heritability appeared

0.48. Panic disorder may be associated with a number of physical diseases. Chromosome 13q appears to harbor several genes responsible for PD and chromosome 22 may carry some susceptibility factors. ▶psychoses, ▶panic obsessive disorder, ▶anxiety; Hamilton SP et al 2003 Proc Natl Acad Sci USA 100:2550.

Panicle: An inflorescence of a compound raceme structure such as of oats. ▶raceme

Panmictic Index: ▶fixation index, ▶panmixis

Panmixis (panmixia): Random mating; in a population there is equal chance for each individual to mate with any other of the opposite sex. ▶Hardy-Weinberg theorem

Panning: The use of antibody affinity chromatography or ELISA for the separation of specific molecules (in analogy to the gold-washing pans of the gold hunters). ▶affinity chromatography, ▶ELISA, ▶phage display; Chen G et al 2001 Nature Biotechnol 19:537.

Panspermia: The theory claiming that life has originated at several places in the universe and spread to earth by meteorites or by other means. ▶origin of life

Panther (*Panthera pardus*, leopard): $2n = 38$: A feline species; in captivity may be crossed with lion but no mating is known to take place in the wild where conspecific sexual partners are available.

Panther: The database for functionally related proteins, signaling pathways. <http://panther.appliedbiosystems.com>.

Pantothenic Acid: A precursor of Coenzyme A (see Fig. P18).

Figure P18. Panthotenate

Pantropic: Can affiliate with many different types of tissues.

PAP (purple acid phosphatases): Ubiquitous metallo-phosphoesterase proteins with phosphatase, exonuclease, 5'-nucleotidase, etc. functions. (See Li D et al 2002 J Biol Chem 277:27772).

Pap (Papanicolaou) Test: A cytological test for pre-malignant or malignant conditions (used primarily on smears obtained from the female urogenital tract). It detects also papilloma virus infections. ▶malignant growth, ▶papilloma virus

PAPA Syndrome (pyogenic sterile arthritis and acne and familial recurrent arthritis, 15p): It may involve also ulcerative skin lesions (pyoderma gangrenosum). It may be caused by defects in the 15-exon CD2-binding protein1 (CD2BP1). ▶CD2; Wise CA et al 2002 Hum Mol Genet 11:961; Shoham NG et al 2003 Proc Natl Acad Sci USA 100:13501.

Papain: A member of a family of proteolytic enzymes with an imidazole group near the nucleophilic SH group, and the former plays a role as a proton donor to the cleaved-off part. Papain cleaves immunoglobulin G into three near equal size fragments and this helped in clarifying the structure of antibodies. ▶proteolytic, ▶calpain, ▶immunoglobulins, ▶antibody

Papanicolaou Test: ▶PAP test

Papaver: ▶poppy

Papaya (*Carica papaya*): A melon-like, edible fruit, latex-producing small tree with four genera and all $2n = 2x = 18$; it is the source of the proteolytic enzyme papain. ▶papain

PapD: Gram-negative bacterial chaperone (28.5 kDa) delivers the components of the pilus from the periplasm. ▶periplasma, ▶chaperones, ▶pilus, ▶Gram negative/Gram positive

Paper Chromatography: A technique for the separation of (organic) molecules in filter paper by applying the mixture in a spot or band at the bottom of the paper and allowing an appropriate solvent to be sucked up and thus carry the components at different speed (to different height) so they can be separated (see Fig. P19). The components become visible by their

natural color or by the application of specific reagents. A large variety of different modifications were worked out in one or two dimensions, in ascending and descending ways. Nowadays paper chromatography is not used very much. ▶chromatography, ▶thin layer chromatography, ▶Rf value, ▶column chromatography, ▶high performance liquid chromatography, ▶affinity chromatography, ▶ion-exchange chromatography

Papillary Renal Cancer, Hereditary: Based on the MET oncogene at human chromosome 7q31, encoding a hepatocyte growth factor receptor. ▶MET, ▶HGF, ▶receptor tyrosine kinase

Papillary Thyroid Carcinoma: Caused by the RET oncogene. It accounts for about 80% of the thyroid cancers that have prevalence in the 10^{-5} range. Its incidence is higher in females than males. ▶RET

Papillation, Bacterial: Secondary colonies develop on the colonies of bacteria.

Papilloma: Pre-malignant neoplasia displaying epithelial and dermal finger-like projections.

Papilloma Virus (HPV, human papilloma virus): A double-stranded DNA ($\approx 5.3 \times 10^6$ Da or ~ 8 kb) virus causing animal and human warts and squamous carcinomas in mice. The HPV-16 and 18 are frequently present in cervical cancer. The E6 viral protein of HPV-16—through a ubiquitin path—is prone to degrade the p53 tumor suppressor if at amino acid position 72 there is an arginine rather than a proline. The E7 protein of strain HPV-18 degrades another tumor suppressor protein RB. The E1 protein is a hexameric helicase (Enemark EJ, Joshua-Tor L 2006 Nature [Lond] 442:270). Apparently, highly effective vaccines have been developed against HPV strains 16 and 18 that most commonly cause viral cervical cancer. HPV is a critical factor in the majority of cases of cervical cancer that which allowed development of strategies to prevent this form of oncogenesis. It is important to note that several other cancers are also associated with HPV infection, including head and neck cancers. Cancer prevention will require the long-term observation of a large number of treated women and it is necessary in the meantime to monitor for unintended adverse consequences of vaccination (Baden LR et al 2007 N Engl J Med 356:1990). There is also an unresolved moral and ethical problem regarding the age of vaccination of adolescent, sexually not active girls. HPV has about 100 different strains and some pose cancer risk whereas some others do not seem to be carcinogenic. HPV is one of the most common causes of sexually transmitted disease and condom use does not offer perfect protection because the transmission is through

Figure P19. Two-dimensional separation of 20 amino acids in a plant extract

the skin. HPV has been used as a genetic vector. ▶papova viruses, ▶p53, ▶retinoblastoma, ▶tumor suppressor, ▶cervical cancer, ▶Pap test, ▶condom, ▶helicases; Wolf JK, Ramirez PT 2001 *Cancer Invest* 19:621.

Papillon-Lefèvre Syndrome: ▶periodontitis

Papova Viruses: A large class of (oncogenic) animal viruses of double-stranded, circular DNA includes the polyoma viruses, the bovine papilloma virus and simian virus 40 (SV40), etc. that have been used as genetic vectors for transformation of animal cells. Also, they have been extensively studied by molecular techniques to gain information on structure and function. ▶polyoma, ▶Simian virus 40, ▶papilloma virus; Soeda E, Maruyama T 1982 *Adv Biophys* 15:1.

PAPS: 3'-phosphoadenosine-5'-phosphosulfate is a sulfate donor in several biochemical reactions, involving cerebroside, glycosaminoglycans and steroids. It is generated by the pathway: ATP + sulfate → adenosine-3'-phosphosulfate (APS) + pyrophosphate, APS + ATP → PAPS + ADP. Mutations at 10q23-q24 (spondyloepimetaphyseal dysplasia, SEMD) locus encoding the PAPSS2 cause short bowed limbs, large knee joints, brachydactyly, curved spinal column (kyphoscoliosis). ▶bone diseases

PAR (pseudoautosomal region): Where recombination may take place between the X and Y chromosomes. The ends of both of the short arm (PAR1) and the long arm (PAR2) have pseudoautosomal regions. ▶pseudoautosomal, ▶X chromosome, ▶Y chromosome, ▶lyonization; Dupuis J, Van Eerdewegh P 2000 *Am J Hum Genet* 67:462.

PAR (protease-activated receptors): The seven-transmembrane G protein-coupled receptors that mediate thrombin-triggered phosphoinositide hydrolysis. Pars are involved in thrombosis, inflammation and vascular biology. Matrix metalloprotease (MMP-1) is an agonist of Par1 (Boire A et al 2005 *Cell* 120:303). Pars may also activate proteases and protect the airways. Par1 has a role in invasive and metastatic cancers. PAR is a cofactor of PAR4. Binding and phosphorylation of PAR4 by Akt is essential for the survival of cancer cells. Inhibition of the PI3K-Akt pathway leads Par4-dependent apoptosis (Goswami A et al 2005 *Mol Cell* 20:33). Par2 is a trypsin receptor. ▶thrombin, ▶phosphoinositides, ▶metalloproteinases, ▶AKT, ▶apoptosis; Kamath L et al 2001 *Cancer Res* 61:5933.

Parabiosis: Two animals joined together naturally such as Siamese twins or by surgical methods and can be used to study the interaction of hormones, transduction signals, etc., in-between two different

individuals. Intrauterine parabiosis develops immune tolerance.

Paracellular Space: The intercellular space in the tissues.

Paracentric Inversion: ▶inversion paracentric

Paracentrotus lividus: Sea urchin; extensively studied by embryologists. ▶sea urchins

Paracrine Effect: A ligand (e.g., hormone) is released by a gland and affects neighboring cells.

Paracrine Stimulation: When one type of cell affects the function (such as proliferation) of another (nearby) cell. ▶autocrine; Janowska-Wieczorek A et al 2001 *Stem Cells* 19:99.

Paracytosis: Passing bacteria through cell layers without disruption of the cells (See van Schilfgaarde M et al 1995 *Infect Immun* 63:4729).

Paradigm: A model or an example to be followed.

Paradox: A statement or phenomenon, which is apparently contradictory to current knowledge but may actually be true.

Paraesthesia (paresthesia): Peripheral nerve damage, disease-caused itching, burning and tickling sensation.

Paraganglioma: ▶mitochondrial diseases in humans

Paraganglion: Cells originating from the nerve ectoderm flanking the adrenal medulla, and darkly stained by chromium salts. These cells may form a type of pheochromocytoma tumors that secrete excessive amounts of epinephrine and norepinephrine. ▶SHC oncogene

Paragenetic: phenotypic alterations not involving hereditary mutation.

Parahemophilia: Determined by homozygosity of semi-dominant autosomal genes. The symptoms involve bleeding similar to the conditions observed in hemophiliacs, bleeding from the uterus (menorrhagia) several days following childbirth. The physiological basis is a deficiency of proaccelerin, a protein factor (V) involved in the stimulation of the synthesis of prothrombin. The therapy requires blood or plasma. ▶antihemophilia factors, ▶hemophilia, ▶pro-thrombin deficiency, ▶hemostasis

Parahox Genes: The hox-like genes in clusters, separate from the hox genes, and has originated by duplication from an ancestral protohox gene. ▶homeotic genes

Parainfluenza Viruses: A group of immunologically related but distinguishable pathogens responsible for some respiratory diseases. ▶Sendai virus

Paralinin: ▶karyolymph

Parallel Cascade Identification: Non-linear systems modeling approach. In biology, it can be used to predict long-term treatment response for cancer on the basis of small differences of gene expression levels. (See Korenberg MJ 2002 J Proteome Res 1:55).

Parallel Substitution: Various organismal lineages may display similar or different nucleotides at a number of sites. The chance of these substitutions at a site (p) in (n) lineages can be predicted on the basis of the binomial distribution, $(p + [1 - p])^n$ and upon expansion, e.g., for $n = 5$ it becomes $p^5 + 5p^4(1 - p) + 10p^3(1 - p)^2 + 10p^2(1 - p)^3 + 5p(1 - p)^4 + (1 - p)^5$ and the same change per any two lines is p^2 . ▶evolution and base substitutions, ▶evolutionary substitution rate, ▶evolutionary tree, ▶parallel variation

Parallel Synthesis: An approach commonly applied in drug development. Several similar compounds are generated simultaneously rather in a sequence, one after the other in order to speed up the process of discovery of effective drugs. ▶combinatorial chemistry

Parallel Variation: Within taxonomically closely or even distantly related groups of organisms similar mutations may occur during evolution. Mutation in regulatory switches may be the basic cause of these alterations. ▶parallel substitution; Vavilov NI 1922 J Genet 12:47; Pagel M 2000 Brief Bioinform 1(2):117.

Paraloci: They have the same properties as pseudoalleles. ▶pseudoalleles

Paralogon: A pair of genes evolutionarily derived from common ancestral sequences.

Paralogous Loci: Originated by duplication that was followed by divergence. However, Paralogs may provide backup in case of defect or damage of one of the pairs (Kafri R et al 2005 Nature Genet 37:295). ▶orthologous loci, ▶isolocus, ▶evolution of proteins, ▶non-orthologous gene displacement, ▶gene family, ▶duplication, ▶subfunctionalization, ▶tetralogue, ▶outparalog, ▶inparalog; Yamamoto E, Knap HT 2001 Mol Biol Evol 18:1522.

Paralogy: Evolution by duplication of a locus. ▶orthologous loci, ▶orthology, ▶homolog

Paramecium: Unicellular Protozoan. Normally reproduces by binary fission, i.e., a single individual splits into two. Each cell has two diploid micronuclei and a polyploid macronucleus. At fission, the micronuclei divide by mitosis while the macronucleus is simply halved. These animals also have sexual processes (*conjugation*). Two of the slipper-shaped cells of opposite mating type attach to each other and proceed

with meiosis of the micronuclei (see Fig. P20). Only one of the four products of meiosis survives in each of the conjugants. Each of these haploid cells divides into four cells (gametes). One of these gametes (male) is passed on into the other conjugating partner through a *conjugation bridge* and fuses with a haploid gamete (female).

Figure P20. *Paramecium aurelia* (500 X) cells with bright and non-bright kappa particles symbionts (1,650X). The symbionts are bacteria. The bright particles contain the so-called R (refractive) bodies, which are bacteriophages. The non-bright kappa can give rise to bright indicating lysogeny. The kappa-free (*kk*) paramecia are sensitive to the toxin produced by the bright particles and may be killed. The K, killer stocks are immune to the toxin. (From Preer JR et al 1974 Bacteriol Rev 38:113 [Photo by C. Kung]; courtesy of Dr. J. R. Preer)

This is a reciprocal fertilization, resulting in diploid nuclei in the conjugants. Subsequently the pair separates into two *exconjugants*. The macronucleus disintegrates then in both. The diploid zygotic nuclei undergo two mitoses and form four diploid nuclei each. Two of the four nuclei function as separate micronuclei of the cells whereas the other two fuses into a macronucleus that become polyploid, and that is responsible for all metabolic functions and for the phenotype. Besides this sexual reproduction (*conjugation*), *Paramecia* may practice self-fertilization (*autogamy*).

Meiosis takes place and the one surviving product divides twice by mitoses. Two of these identical cells then fuse and form two diploid, isogenic micronuclei.

If the conjugation lasts longer, cytoplasmic particles may also be transferred through the conjugation bridge. Chromosome numbers may be 63–123; in the macronuclei there may be 800 or more chromosomes. *P. tetraurelia* genome includes 39,642 genes and 80% carry introns of mean 25 bp. The large gene number is apparently the result of whole genome duplication (Aury J-M et al 2006 Nature [Lond] 444:171). ▶killer

strains, ►symbionts hereditary, ►*Ascaris*, ►macro-nucleus, ►chromosome diminution, ►duplication, ►polyploidy, ►internally eliminated sequences, ►cortical inheritance, ►conjugation paramecia; Sonneborn TM 1974 In: King RC (Ed.) Handbook of Genetics, vol. 2, Plenum, New York, p. 469; Prescott DM 2000 Nature Rev Genet 1:191; *Paramecium tetraurelia* database: <http://paramecium.cgm.cnrs-gif.fr>.

Parameter: A quantity that specifies a hypothetical population in some respect or a variable to which a constant value is attributed for a specific purpose or process. Statistics usually denotes parameters by Greek letters and Latin letters indicates the computed values.

Parameter Alpha: ►alpha parameter

Parametric Methods in Statistics: Involves explicit assumptions about population distribution and parameters such as the mean, standard deviation of the normal distribution, the p parameter of the *Bernoulli process*, etc. ►Bernoulli process, ►normal distribution, ►non-parametric statistics, ►robustness

Parameter Space: In a dynamic system the values of the various parameters of a model are constrained within this limit.

Paramyxoviruses: Negative-sense retroviruses of 15–19 kb RNA containing 6–10 genes. They are infectious to a wide range of mammals. In humans, they cause influenza-like respiratory diseases. (See Gotoh B et al 2002 Rev Med Virol 12:337).

P

Paramutation: A *paramutable* allele becomes a *paramutant* (paramutated) in response to a *paramutagenic* allele if the two are in heterozygous condition. The alteration is similar but not identical to the paramutagenic allele. Both *paramutability* and paramutagenic functions are allele-specific. In contrast to gene conversion, paramutation may take place at low frequency and also in the absence of a paramutagenic allele. At the R locus of maize partial reversion of the paramutant may happen but this has not been observed at the B locus of maize. The paramutant phenotype at the R locus may vary but at the B locus, the phenotype appears to be uniform. The exact mechanism of this heritable alteration is not fully understood.

Apparently at the R locus of maize hypermethylation is involved, at the B locus involvement of methylation has not been detected. Distant upstream sequences play regulatory role in the expression and paramutation of the B' locus (Stam M et al 2002 Genetics 162:917). At the pl locus the paramutation seems to results in a genetic alteration of the chromatin structure, which affects the regulation of the expression of the gene during development. It appears that the level of

transcription is reduced at the paramutant allele compared to that in the paramutable one.

Although paramutation has been considered an endogenous mechanism, it appears that in the promoter region of the two r alleles in the homozygotes the *doppia* (CACTA) transposable elements are present within the 387 bp σ region that is intercalated between the two S elements in opposite orientation. (These elements are called S because they are responsible for anthocyanin coloration of the seed by this complex locus. The elements responsible for coloration of the plant were named P). Paramutation of the bl locus of maize depends on an RNA polymerase encoded by the *mop1* gene (*mediator of paramutation*). Paramutation at the bl locus involves the presence of non-coding tandem repeats of an

Figure P21. Paramutation results in reduced pigmentation in the triploid aleurone of maize. The R^r homozygotes are fully colored (when all other color-determining alleles are present). The r homozygotes are colorless. The rr genotype is responsible for the dark mottled aleurone. R^{st} causes paramutation (stippling) of the R^r paramutable allele that may be manifested in different grades. In the crosses the pistillate parents are shown first, left. (Courtesy of Brink RA see also 1956 Genetics 41:872)

853 bp sequence 100 kb upstream. The number of repeats may be 7 to 1. The strength of the paramutation is correlated with the number of these repeats and a single copy is not sufficient for paramutation. The RNA polymerase transcribes both strands of the repeats (Alleman M et al 2006 Nature [Lond] 442:295).

Paramutation is not a general property of all genes although similar phenomena have been observed at

a few other genes in maize and other plants. This phenomenon seems to violate the Mendelian principle that alleles segregate during meiosis independently and during the process, no “contamination” takes place. Paramutation in the broad sense involves several types of gene silencing in various organisms. Paramutation-like phenomenon attributed to transmethylation was observed in mouse (Herman H et al 2004 Nature Genet 34:199). A new mechanism of paramutation was reported in mouse. Insertion of a 3 kilobase *LacZ-neomycin* cassette into the *Kit* gene downstream of initiator ATG site resulted in mutation involving white spots in the animals because inactivation of a tyrosine kinase receptor and defect in melanogenesis (►phenotype on the reconstructed image of an animal). Although the homozygotes were lethal, the heterozygotes expressed the phenotype as illustrated. The proven wild type individuals (lacking the insertion) among the progeny of heterozygotes displayed the white patches on the tail and feet as did the heterozygous mutants. This phenotype was transmitted by male and female to the offspring and there was a reduced level of *Kit* mRNA and an accumulation of abnormal size non-polyadenylated RNA molecules. The paramutant condition was transmitted through meiosis for several generations but eventually it was diluted out. Injection into fertilized eggs either the total RNA from *Kit^{tm1Alf/+}* or *Kit*-specific microRNA also induced the white tail (see Fig. P22). The observations indicate a particular type of epigenetic inheritance of RNA molecules (Rassoulzadegan M et al 2006 Nature [Lond] 441:469). This phenomenon bears similarities to the case in the plant *Arabidopsis* claiming that a cache of RNA can be maintained in the nuclei and cause the reappearance of an atavistic trait (Lolle S et al 2005 Nature [Lond] 434:505). Newer information indicates, however, that the apparent “atavism” is due to contamination by pollen of the *Arabidopsis* mutant *HOTHEAD*, which has protruding stigma making unexpected cross-pollination easier (Pennisi E 2006 Science 313:1864). ►gene conversion, ►copy choice, ►directed mutation, ►localized mutagenesis, ►pan-genesis, ►blending inheritance, ►presence-absence hypothesis, ►graft hybrid, ►co-suppression, ►RIP, ►epigenesis, ►position effect, ►transvection, ►tissue specificity, ►atavism; Brink RA 1960 Quart Rev Biol 35:120; Hagemann R, Berg W 1978 Theor Appl Genet

53:113; Chandler VL 2000 Plant Mol Biol 43 (2–3):121; Lisch D et al 2002 Proc Natl Acad Sci USA 99:6130; Chandler VL, Stam M 2004 Nature Rev Genet 5:532; Chandler VL 2007 Cell 128:641.

Paramyotonia: Periodic paralysis (gene located in human chromosome 17). ►myotonia

Paramyxovirus: Single-stranded RNA viruses with a genome of 16–20 kb. Members of this group cause human mumps, respiratory diseases in human and other animals, including birds and reptiles. ►RNA viruses

Paranemic Coils: The two components of the coil can be separated from each other without any entanglement as one can easily pull apart two spirals that were pushed together after they were wound separately, i.e., they are not interlocked. ►plectonemic coils

Paraneoplastic Neurodegenerative Syndrome: ►auto-immune diseases

Paranoia: A psychological disorder in more (paranoia) or less severe (paranoid) state. The major characteristics are delusions of persecution (delusional jealousy, erotic delusions) or less frequently by feeling of grandiosity. It differs from schizophrenia in that, the rest of the personality and mental capacity may remain normal. Frequently, however, paranoid schizophrenia may occur. The precipitating factors are insecurity, frustration, physical illness, drug effects, etc. There is also an apparently undefined genetic component. ►schizophrenia, ►affective disorders

Paranome: Genes within gene families; the entire sets of duplicated genes. ►gene family

Paranormal: Beyond the normal biological expectation, e.g., extrasensory perception. It has been reported (Cha KY et al 2001 J Reprod Med) that prayer for success of in vitro fertilization approximately doubled the success of pregnancy in an international, randomized, double-blind clinical trial involving 219 women. More recently, experts questioned the outcome of this study and suspected inappropriate handling of the experiment (Nature [2004] 429:796). In the nineteenth century, Francis Galton, the father of biometrics, concluded that prayer has unlikely influence on worldly events because the number of shipwrecks was not effected by the fact that praying missionaries were aboard or royalties, for whom their subjects regularly prayed, did not live longer than other citizens. In some instances, when prayer provides comfort, beneficial psychological effects may result (Handzo G et al 2004 N Engl J Med 351:192; ►creationism

Paraoxonase (PON1, 7q21.3): May be associated with high-density lipoprotein in the blood plasma. It may

protect against coronary heart disease by destroying oxidized lipids, responsible for inflammation. It may detoxify organophosphate pesticides (parathion, chlorpyrifos [Dursban]). ▶ **arylesterase**, ▶ **cholinesterase**, ▶ **pseudocholinesterase**, ▶ **HDL**, ▶ **Kupffer cell**; Brophy VH et al 2001 *Am J Hum Genet* 68:1428.

Parapatric Speciation: Groups of organisms inhabiting an overlapping region become sexually isolated. ▶ **allopatric**, ▶ **sympatric**

Paraphyletic Group: Does not include all descendants of the latest common ancestor.

Paraplegia: The paralysis of the lower part of the body; it may be hereditary. ▶ **Pelizaeus-Merzbacher disease**, ▶ **Silver syndrome**, ▶ **spastic paraplegia**, ▶ **Mast syndrome**, ▶ **ALS**

Paraplegin: ▶ **mitochondrial disease in humans**

Paraptosis: A programmed neuronal cell death different from apoptosis in as much it is mediated by a caspase-9, which is independent of Apaf-1 and it does not respond to Bcl-X. ▶ **apoptosis**, ▶ **Apaf-1**, ▶ **BCL**; Sperandio S et al 2000 *Proc Natl Acad Sci USA* 97:14376.

Paraprotein: An abnormally secreted normal or abnormal protein, e.g., the Bence-Jones protein in myelogenous myeloma. It is also called M component. ▶ **Bence-Jones protein**

Paraquat: An artificial electron acceptor of photosystem I and a lung toxicant. It may produce oxidative stress by indirect production (through cellular diaphorases) of superoxide radicals. ▶ **diquat**, ▶ **photosystem I**, ▶ **diaphorase**, ▶ **superoxide**, ▶ **ROS**

Pararetrovirus: The genetic material is double-stranded DNA but it is replicated with the aid of an RNA molecule, e.g., in hepadnaviruses and caulimoviruses. They may occur in many copies in higher eukaryote genomes. ▶ **animal viruses**, ▶ **plant viruses**, ▶ **retroviruses**, ▶ **hepatitis B virus**, ▶ **cauliflower mosaic virus**; Richert-Poggeler KR, Shepherd RJ 1997 *Virology* 236:137; Gozuacik D et al 2001 *Oncogene* 20:6233.

Parascaris: A group of nematodes. ▶ **Ascaris**

Parasegment: The unit of a metamer complex consisting of the posterior part of one segment and the anterior part of another in insect larval and subsequent stages. ▶ **morphogenesis**

Paraselectivity: An apparent (but not real) selectivity in pollination among plants.

Parasexual Mechanism of Reproduction: The somatic-cell fusion and mitotic genetic recombination. The processes bear similarities to those common at sexual reproduction but do not involve sexual mechanisms.

▶ **mitotic recombination**, ▶ **cell fusion**, ▶ **somatic cell genetics**; Pontecorvo G 1956 *Annu Rev Microbiol* 10:393.

Parasitemia: The blood contains parasites, e.g., *Plasmodium*. ▶ **thalassemia**, ▶ *Plasmodium*

Parasitic: That which lives on and takes advantage of another live organism. ▶ **biotrophic**, ▶ **parasitoid**; <http://www.ebi.ac.uk/parasites/parasite-genome.html>; various parasites' database: <http://fullmal.ims.utokyo.ac.jp>.

Parasitic DNA: same as DNA selfish.

Parasitoid: Lives on another organism and eventually destroys it like some wasps and viruses. Some plants—upon attack and wounding by some insects—synthesize and emit host and parasite specific volatile compounds that attract parasitoid wasps that in turn may destroy the insects. The parasitoid wasp *Cotesia congregata* of the lepidopteran host *Manduca sexta* harbors Polydnavirus. The virus is injected into the host along with the parasitoid egg. The viral genome controls the host immune system and protects the wasp progeny development inside the host. The virus genome is 567,670 bp contained by 30 DNA circles of 5–40 kb, including 156 coding sequences of 66% AT; 69% of the viral genes has introns. The rest of the viral DNA is non-coding (Espagne E et al 2004 *Science* 306:286). ▶ **parasitic**, ▶ **biological control**, ▶ **aphid**

Paraspeckles: Formed from RNA-binding proteins in the cell nucleus within the interchromatin nucleoplasmic space, usually at the periphery of the nucleolus and in the vicinity of the nuclear speckles. ▶ **speckles**; Fox AH et al 2002 *Curr Biol* 12:13.

Parasterility: Caused by incompatibility between genotypes that may be fertile in other combinations. ▶ **self-incompatibility alleles**, ▶ **Rh blood group**

Parastichies: The imaginary helical line in phyllotaxis. ▶ **phyllotaxis**

Parathormone (parathyroid hormone, 11p15.3-p15.1): Produced by the parathyroid gland next to the thyroid gland. It is a regulator of calcium and phosphate metabolism (mediated by cAMP) primarily in the bones, kidneys and the digestive tract. A recessive hypoparathyroidism was mapped to Xp27. ▶ **hypercalcemia-hypocalciuria**, ▶ **hyperparathyroidism**, ▶ **enchondromatosis**; Healy KD et al 2005 *Proc Natl Acad Sci USA* 102:4724.

Parathyroid Hormone: Regulates Ca^{2+} level in animals. ▶ **parathormone**

Paratope: The epitope-binding site of the antibody Fab domain. ▶ **antibody**, ▶ **epitope**

Paratransgenic: An insect, which has transgenic symbionts inhabiting its gut. *Rhodnius prolixus* carries the actinomycete bacterium *Rhodococcus rhodnii* with which it has a symbiotic relationship. *R. prolixus* is a blood-sucking arthropod, vector of *Trypanosoma cruzi*, responsible for Chagas disease. When *R. rhodnii* is transformed by cecropin A, a 38-amino acid antimicrobial peptide derived from the moth *Hyalophora cecropia*, the peptide diffuses into the insect and lyses *Trypanosoma cruzi* within the insect without serious damage to *R. rhodnii* and thus effectively curtails the propagation of the protozoan. This is a more attractive defense than using chemical pesticides. ▶transgenic, ▶*Trypanosoma*, ▶Chagas disease, ▶CRUZIGARD; Beard CB et al 2001 Int J Parasitol 31:621.

Parcelation: The relative lack of pleiotropic effects between two sets of non-overlapping traits.

Parenchyma: In plant biology it means storage cells, either near isodiametric, *spongy parenchyma*, closer to the lower surface of the leaves or the *palisade parenchyma* consisting of one or two layers of columnar cells with their long axis perpendicular to the upper epidermis. Both types of tissues contain conspicuous intercellular space. In zoology, the parenchyma cells mean the functional units, rather than the network of an organ or tissue. ▶palisade cells

Parens Patriae: The state or community right to intervene against individual rights or beliefs and protect the interest of a person against potentially serious or actually life-threatening conditions, e.g., compulsory immunization, genetic screening, prohibition of incest, etc.

Parental Ditype: ▶tetrad analysis

Parental Histone Segregation: In front of the DNA replication fork the existing nucleosome structure is temporarily and reversibly disrupted to make nascent

DNA readily accessible to the replication protein machinery (see Fig. P23).

Parenteral: The application of a substance by injection rather than by oral means.

Parent-of-Origin Effect: May be due to the differences in the cytoplasm, differential transmission of defective chromosomes through the two sexes, differences in trinucleotide-repeat expansions, endosperm: embryo chromosomal differences in the reciprocal crosses in case of polyploids and imprinting. ▶imprinting, ▶trinucleotide repeats, ▶uniparental disomy, ▶uniparental inheritance; Morrison IM, Reeve AE 1998 Hum Mol Genet 7:1599; Haghighi F, Hodge SE 2002 Am J Hum Genet 70:142.

Pareto Distribution: $f(x) = \frac{\gamma \alpha^\gamma}{x^{\gamma+1}}$ Applicable for the gene expression profiles. Some genes are expressed at very high level other transcripts occur once or even less per cell thus the distribution is highly skewed by the low-abundance transcripts (see Fig. P24). The Pareto probability distribution is: $\alpha \leq x < \infty, \alpha > 0, \gamma > 0$, mean = $\gamma \alpha / (\gamma - 1, \gamma > 1$ and variance = $\gamma \alpha^2 [(\gamma - 1)^2 (\gamma - 2), \gamma > 2$ (See Kuznetsov VA et al 2002 Genetics 161:1321).

Figure P24. A hypothetical Pareto distribution

Parietal: Situated on the wall or attached to the wall of a hollow organ.

Figure P23. Nucleosome remodeling—Parental histone segregation

Periodontal Disease: Involves inflammation of the tissues surrounding teeth such as gingiva, ligaments, gum, etc. ► [point-of-care test](#)

Paris Classification: Paris classification of human chromosomes standardized (in 1971) the banding patterns and classified them by size groups; it is very similar to what is used today. Current maps show, however, only one of the two chromatids. ► [human chromosomes](#), ► [Denver classification](#), ► [Chicago classification](#)

Parity: Parity in gene conversion the process can go equally frequently in the direction of one or the other allele. ► [gene conversion](#); Fogel S et al 1971 Stadler Symp 1–2:89.

Parity: In human biology, it is the condition that a woman had borne offspring. Natural selection does not necessarily favor maximal reproduction because reproduction imposes fitness costs, reducing parental survival, and offspring quality. Parents in a pre-industrial population in North America incurred fitness costs from reproduction, and women incurred greater costs than men. The survivorship and reproductive success (Darwinian fitness) of 21,684 couples, married between 1860 and 1895, identified in the Utah Population Database showed that increasing number of offspring (parity) and rates of reproduction were associated with reduced parental survivorship, and significantly more for mothers than fathers. Parental mortality resulted in reduced survival and reproduction of offspring, and the mothers' mortality was more detrimental to offspring than the fathers' were. Increasing family size was associated with lower offspring survival, primarily for later-born children, indicating a tradeoff between offspring quantity versus quality (Penn DJ, Smith KR 2007 Proc Natl Acad Sci USA 104:553). ► [fitness](#), ► [reproductive rate](#), ► [fecundity](#), ► [fertility](#)

Parity Check: In a digital system it reveals whether the number of ones and zeros is odd or even.

Parkin: ► [Parkinson's disease](#)

Parking: A set of rules for seeding in which no seed overlaps with any other seedings. It is an iterative procedure that may be used at the early phase in genome sequencing. Each iteration sequences a new portion of non-overlapping piece of the DNA. Aside for non-overlaps, the sequences are chose at random. ► [seeding](#), ► [genome projects](#); Roach JC et al 2000 Genome Res 10:1020.

Parkinsonism: A secondary symptom caused either by drugs, or inflammation of the brain (encephalitis), or Alzheimer's disease, or Wilson's disease, or Huntington's chorea, etc. ► [Parkinson's disease](#) and the conditions named above, ► [tau](#)

Parkinson Disease (PD, PARK): A shaking palsy (bradykinesia) generally with late onset, however juvenile forms also exist. PD may include mental depression, dementia, reduced olfactory abilities and deficiency of several different substances, notably dopamine, from the nervous system. The genetic determination of the heterogeneous symptoms is unclear; autosomal dominant, recessive, X-linked, polygenic and apparently only environmentally caused phenotypes have been observed. The prevalence of PD is 0.001 and it may be 0.01 over age 50 but perhaps no more than 10% of the cases are familial.

Defects in the mitochondrial complex I resulting in oxidative stress favor the development of PD (Canet-Avilés RM et al 2004 Proc Natl Acad Sci 101:9103). Conditional knockout mice (termed MitoPark mice), with disruption of the gene for mitochondrial transcription factor A (*Tfam*) and in progressive degeneration of the nigrostriatal dopamine system (DA) neurons have reduced mtDNA expression and respiratory chain deficiency in midbrain DA neurons, which, in turn, leads to a parkinsonism phenotype with adult onset of slowly progressive impairment of motor function, accompanied by formation of intraneuronal inclusions and dopamine nerve cell death. Confocal and electron microscopy show that the inclusions contain both mitochondrial protein and membrane components demonstrating that respiratory chain dysfunction in DA neurons may be of pathophysiological importance in PD (Ekstrand MI et al 2007 Proc Natl Acad Sci USA 104:1325). Endocannabinoids may have beneficial effects on motor deficits in PD and Huntington chorea (Kreitzer AC, Malenka RC 2007 Nature [Lond] 445:643).

A PTEN-induced putative kinase (*PINK1*) mutation in *Drosophila* that has high similarity to human PINK1 also encodes a mitochondrially located protein and it is complemented by parkin (Park J et al 2006 Nature [Lond] 441:1157; Clark IE et al 2006 Nature [Lond] 441:1162). Loss-of-function mutations in a previously uncharacterized, predominantly neuronal P-type ATPase gene, *ATP13A2*, underlying an autosomal recessive form of early-onset Parkinsonism with pyramidal degeneration and dementia (PARK9, Kufor-Rakeb syndrome) were observed. The pyramidal cells are excitatory neurons in cerebral cortex. The wild-type protein was located in the lysosome of transiently transfected cells; the unstable truncated mutants were retained in the endoplasmic reticulum and degraded by the proteasome (Ramirez A et al 2006 Nature Genet 38:1184).

The herbicide paraquat, the fungicide maneb, the insecticide rotenone and other environmental toxins may contribute to PD by inhibiting complex I (Dawson TM, Dawson VL 2003 Science 302:819).

Mitochondrially coded nicotinamide adenine dinucleotide dehydrogenase complex plays a role in reduced susceptibility (van der Walt JM et al 2003 *Am J Hum Genet* 72:804).

An early onset PD was located to human chromosome Xq28 and another (PARK6) to 1p35-p36. Mitochondrially localized PTEN-induced kinase 1 (PINK1, 1p35) mutations are involved in PARK6 (Valente EM et al 2004 *Science* 304:1158). PINK contains a serine-threonine protein kinase domain; it localized in mitochondria. An autosomal dominant form is in chromosome 22. Another locus encoding spheres of protofibrils of α -synuclein was assigned to human chromosome 4q21-q23. The α -synuclein gene is apparently responsible for only a minor fraction of Parkinsonism. A susceptibility gene (SNCA) has been located also to human chromosome 17q21. Multiple copies of SNCA may occur in a single nucleus. A low penetrance (40%), late onset (~60 years) gene is at 2p13. Autosomal dominant juvenile Parkinsonism gene (1395 bp ORF) encoding the 465-amino acid *parkin* protein was located to 6q25.2-q27. Parkin is an E3 ubiquitin protein ligase and ubiquitin-proteasome deficit favors the development of PD and its S-nitrosylation inhibits its normal protective action (Kung KKK et al 2004 *Science* 304:1328). Parkinson disease is Parkinsonism without the formation of Lewy bodies. Several other loci are also involved with the development of this disease. Protein DJ-1 (1p36)—situated in the mitochondria—is a protein regulating mRNA stability and its defect can cause Parkinsonism.

The parkin gene appears to be a suppressor of ovarian cancer and adenocarcinoma (Cesari R et al 2003 *Proc Natl Acad Sci USA* 100:5956). In some cases a missense mutation in the carboxy terminal hydrolase L1 (UCH-L1, 4p14), component of the ubiquitin complex, localized in the Lewy bodies, is responsible for PD. Not all forms of PD shows Lewy bodies. Loss of dopaminergic neurons in the substantia nigra is usually associated with the disease. Glial cell line-derived neurotrophic factor (GDNF) has nutritive effects on the dopaminergic nigral neurons. In an autosomal recessive juvenile PD parkin-associated endothelin receptor-like (Pael-R) accumulates apparently because a misfolded Pael-R is not degraded if there is a defect in parkin. LRRK2 (PARK8, 12p12) is a leucine-rich repeat kinase gene involving Lewy body disease of advanced adult age.

Parkin has several other substrates and that explains the complicated etiology of the different forms of PD (Imai Y et al 2001 *Cell* 105:891; Shimura H et al 2001 *Science* 293:263).

Various tomography techniques facilitate detection of susceptibility to PD before the appearance of clinical symptoms. The imaging can measure the

integrity of dopamine in the substantia nigra of the brain. The procedure is based on the conversion of 18F-DOPA into 18F-dopamine or by the use of DOPA transporter (DAT) ligands. The reduction in DAT ligand uptake correlates with the loss of dopamine in the corpus striatum (the striped gray substance in front and beside the thalamus in the brain) and this is characteristic for aging and particularly for incipient PD. Also, loss of fluorodeoxyglucose distinguishes PD from other neurodegenerative diseases. Dopamine dysfunction may be indicated also by olfactory impairment (see DeKosky ST, Marek K 2003 *Science* 302:830).

Gene therapy using lentivirus vector carrying the GDF gene, injected into the brain (striatum and substantia nigra) of old monkeys or young monkeys pretreated with a nigrostriatal degeneration inducing agent (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine [MPTP]) reversed the functional deficits and prevented degeneration, respectively. Anticholinergics (blocking choline) and dopamine, glial-cell-derived neurotrophic factor (GDNF) treatments may be somewhat beneficial. An alternative approach may be using gene therapy by expressing transfected tyrosine hydroxylase or aromatic amino acid decarboxylase in the striated muscle cells. These enzymes can produce dopamine yet the response is below expectation. New approaches appear more promising ([▶ gene therapy](#)). Transplantation of fibroblasts equipped for secretion of BDNF and GDNF into the brain appears promising in animal models. Inhibition of cyclooxygenase (COX-2) seems to prevent the formation of the oxidant dopamine-kinone, which has been implicated in Parkinsonism (Teismann P et al 2003 *Proc Natl Acad Sci USA* 100:5473). Electric shocks localized to the globus pallidus (a medial part of the brain) had beneficial effects in some cases. Caspase-3 may be a conditioning factor in the apoptotic death of dopaminergic neurons in PD. Embryonic stem cells may develop into dopamine-producing neurons in the brain of the mouse and seem to be promising for cell-replacement therapy of PD (Kim J-H et al 2002 *Nature [Lond]* 418:50; Barberi T et al 2003 *Nature Biotechnol* 21:1200). Midbrain proteins Lmx1a and Msx1 mediate dopamine neuron differentiation of proneural protein NGN2 and seem important for cell replacement therapy in PD (Andersson E et al 2006 *Cell* 124:393). Activation of intracellular neurotrophic signaling pathways by vector transfer is a feasible approach to neuroprotection and restorative treatment of neurodegenerative disease. Adeno-associated virus 1 transduction with a gene encoding a myristoylated, constitutively active form of the oncoprotein Akt/PKB had pronounced trophic effects on dopamine neurons of adult and aged mice, including increases in neuron size, phenotypic markers, and sprouting. Transduction confers almost complete

protection against apoptotic cell death in a highly destructive neurotoxin model (Ries V et al 2006 Proc Natl Acad Sci USA 103:18757). Nix, a pro-apoptotic BH3-only protein, promotes apoptosis of non-neuronal cells. Using a yeast two-hybrid screen with POSH (plenty of SH3 domains, a scaffold involved in activation of the apoptotic JNK/c-Jun pathway) as the bait, identified an interaction between POSH and Nix and contributed to cell death in a cellular model of Parkinson disease (Wilhelm M et al 2007 J Biol Chem 282:1288). The disease-linked processes are detectable in peripheral blood by 22 unique genes differentially expressed in patients with PD versus healthy individuals. Such an approach may provide biomarkers for early clinical detection of the disease (Scherzer CR et al 2007 Proc Natl Acad Sci USA 104:955). Multiple axon-guidance pathway genes may predispose to PD (Lesnick TG et al 2007 PloS Genet 3(6):e98). ▶parkinsonism, ▶neuromuscular diseases, ▶dopamine, ▶adeno-associated virus, ▶Akt, ▶tyrosine hydroxyls, ▶Lewy body, ▶Kufor-Rakeb syndrome, ▶GDNF, ▶BDNF, ▶dopamine, ▶mitochondrial disease in humans, ▶substantia nigra, ▶synuclein, ▶caspase, ▶ubiquitin, ▶tau, ▶stem cells, ▶brain human, ▶tomography, ▶PTEN, ▶argyrophilic grains, ▶BAK, ▶cannabinoids, ▶axon guidance; Dawson TM 2000 Cell 101:115; Kordower JH et al 2000 Science 290:767; Valente EM et al 2001 Am J Hum Genet 68:895; Vaughan JR et al 2001 Ann Hum Genet 65:111; Lansbury PT Jr, Brice A 2002 Curr Opin Genet Dev 12:299; Betarbet R et al 2002 BioEssays 24:308; Cookson MR 2005 Annu Rev Biochem 74:29; Farrer MJ 2006 Nature Rev Genet 7:306.

Paromomycin (C₂₃H₄₅O₁₄N₅): An aminoglycoside antibiotic. It may cause translational errors by increasing the initial binding affinity of tRNA. Oral LD₅₀ in mice is 1625 mg/kg. ▶phenotypic reversion, ▶aminoglycoside antibiotics, ▶LD50

Parotid Gland: The salivary gland; the proline-rich parotid glycoprotein is encoded in human chromosome 12p13.2.

Parexysm: Recurring events such as convulsions (but most commonly normal conditions in between), sudden outbreak of disease.

Parexysmal Nocturnal Hemoglobinuria: A dominant human chromosome 11p14-p13 susceptibility of the erythrocytes to destruction by the complement because of a deficiency in protectin (HRF20/CD59) and DAF. ▶complement, ▶membrane attack complex, ▶DAF, ▶angioneuritic edema, ▶CD59, ▶protectin, ▶hemoglobin

PARP (poly[ADP-ribose] polymerase): An enzyme involved in surveillance and base excision repair of

DNA and NAD⁺-dependent chromatin remodeling (Kim MY et al 2004 Cell 119:803). PARP is involved in puff formation of *Drosophila* gene loci (Tulin A, Spradling A 2003 Science 299:560). It is cleaved by an ICE-like proteinase. Its deficiency increases the sensitivity to radiation damage, recombination and sister chromatid exchange. PARP is required also for the assembly and structure of the spindle (Chang P et al 2004 Nature [Lond] 432:645). PARP-deficient mice are viable and free of tumors and inhibitors of PARP/DNA repair activity can selectively kill BRCA2 defective tumor cells (Bryant HE et al 2005 Nature [Lond] 434:913). PARP deficiency prevents homologous recombination repair of damaged BRCA1 and BRCA2 eventually apoptosis eliminates the mutant cells (Farmer H et al 2005 Nature [Lond] 434:917). ▶ICE, ▶apoptosis, ▶puff, ▶tankyrase, ▶telomeres, ▶spindle, ▶DNA repair, ▶breast cancer, ▶Kif; Bauer PI et al 2001 FEBS Lett 506(3):239; Lavrik OI et al 2001 J Biol Chem 276:25541.

PARS (poly[ADP-ribose] synthetase): PARS attaches ADP-ribose units to histones and to other nuclear proteins. It is activated when DNA is damaged by nitric oxide.

Parser: A software for reading flat files for further processing. ▶flat file

Parsimony: ▶maximal parsimony, ▶evolutionary tree

Parsing: Resolve it to parts or components. ▶exon parsing, ▶pars means part in Latin

Parsley (*Petroselinum crispum*): The roots and leaves of parsley are used for flavoring; 2n = 2x = 22 (see Fig. P25).

Figure P25. Parsley

Parsnip (*Pastinaca sativa*): A root vegetable; $2n = 2x = 22$ (see Fig. P26).

Figure P26. Parsnip

Parsonage–Turner Syndrome (Feinberg syndrome/Tinel syndrome/Kiloh–Nevin syndrome): The syndrome is most likely to be identical with hereditary amyotrophic neuralgia; it is also very similar to the Guillain–Barré syndrome. ▶[amyotrophy hereditary neuralgic](#), ▶[Guillain–Barré syndrome](#)

Parthenocarp: The development of fruit without fertilization. It may have horticultural application by producing seedless apple varieties such as Spencer Seedless or Wellington Bloomless. The gene responsible in these apples is homologous to *pistillata* of *Arabidopsis*. ▶[parthenogenesis](#), ▶[apomixia](#), ▶[seedless fruits](#), ▶[flower differentiation in Arabidopsis](#); Yao J et al 2001 Proc Natl Acad Sci USA 98:1306.

Parthenogenesis: Embryo production from an egg without fertilization. Parthenogenesis may be induced in sea urchins by hypotonic media or in some amphibia by mechanical or electric stimulation of the egg. In some fish, lizards and birds (turkey) it occurs spontaneously. Parthenogenesis in animals is most common among polyploid species. Parthenogenetic individuals produce only female offspring. On theoretical grounds, parthenogenesis may be disadvantageous because it deprives the species of elimination of disadvantageous mutations on account of the lack of recombination available in bisexual reproduction. Parthenogenesis may cause embryonic lethality in mouse if the imprinted paternal genes are not expressed. Parthenogenesis is not known to occur in humans (or generally in mammals but deletion of

imprinting may yield viable parthenogenetic mouse), however it may exist as a chimera when after fertilization, the male pronucleus is displaced to one of the blastomeres and then the maternal chromosome set in the other blastomere is diploidized. The failure of parthenogenetic development of mammalian offspring is due to the requirement for imprinting (Kono T et al 2004 Nature [Lond] 428:860). Fusion of two oocyte nuclei can produce, however, viable, fertile mouse. Many plant species successfully survive by asexual reproduction as an evolutionary mechanism. Parthenogenesis in plants is called apomixis or apomixia. Asexually reproducing plant populations appear to be preponderant under conditions marginally suitable for the species is called *geographic parthenogenesis*. ▶[apomixia](#), ▶[gynogenesis](#), ▶[parthenocarp](#), ▶[RSK](#), ▶[imprinting](#), ▶[oocyte](#); Mittwoch U 1978 J Med Genet 15:165; Cibelli JB et al 2002 Science 295:819; Krawetz SA 2005 Nature Rev Genet 6:633.

Parthenote: An egg stimulated to divide and develop to some extent in the absence of fertilization by sperm. Parthenotes may offer possibilities for stem cell production for therapeutic purposes when embryonic stem cells are prohibited. ▶[parthenogenesis](#), ▶[apomixia](#); Kiessling AA 2005 Nature [Lond] 434:145.

Partial Digest: The reaction is stopped before completion of nuclease action and thus the DNA is cut into various size fragments some of which may be relatively long because some of the recognition sites were not cleaved. ▶[restriction enzyme](#)

Partial Diploid: ▶[merozygote](#)

Partial Dominance: An incomplete dominance, semi-dominance.

Partial Linkage: The genes are less than 50 map units apart in the chromosome and can recombine at a frequency proportional to their distance. ▶[crossing over](#), ▶[recombination](#)

Partial Trisomy: Only part of a chromosome is present in triplicate. ▶[trisomy](#)

Particulate Inheritance: The modern genetic theory that inheritance is based on discrete particulate material (written in nucleic acid sequences) transmitted conservatively rather than according to the pre-Mendelian theory of pangenesis, which claimed that the hereditary material is a miscible liquid subject to continuous changes under environmental effects. According to the particulate theory of genetics, genes are discrete physical entities that are transmitted from parents to offspring without blending or any environmental influence, except when mutation or gene conversion

or imprinting occurs. ►pangenesis, ►gene conversion, ►mutation, ►imprinting, ►blending inheritance

Particulate Radiation: ►physical mutagens

Partington Syndrome (Xp22.13): Primarily mild or moderate mental retardation accompanied by developmental anomalies caused by polyalanine expansion in the *aristaless-like* homeobox gene. (*al*, *aristaless* alleles were discovered early in *Drosophila* and mapped to chromosome 2.4; some involved cytologically detectable inversions. Mammalian homologs exist.) At this chromosomal area several other similar mental retardation genes occur. Some have recessive expression others are dominant. ►homeotic genes, ►mental retardation, ►mental retardation X-linked

Partitioning (segregation): The distribution of plasmids and/or the bacterial chromosome(s) into dividing bacterial cells. It may be a passive process mediated by the attachment of the DNAs to the cell membrane. The partition depends on ParA and ParB proteins by the P1 plasmid. ParB recognizes at the partition site a dimeric B box and at the opposite ends two A boxes with helix-turn-helix (HTH) domains (see Fig. P27). The HTH domains emanate from the dimerized DNA-binding modules composed of a six-stranded β -sheet coiled coil that binds the B boxes (Schumacher MA, Funnell BE 2005 Nature [Lond] 438:516). A bacterial tubulin-like protein FtsZ may carry out the separation. Plasmid and bacterial genes control the process. The bacterial chromosome or some of the plasmids seem to have a centromere-like protein that may bind to the cell poles and to 10 copies of a sequence situated along a 200 kb region near the replicational origin. The loss of the chromosome in the new cells is less frequent than 0.003. The segregation of plasmids present in multiple copies is more complex. Mechanisms (“addiction” system) exist to resolve plasmid dimers and to ensure that each cell would have at least one copy of a plasmid. The two-component addiction module include a stable toxin and a labile antitoxin. The plasmid-free cells may be eliminated (Engelberg-Kulka H, Glaser G 1999 Annu Rev Microbiol 53:43). ►segregation, ►cell division, ►addiction module, ►plasmid maintenance; Hiraga S

Figure P27. Partitioning

2000 Annu Rev Genet 34:21; Gordon GS, Wright A 2000 Annu Rev Microbiol 54:681; Draper GC, Guber JW 2002 Annu Rev Microbiol 56:567.

Partitioning: In statistics, breaking down the variances among the identifiable experimental components or in a compound chi square to reduce the quantity of the residual or error variance. ►analysis of variance

Parturition: The labor of child delivery.

Parvoviruses: Non-enveloped, icosahedral (18–25 nm), single-stranded DNA (~5.5 kb) viruses. The group includes the densovirus of arthropods, the autonomous, lytic parvoviruses and the adeno-associated viruses. ►icosahedral, ►adeno-associated virus, ►autonomous parvovirus, ►oncolytic viruses; Lukashov VV, Goudsmit J 2001 J Virol 75:2729.

Parvulin: A very small monomeric 92-amino acid prolyl isomerase of *E. coli* involved in protein maturation. Similar proteins occur in yeast (Ess1, 19.2 kDa) and humans (Pin1, 18 kDa) and *Drosophila* (dodo, 18.3 kDa). Ess1 may not have isomerase activity, but Pin1 does. In the absence of Ess1 the nuclei fragment and growth ceases, dodo has apparently similar function as Ess1 and it is interchangeable. Pin regulates mitotic progression by interacting with CDC25 and NIMA. ►PPI, ►peptidyl-prolyl isomerases, ►CDC25, ►NIMA; Rulten S et al 1999 Biochem Biophys Res Commun 259:557.

PAS Domain (Per-Arnt-Sim): A shared motif of proteins involved in the regulation of the circadian rhythm of the majority of eukaryotes. PAS domain serine/threonine kinases also regulate several different signaling pathways including drug response. ►circadian rhythm; Rutter J et al 2001 Proc Natl Acad Sci USA 98:8991.

PASA: A special PCR procedure by which chosen allele(s) can be amplified if the primers match the end of that allele. ►PCR; Smith EJ, Cheng HH 1998 Microb Comp Genomics 3:13; Shitaye H et al 1999 Hum Immunol 60:1289.

Pascal Triangle: Represents the coefficients of individual terms of expanded binomials: $(p + q)^n$:

$$1p^n + \frac{n}{1!(n-1)!}p^{n-1}q + \frac{n!}{2!(n-2)!}p^{n-2}q^2 + \dots + \frac{n!}{(n-1)!1!}p^{n-(n-1)}q^{n-1} + 1q^n$$

Since genetic segregation is expected to comply with the binomial distribution, the coefficients indicate the frequencies of the individual phenotypic (or in case of trinomial distribution) genotypic frequencies. ►binomial distribution, ►trinomial distribution, see Table P1.

Table P1. The Pascal triangle represents the coefficients of individual terms of expanded binomials. The exponent of the binomial is n . The figures display a symmetrical hierarchy. The frequency of a particular class can be readily calculated because the sum of the coefficients is displayed at the bottom of the columns. Mendelian segregation follows the binomial distribution

Passage: The transfer of cells from one medium to another.

Passenger DNA: A DNA inserted into a genetic vector.

Passenger Proteins: Include the inner centromeric protein (INCENP), which is a substrate for Aurora, the Aurora B kinase, the TD-60 autoimmune antigen, the inhibitor-of-apoptosis protein Survivin/BIR-1. These proteins are situated at the centromeres and move the spindle at late metaphase and anaphase. ▶centromere, ▶mitosis, ▶Aurora, ▶Survivin; Bishop JD, Schumacher JM 2002 J Biol Chem 277:27577.

Passive Immunity: Acquired by the transfer of antibodies or lymphocytes

Passive Transport: Does not require special energy donor for the process. ▶active transport

Pasteur Effect: The fast reduction of respiration (glycolysis) if O₂ is added to fermenting cells.

Pasteurella multocida: A pathogenic bacterium causing cholera in birds, bovine hemorrhagic septicemia, atrophic rhinitis (inflammation of the nasal mucosa) in pigs, and humans may be infected by it through cat or dog bites. The sequenced genome of 2,257,487 bp contains ~2014 coding sequences. ▶Yersinia; May BJ et al 2001 Proc Natl Acad Sci USA 98:3460.

Pasteurization: Reducing (killing) the microbe population in a material by heating at a defined temperature for a specified period of time. ▶aseptic, ▶axenic, ▶autoclaving

PAT1 (Ran1): A protein kinase required for the continuation of mitotic division in fission yeast. Its inactivation triggers the switch to meiosis. ▶meiosis, ▶Ran1

Patatin: A glycoprotein like storage protein in potato with lipid acid hydrolase and esterase activity. It inhibits pests' larvae. It constitutes ~40% of the soluble proteins in the tubers. ▶potato; Hirschberg HJ et al 2001 Eur J Biochem 268:5037.

Patau's Syndrome: Caused by trisomy for human chromosome 13. This is one of the few (X, Y, 8, 18, 21, 22) trisomies that can be carried to term but it generally leads to death within six months because of severe defects in growth, heart, kidney and brain failures. It is accompanied by face deformities (severe hare lip, cleft palate), polydactyly, clubfoot, defects of the genital systems, etc. (see Fig. P28). Definite identification is carried out by cytological analysis, including FISH with the available

chromosome-13-specific probes. An old designation of trisomy 13 was trisomy D because chromosome 13 belonged to the D group of human chromosomes. ▶trisomy, ▶aneuploidy, ▶polydactyly, ▶hare lip, ▶clubfoot

Figure P28. Patau syndrome. (Courtesy of Dr. Judith Miles)

Patch (Ptc): ▶sonic hedgehog, ▶hedgehog

Patch (patched duplex): The resolution of a recombination intermediate (Holliday junction) without an exchange of the flanking markers (can be gene conversion). ▶Holliday model L

Patch Clamp Technique: The method to measure the flow of current through a voltage gated ion channel by tightly pressing an electrode against the plasma membrane. It is used also for the sensitive in situ study of neurotransmitters. ▶ion channels

Patch Mating: Actin patches of the cytoskeleton can be used in yeast to quantify the number of viable diploid cells in the presence of silencer genes, which regulate the expression of mating types. Actin patches are detectable for duration about 10 seconds at sites of polarized growth and then rapidly disappear. ▶mating type determination in yeast; Smith MG et al 2001 J Cell Sci 114(pt 8):1505.

Patella Aplasia-Hypoplasia (PTLAH, 17q21-q22): The absence or reduction of the size of the knee cap. The symptoms occur also in various syndromes such as the Coffin-Siris syndrome, trisomy 8 syndrome. ▶Coffin-Siris syndrome, ▶nail-patella syndrome

Patent: The so-called gene patents do not protect the DNA (or ESTs) sequence itself, rather the process of manipulation is the object. The gene "ownership" only prevents the use or selling a particular sequence without permission. In general, according to US patent laws, the patent is protected for 17 years from date of issue. A requisite for patenting is that the

subject of the patent application would be new and non-obvious and practically useful, e.g., a probe for a gene. Natural DNA sequences are not patentable, but purified or isolated recombinant molecules or parts of a vector are patentable. Legal patentability requirements: (i) usefulness, (ii) novelty, (iii) being non-obvious, and (iv) definiteness of description. A further requirement is “enablement,” i.e., a trained person after reading the patent description can use the “invention” without further research. In October 1998, USA, the first patent was awarded to an EST. Once a patent is issued, even further, originally undisclosed applications are protected. Also, another person after isolating a full-length open reading frame using an STS may obtain a patent but not without the permission of the “inventor” of the patented STS. During the period of patent, the patent-holder can prevent anybody from using it, including those who invented the same independently or even those who improved on the procedure to such an extent that the second invention meets the requirements for patenting. However, the inventor is obligated by law to disclose the invention in sufficient technical detail so that anybody with proper expertise can use it. The fact that an invention was arrived at under federal financial support does not exclude patentability but the inventor must report the patentable invention to the sponsoring agency. The intention of the government is that the invention would be used at maximum benefit to the public that can be achieved most effectively by commercial private enterprises. Laboratory assays, reagents and procedures, including computer programs may also be patentable. By 2005, more than 4000 genes were patented and three-fourths of them by single individuals. Presenilin gene (PSN2) has 8 patent owners for 9 patents and breast cancer gene (BRCA1) has 12 owners for 14 patents. Of the 292 cancer genes reported by 2004, 131 are patented (Jensen K, Murray F 2005 Science 310:239).

The patenting of the outcome of genetic research may be harmful to science if the investigators keep the ongoing work a secret until it becomes patentable. Patenting basic research products (upstream inventions) is detrimental to society because it may prevent the development of new useful (commercial) products. The Bayh–Dole Act allows the “exemption for research” to facilitate the use of the results of basic research. Unfortunately, this exemption is difficult to define and is subject to controversy (Holman C 2006 Cell 125:629). The exemption can be applied to the patent (effectiveness, usefulness) itself but does not permit application of the patent (Kaye J et al 2007 Nature Biotechnol 25:739). If the discovery is published through proper means of scientific communications prior to the patent application, it is disqualified from

patenting. It is generally easier to patent a product than a process. Natural products (e.g., proteins) are usually not patentable unless they are modified in some way and are different from the natural product in structure or function and these properties were not generally known. A DNA sequence, identified as the coding unit for a genetic disease or a genetic marker in its vicinity, may be patentable but a cloned gene that may be used for translating a protein may be not. DNA markers are patentable only if their direct use can be determined. The concept of patenting biological material raises several moral objections but it is defended by the biotechnology industry because it takes 100s of millions of dollars for the completion of such projects, and without the financial means, these investigations cannot be maintained. Between 1981 and 1995, a total of 1175 human DNA sequences were patented. If the subject of the patent has been published or in use for more than one year prior to the date of the patent application, it will not be approved. If another person can prove that he/she invented the object before the date of publication by others, the person may still be entitled to a patent. The patent laws vary in different countries, and new legislation may take place any time. The European Union is now approving patents for human genes and transgenic animals and plants. An alternative to patenting is Trade Secret Protection. One way of preventing another person from patenting an invention is public disclosure, e.g., publication in sufficient details (e.g., in a scientific journal). This ensures that another party would not be able to claim priority for the invention, which is one of the requisites for patenting. Publications may not necessarily provide an effective and lasting protection. Patent infringement usually does not entitle the patentee for more financial compensation than the reasonably calculated loss of royalty or profit caused by the infringement. It must also be verified that the original patent description do not include deceptive assertions.

The justification of an existing patent may be challenged administratively by *inter partes* re-examination request to the US Patent and Trademark Office (USPTO, Washington DC, USA). The claim must prove substantial new question of patentability based on a “prior art” document and requires a fee of \$8800. This procedure has monetary advantages vis-à-vis litigation (Derzko NM, Behringer JW 2003 Nature Biotechnol 21:823). The patent regulations are subject to changes and it is advisable to seek consent from the owners of the patent even when the invention is used only for laboratory research. A recent analysis revealed many problems with patents granted by USPTO. The patents examined had problems with description (37.5%), enablement/utility (42.4%) novelty/non-obviousness (6.9%) and

definiteness (13.1%). The conclusion faulted insufficient educational background of the examiners with most of the problems (Paradise J et al 2005 Science 307:1566). ▶STS, ▶EST, ▶SNP, ▶Herfindahl index, ▶presenilin, ▶breast cancer, ▶cancer, ▶Cohen-Boyer patent on recombinant DNA; Eisenberg RS 1992 p 226. Patent Ductus Arteriosus (6p12): The ductus arteriosus connects the lung artery and the aorta and shunts away blood from the lung of the fetus. Normally it fades away after birth. In ~1/2000 cases, this does not happen and the duct stays open and causes heart defect. The disease may be caused by fetal rubella infection and apparently by autosomal dominant gene(s). The 6p12-p21 dominant *Char syndrome* involves patent ductus, facial anomalies and abnormal fifth digit of the hand (see Fig. P29).

Figure P29. Char syndrome. In the Char syndrome the middle phalanx of the fifth digit is missing

The basic problem is traced to TFAP2B neural crest-related transcription factor that does not bind properly to its target. Risk of recurrence in an affected family is about 1–2%. General incidence is less than 10% of that. ▶risk, ▶aneurysm; Zhao F et al 2001 Am J Hum Genet 69:695.

Paternal Leakage: The transmission of mitochondrial DNA through the males. Generally, mitochondria are not transmitted through the animal sperm because mitochondrial DNA of spermatozoon is destroyed by ubiquitination in the oocytes (Sutovsky P et al 2000 Biol Reprod 63:582). In mice, apparently the male transmission of mitochondria is within the range of 10^{-5} . In interspecific mouse crosses, paternal mitochondria are transmitted but they are eliminated during early embryogenesis or later during development (Kaneda H et al 1995 Proc Natl Acad Sci USA 92:4542). Heteroplasmy is rare. The role of transmission of mitochondria in humans is not clear. Some cytological observations may indicate the incorporation of the midpiece of the sperm (containing mitochondria) into the egg. Genetic evidence for human paternal transmission of mitochondria is rare (Schwartz M, Vissing J 2002 N Engl J Med 347:576).

In some molluscs (mussel), there is a strong biparental inheritance of mtDNA. In *Mytilus* the paternal and maternal mtDNA displays 10–20% nucleotide divergence. The females transmit just one type of mitochondria to sons and daughters whereas the males transmit a second type of mtDNA genome to the sons. Biparental transmission of mtDNA may also occur in interspecific crosses of *Drosophila*. In *Paramecia*, mitochondria may be transmitted through a cytoplasmic bridge. In fungi, the transfer is maternal although in some heterokaryons cytoplasmic mixing may take place. In some slime molds, mtDNA transmission is also mating type dependent. In *Physarum polycephalum* different *matA* alleles regulate the mtDNA transmission but a plasmid gene may also be involved and recombination can take place between mtDNAs. In *Chlamydomonas* algae, several genes around the mating type factors were implicated. In the contact zone of hybridizing conifers (*Picea*) recombinant mtDNA was observed as apparent result of paternal leakage (Jaramillo-Correa JP, Bousquet J 2005 Genetics 171:1951). ▶mtDNA, ▶plastid male transmission, ▶Eve foremother, ▶mitochondrial disease in humans, ▶mitochondrial genetics, ▶plastid genetics, ▶doubly uniparental inheritance, ▶*Paramecium*, ▶heteroplasmy; Eyre-Walker A 2000 Philos Trans R Soc Lond B Biol Sci 355:1573; Shitara H et al 1998 Genetics 148:851; Yang X, Griffith AJ 1993 Genetics 134:1055; Meusel MS, Moritz RF 1993 Curr Genet 24:539.

Paternal Transmission: Imprinting causes paternal transmission of certain genes. Some of the human insulin and the insulin-like growth factor alleles may be preferentially inherited through the paternal chromosome and cause early-onset obesity. ▶imprinting, ▶obesity, ▶paternal leakage; Le Stunff C et al 2001 Nature Genet 29:96.

Paternity Exclusion: Based on genetic paternity tests.

►paternity testing, ►DNA fingerprinting, ►Y chromosome, ►alternate paternity

Paternity Testing: Frequently required in civil litigation suits, it might have significance for medical, population, immigration, archeological and other cases. The laboratory procedures are generally the same as used for DNA fingerprinting. Here, as in DNA fingerprinting in general, the exclusion of paternity is simple and straightforward. However, the determination of identity may pose more difficulties because in the multilocus tests more than 10% of the offspring may show one band difference and 1% may show two, due to mutation. Therefore, Penas and Chakraborty (Trends Genet 10:204 [1994]) recommended the formula shown in Figure P30.

$$PI = \frac{\binom{N}{U} \mu^U (1 - \mu)^{N-U}}{\binom{n}{U} X^{n-U} (1 - X)^U}$$

Figure P30. Penas-Chakraborty formula

PI = paternity index, μ = mutation rate, X = band-sharing parameter, N = total number of bands per individual, n = number of test bands, U = number of bands not present in the alleged father. In rare instances (mistakes at maternity wards) similar test may be necessary to test maternity. The biological father of a child—even if the paternity can be accurately proven—cannot assert paternal rights against the will of the mother if she was/is married to another man (Hill JL 1991 N Y Univ Law Rev 66:353). When “the child is born to a mother who is single or part of a lesbian couple, law does permit the biological father to assert his paternal rights, even if he clearly stated his intention prior to conception to have no relation” (Charo RA 1994 In: Frankel MS, Teich A (Eds.) The Genetic Frontier. Ethics, Law and Policy, American Association of Advance Science, Washington DC). ►Y chromosome, ►forensic genetics, ►DNA fingerprinting, ►forensic index, ►utility index, ►surrogate mother, ►microsatellite typing

Path Coefficient: This method of Sewall Wright was worked out for studying mathematically and by diagrams, the paths of genes in populations and genetic events determining multiple correlations. Here it is not possible to discuss meaningfully the mathematical foundations but one type of graphic application for determining some relations between

offspring and parents can be found under F and inbreeding coefficient. ►inbreeding coefficient, ►correlation; Wright S 1923 Genetics 8:239; Wright S 1934 Ann Math Stat 5:161.

Pathogen: An organism (microorganism) capable of causing disease on another. (See pathogen database: <http://www.nmpdr.org>; ►vectors for pathogens, ►Brucella, ►Rickettsia, ►Coxiella and viruses: <https://patric.vbi.vt.edu>).

Pathogen Identification: The food industry may need rapid and highly sensitive methods for the detection of live pathogens in various products. In case of viable *E. coli* cells, this is feasible by infection with compatible bacteriophages carrying bacterial luciferase inserts. The genes in the phages are expressed only in live bacteria and if such are present, with a high-powered luminometer or by a microchannel plate enhanced image analyzer, even a single bacterial cell emitting light may be detected. Immunoassays and PCR are also useful for the detection of the presence of pathogens. An apparently very fast procedure is based on B lymphocyte sensors (CANARY: cellular analysis and notification of antigen risks and yields), which are engineered with the potential to express green fluorescent protein (GFP, aequorin) and membrane-bound antibodies specific for the pathogen of interest. GFP is a calcium-activated light emitter. When the antibody binds the pathogen, the intracellular calcium concentration is elevated within seconds and fluorescence is readily detectable. A bio-conjugated nanoparticle-based fluorescence immunoassay for in situ pathogen quantification detects single bacteria within 20 min (Zhao X et al 2004 Proc Natl Acad Sci USA 101:15027). For epidemic surveillance of respiratory pathogens, identification and strain typing can employ electrospray ionization mass spectrometry and polymerase chain reaction amplification from highly conserved genomic regions even from polymicrobial mixtures (Ecker DJ et al 2005 Proc Natl Acad Sci USA 102:8012). ►luciferase bacterial, ►immunological test, ►B lymphocytes, ►bioterrorism, ►PCR, ►aequorin, ►electrospray MS, ►polymerase chain reaction, ►quenched autoligation probe, ►quantum dot; Rider TH et al 2003 Science 301:213; GeneDB, bacterial, protozoa, fungal gene sequences: <http://www.genedb.org/>.

Pathogen-Derived Resistance: The protection of plants against certain pathogens by the transgenic expression of viral coat proteins, other proteins, antisense sequences, satellite and defective viral sequences. ►host-pathogen relations, ►plantibody

Pathogenesis Related Proteins (PR): A variety of acidic or basic proteins synthesized in plants upon infection

with pathogens. The chitinases and glucanases apparently act by damaging the cell wall of fungi, insects or even bacteria. ►[host–pathogen relations](#), ►[SAR](#)

Pathogenic: Capable of causing disease. (See Hill, A.V. S. 2001 *Annu Rev Genome Hum Genet* 2:373).

Pathogenicity Island (PAI): A group of genes in a pathogen involved in the determination and regulation of pathogenicity. In *Helicobacter pylori*, these islands are delineated by 31 bp direct repeats (DR), and indicate that horizontal transfer acquired these. Commonly the same genes are present between the ends of this large insert and the chromosomal genes in both pathogenic and non-pathogenic species of the same group of bacteria. Frequently, the insert is adjacent to a tRNA 3' sequence or a codon for an unusual amino acid. The DNA inserts encode a rather specific secretory system (type III) and elements of transport and bacterial surface effectors located then next to host cell receptors. The PAI may carry insertion elements, integrases and transposases and their sequences may be unstable. Their location may change within the same bacterium. This organization is conducive to effective subversion the host defense system. The size of the pathogenicity islands may vary from 10 to 200 kb or more. The base composition of the islands and the codon usage may differ from that of the core DNA. In some bacteria only a single PAI occurs, in others there are several. Similar mechanisms operate in both animals and plants. ►[transmission](#), ►[cholera toxin](#), ►[host–pathogen relations](#), ►[integrase](#), ►[transposase](#), ►[secretion system](#), ►[codon usage](#), ►[Helicobacter pylori](#), ►[symbionts](#); Hacker J, Kaper JB 2000 *Annu Rev Microbiol* 54:641; <http://www.gem.re.kr/paidb>.

Pathogenicity Islet: These are similar in some functions to pathogenicity islands but their size is much smaller, 1–10 kb.

Pathovar: Plant varieties or species, which share disease susceptibility/resistance genes. Alternatively, a plant pathogen that is specific for a taxonomic group of plants.

Pathway Tools (<http://bioinformatics.ai.sri.com/ptools/>): Software for determining metabolic and signaling pathways and database. ►[EcoCyc](#), ►[MetaCyc](#), ►[BioCyc](#)

Pathways: Guide to metabolic, molecular, immunological and many other processes and interactions: <http://www.pathguide.org/>; network tools: <http://visant.bu.edu/>.

Patrilocality: An anthropological term indicating that males more frequently bring in mates from outside

their location than moving to the location of the females.

Patristic Distance: The sum of the length of all branches connecting two species in an evolutionary tree. ►[evolutionary tree](#)

Patroclinous: Inheritance through the male such as the Y chromosome, androgenesis, fertilization of a nullisomic female with a normal male, through non-disjunction the chromosome to be contributed by the female is eliminated, some of the gynandromorphs, sons of attached-X female *Drosophila*, etc. ►[gynandromorph](#), ►[nondisjunction](#), ►[attached-X](#)

Patronymic: A designation indicating the descent from a particular male ancestor, e.g., Johnson, son of John or O'Malley descendant of Malley. Common family names may assist in isolated populations to establish relationships. This analysis may be improved by studies of Y-chromosomal molecular markers. ►[isonymy](#), ►[Y chromosome](#)

Pattern Formation during Development: Pattern formation specifies the arrangement of the cells in three dimensions. Developmental patterns may begin by intracellular differentiation (animal pole, vegetal pole, yolk), positional signals between cells and intracellular distribution of the receptors to various signals. Fibroblast growth factor and transforming growth factor- β have apparently major roles as epithelial and mesoderm induction signals. The *Drosophila* gene *fringe* (*fng*) is involved with mesoderm induction and in wing embryonal disc formation. Juxtaposition of *fng*-expressing and non-expressing genes is required for establishing the dorsal ventral boundary of wing discs. The gene *fng* is expressed in the dorsal half of the wing disc whereas *wingless* (*wg*, 2-30) is limited to the dorsal-ventral boundary. Gene *hedgehog* (*hh*, 3-81) is expressed in the posterior half, and *decapentaplegic* (*dpp*, 2-40) is detected in the anterior-posterior boundary. Anterior-posterior patterning in *Drosophila* is affected by the *trithorax* (*trx*), *Polycom* (*Pc-G*) family members such as *extra sex combs* (*esc*). The homolog of the latter, *eed* (embryonic ectoderm development) controls anterior-posterior differentiation in mouse. Homologs to these genes have been identified in other animals and humans as well. In *Xenopus*, it appears that the FNG protein is translated with a signal peptide (indicating that it is secreted), in the proFNG, peptide is terminated with a tetrabasic site for proteolytic cleavage and after this processing it is ready for the normal function. *Wingless* of *Drosophila* is homologous to *Wnt1* mouse mammary tumor gene. The branching pattern of trachea and lung, respectively in *Drosophila* and mammals is controlled primarily by the fibroblast growth factor

signaling pathway. This is used reiteratively in repeated sequences of a branching. At each stage different feedback and other control signals provide the specifications (Metzger RJ, Krasnow MA 1999 Science 284:1635). In mice, mutation of the *Foxn1* gene causes follicular development to terminate just after it starts accumulating pigments. Then the immature follicles restart the developmental process and the skin color of the animal displays the striped pattern (Suzuki N et al 2003 Proc Natl Acad Sci USA 100:9680). Vascular mesenchymal cells can differentiate into specific embryonic structures and in adult diseases the process may be restarted again and bone osteoblasts may arise in the walls of the arteries or in the cardiac walls under the influence of morphogens. The process may be mathematically modeled (Garfinkel A et al 2004 Proc Natl Acad Sci USA 101:9247). In bacteria pattern formation can be programmed in a synthetic system by acyl-homoserine chemical signals emitted by labeled “sender” cells to “receiver” cells in Petri plate cultures (see Fig. P31).

Figure P31. Pattern formation induced by the sender cells (darker color) in the receiver cells (lighter color) lawn of bacteria. In the experiments the two types of cells were distinguished by fluorescence. (Redrawn after Basu, S. et al. 2005 Nature [Lond] 434: 1130)

A newer idea posits that the mechanical control of form precedes pattern formation (Ingber DE 2005 Proc Natl Acad Sci USA 102:11571). Using micro-fabrication for controlling the organization of sheets of cells revealed the emergence of stable patterns of proliferative foci. Concentrated growth corresponded to regions of high tractional stress and could be measured by micromechanical force sensor. Inhibiting actomyosin-based tension or cadherin-mediated connections between cells disrupted spatial pattern of proliferation. The conclusion is that contraction of cells, an existence of pattern of mechanical forces, is due to multicellular organization and the tissue form is an active regulator of tissue growth (Nelson CM et al 2005 Proc Natl Acad Sci USA 102:11594).

Developmental pattern formation is under genetic control also in plants (Lee MM, Schiefelbein J 1999 Cell 99:473). The progress has been much slower, however, because the plant tissues and cells are more liable to dedifferentiation and redifferentiation. Mutants have been obtained with clear differences

in morphogenesis, with the exception of flower differentiation and photomorphogenesis, much less is known about the molecular mechanisms involved. Down-regulation of the MYB transcription factor gene (*PHANTASTICA*) changes compound pinnate (left) leaves into palmate compound (right) leaves (see Fig. P32) (Kim M et al 2003 Nature [Lond] 424:438). ▶morphogenesis, ▶morphogenesis in *Drosophila*, ▶RNA localization, ▶flower differentiation, ▶photomorphogenesis, ▶MADS box, ▶signal transduction, ▶homeotic genes, ▶cell lineages, ▶fibroblast growth factor, ▶actomyosin, ▶cadherin; reaction–diffusion model of leaf venation as a mechanism of pattern formation: Dimitrov P, Zucker SW 2006 Proc Natl Acad Sci USA 103:9363; Malakinski G, Bryant P (Eds.) 1984 Pattern Formation: A Primer in developmental biology, Macmillan, New York; Comparative Pattern Formation in Plants and Animals: Willemsen V, Scheres B 2004 Annu Rev Genet 38:587.

Figure P32. Pinnate (left); palmate (right)

Pattern Recognition Receptors (PRR): These are tools of the innate immunity system. They recognize pathogen-associated molecular patterns (PAMPs) that are essential for the survival of the pathogen and are therefore stable. PRRs are hereditary, are conserved across phylogenetic categories, expressed constitutively and do not require immunological memory. PRRs recognize pathogen-associated molecular patterns such as exist in lipopolysaccharides, proteoglycans or double-stranded RNA. (See Qkira S et al 2006 Cell 1214:763; innate immunity, Toll, host–pathogen relationship, downstream pathways: Lee MS, Kim Y-J 2007 Annu Rev Biochem 76:447.

PAU Genes: ▶seripauperines

pauling: ▶evolutionary clock

PAUP (phylogenetic analysis using parsimony): A computer program for the analysis of evolutionary descent on the basis of molecular data. ▶evolutionary distance, ▶evolutionary tree

Pause: RNA polymerase, I, II and III do not operate continuously at the same rate but due to various causes, their transcription may hesitate and then

resume synthesis. A minimal functional element of PAUSE-1 is TCTN_xAGAN₃T₄ where $x = 0, 2$ or 4 . Various elongation proteins such as ELL, Elongin, and transcription factor TFIIF may mediate pausing. The pause may facilitate the binding of regulatory factors. Pausing and backtracking allows the binding of the RfaH suppressor factor of early termination (Artsimovich I, Landick R 2002 Cell 109:193). Pausing may allow for proofreading and elimination of misincorporated bases (Shaevitz JW et al 2003 Nature [Lond] 426:684). Sequence-specific pause sites have been revealed (Herbert KM et al 2006 Cell 125:1083). ▶attenuator region, ▶Nus [▶lambda phage], ▶σ; Ogbourne SM, Antalis TM 2001 Nucleic Acids Res 29:3919.

Pausing, Transcriptional (hesitation): The discontinuity of the transcriptional process by all RNA polymerases. As a consequence there is a heterogeneity of the transcripts because of the differences in recognition of modulating factors such as attenuation, transcription factors TFIIF, ELL, silencers, nus (λ phage), antitermination signal, etc. Paucity of a nucleotide(s) or too high concentration of it may slow down transcription. RNA polymerase often pauses before a GTP is incorporated. Pause signals have been detected in both the template and the non-template DNA strands. Generally, hairpin structures (RNA base-pairing) favor pausing although secondary structure may not be the sole cause of it. DNA sequences 16–17 bp downstream of the pause may alter the conformation of the polymerase and the pause. Even the non-template strand may have an effect. ▶arrest transcriptional, terms named under separate entries; Davenport RJ et al 2000 Science 287:2497.

PAX (paired box homeodomains): They are so called because they include two helix-turn-helix DNA-binding units. Several PAX proteins are known to be encoded in at least five different chromosomes and they mediate the development of the components of the eyes in insects (compound eyes) and humans, teeth, the central nervous system, the vertebrae, the pancreas and tumorigenesis. The 130-residue paired domain binds DNA and functions as a transcription factor for B cells, histones and thyroglobulin genes. The *Pax5* gene encodes the BSAP transcription factor. Mutation in *Pax5* arrests B cells at the pro-B stage. BSAP may also promote the expression of CD19 and indirectly IgE synthesis. BSAP may block the immunoglobulin heavy chain 3'-enhancer and isotype switching and the formation of the pentameric IgM antibody. The activator motifs of BSAP display about 20 times higher binding affinity to the DNA than the repressor motif yet the activator or repressor function depends primarily on the context of the

motif. The level of BASP is high in the pre-B and immature B cell stages and after the antigen signal has arrived its level greatly diminished by signals from IL-2 and IL-5. Overexpression of BSAP results in its repressor activity. PAX6 (11p13) mutations cause absence of the iris of the eye (aniridia) without elimination of vision but other general neurodevelopmental problems. ▶Waardenburg syndrome, ▶DiGeorge syndrome, ▶aniridia, ▶Wilms tumor, ▶renal-coloboma syndrome, ▶hypodontia, ▶rhabdomyosarcoma, ▶animal models, ▶B cell, ▶immunoglobulins, ▶histones, ▶thyroglobulin, ▶hox, ▶homeotic genes, ▶isotype switching, ▶FKP, ▶goiter familial, ▶helix-turn-helix motif, ▶integrin, ▶PTIP, ▶myoblast, ▶neural crest; Balczarek KA et al 1997 Mol Biol Evol 14:829; Chi N, Epstein JA 2002 Trends Genet 18:41; Pichaud F, Desplan C 2002 Curr Opin Genet Dev 12:430; <http://pax2.hgu.mrc.ac.uk/>; <http://pax6.hgu.mrc.ac.uk/>.

PAZ Domain (Piwi/Argonaute/Zwille): In Argonaute 1 protein it consists of a left-handed, six-stranded β-barrel capped at one end by two α-helices and wrapped on one side by a distinctive appendage, which comprises a long β-hairpin and a short α-helix. The PAZ domain binds a 5-nucleotide RNA with 1:1 stoichiometry. It plays a role in RNAi function and it is present in both Argonaute and Dicer proteins. ▶Argonaute, ▶Dicer, ▶RNAi; Yan KS et al 2003 Nature [Lond] 426:469; Lingel A et al 2003 Nature [Lond] 426:465; Ma J-B et al 2004 Nature [Lond] 429:318; PIWI domain structure: Parker JS et al 2005 Nature [Lond] 434:663; Ma J-B et al 2005 Nature [Lond] 434:666.

PBAF: An ATP-dependent chromatin remodeling complex. ▶chromatin remodeling; structure of PBAF: Leschziner AE et al 2005 Structure 13:267.

Pbp74: ▶Hsp70

pBR322: A non-conjugative plasmid (constructed by Bolivar & Rodriguez) of 4.3 kb, can be mobilized by helper plasmids because (although it lost its mobility gene) it retained the origin of conjugal transfer (see Fig. P33). It is one of the most versatile cloning vectors with completely known nucleotide sequence and over 30 cloning sites. It carries the selectable markers ampicillin resistance and tetracycline resistance. Insertion into these antibiotic resistance sites permit the detection of the success of insertion because of the inactivation of these target genes results in either ampicillin or tetracycline sensitivity. Although its direct use of this 20-year old plasmid has diminished during the last years, pBR322 components are present in many currently used vectors. ▶plasmid, ▶vectors, ▶Amp, ▶tetracycline; Bolivar, F., Rodriguez RL et al 1977 Gene 2:95.

PBS: Phosphate buffered saline. ►saline

PBSF (pre-B cell growth-stimulating factor): A ligand of CXCR controlling B cell development and vascularization of the gastrointestinal system. ►CXCR, ►lymphocytes; Egawa T et al 2001 Immunity 15:323.

PBX1, PBX2: Transcription factors involved in B cell leukemias, encoded in human chromosomes 1q23 and 3q222, respectively. ►leukemia

p. c.: ►post coitum

PC4 (positive co-activator of transcription): PC4 interacts with activator protein-1 (AP-2) and facilitates transcription, and may relieve the self-interference of AP-2. ►transcription, ►AP1; Zhong L et al 2003 Gene 320:155.

PCA (principal component analysis): A multivariate statistical method that separates the original variables into independent variables and associated variances. It may be useful for the interpretation of microarray data. (See Méndez MA et al 2002 FEBS Lett 522:24).

PCAF: A human acetyltransferase of histones 3 and 4. ►p300, ►TAF_{II}230/250, ►histone acetyltransferases,

►nucleosome, ►signal transduction, ►chromatin remodeling, ►bromodomain, ►INHAT; Blanco JC et al 1998 Genes Dev 12:1638.

PCB: Polychlorinated biphenyl is an obnoxious industrially employed carcinogen. A *Pseudomonas* enzyme may break it down. ►environmental carcinogens, ►sperm

PCD: ►apoptosis

pCIP: A co-activator protein, interacting with p300 (CREB) and regulates transcription and somatic growth of mammals. ►signal transduction, ►nuclear receptors; Wang Z et al 2000 Proc Natl Acad Sci USA 97:13549.

PCL: Putative cyclin. ►cyclin

PCNA (proliferating cell nuclear antigen): An auxiliary protein (a processivity factor) in pol δ and pol ϵ functions in eukaryotes. It has a similar role in DNA replication in general, and in the cell cycle and repair. Its function is similar to that of the β subunit of the prokaryotic pol III, it provides a "sliding clamp" on the DNA to be replicated. Binding to p21 may inhibit

PCNA replicative function. PCNA also binds other proteins such as cyclin D, FEN1/Rad27/MF1, DNA ligase 1, GADD, DNA methyltransferase, DNA repair proteins XPG, MLH and MSH. The protein interaction (PIP-box) provides a dock for interaction with replication and repair proteins (Bruning JB, Shamoo Y 2004 Structure 12:2209). The PCNA-interacting mutations in PCNA alter the conditions for nucleosomal assembly by interacting with CAF. Under such conditions, silencing by heterochromatin is reduced or lost. Some mutations in RFC may compensate for defects in PCNA. If the DNA is damaged, PCNA is modified by mono-ubiquitination at lysine residue 164 or a lysine 63-linked multi-ubiquitin chain to allow error-free or error-prone replication bypass of the damaged site. Ubiquitination of PCNA at lysine 164 specifically activates DNA polymerase η and Rev1, a deoxycytidyl-transferase in mutagenic replication of DNA (Garg P, Burgers PM 2005 Proc Natl Acad Sci USA 102:18361). In addition, SUMO-modified PCNA may recruit Srs2 helicase, which disrupts recombination by affecting Rad51 protein (Pfander B et al 2005 Nature [Lond] 436:428). ▶DNA replication, ▶eukaryotes, ▶cell cycle, ▶DNA polymerases, ▶ligase DNA, ▶p21, ▶cyclins, ▶ABC excinuclease, ▶excision repair, ▶mismatch repair, ▶sliding-clamp, ▶methylation of DNA, ▶Rad27/Fen1, ▶RFC, ▶CAF, ▶heterochromatin, ▶ubiquitin, ▶SUMO, ▶Srs, ▶Rad51; Karmakar P et al 2001 Mutagenesis 16:225; Ola A et al 2001 J Biol Chem 276:10168; López de Saro FJ, O'Donnell M 2001 Proc Natl Acad Sci USA 98:8376; Lau PJ, Kolodner RD 2003 J Biol Chem 278:14; crystal structure of binding domains: Kontopidis G et al 2005 Proc Natl Acad Sci USA 102:1871; review: Moldovan G-L et al 2007 Cell 129:665.

PCR: ▶polymerase chain reaction

PCR, Asymmetric: By using unequal amounts of amplification primers, an excess of single-strand copies of DNA can be obtained (Gyllensten UB, Erlich HA 1988 Proc Natl Acad Sci USA 85:7682). ▶polymerase chain reaction, an improved procedure: Pierce KE et al 2005 Proc Natl Acad Sci USA 102:8609.

PCR, Allele-Specific: Used to screen a population for a particular allele-specific mutation, e.g., mutations responsible for MELAS in the aging human mitochondrial DNA. One of the most common mutations in this anomaly involves the transition A→G at site 3243. If the primer containing the complementary base C is used, the mutant sequence from appropriate tissues is successfully amplified and can be detected by gel electrophoresis. The same C primer does not generate substantial quantity of the fragment using

the wild type template. Thus, by this procedure, the approximate frequency of this allele-specific mutation or recombination can be determined. ▶polymerase chain reaction, ▶mitochondrial disease in humans, ▶transition mutation, ▶hot-start PCR; Ugozzoli L, Wallace RB 1992 Genomics 12:670.

PCR, Broad-Based: Uses primers, which amplify a broad base of genes, e.g., the microbial rRNA genes or a group of viral genes common to the majority of related species in order to facilitate molecular identification of same pathogens. RDA and other procedures may supplement the analysis. ▶RDA

PCR, Competitive: Used for quantifying DNA or RNA. The competitor nucleic acid fragment of known concentrations in serial dilutions is co-amplified with another (the experimental) nucleic acid of interest using a single set of primers. The beginning quantity of the experimental molecules is estimated from the ratio of the competitor and experimental amplicons obtained during the PCR procedure that are supposedly amplified equally. The quantity of the unknown DNA is determined by the equivalence-point (EQP) where the experimental and the competitor show the same signal intensity indicating that their amounts is the same. A simplified new version is described by Watzinger F et al 2001 Nucleic Acids Res 29(11):e52.

PCR, Discriminatory: A method to detect small mismatches or point mutations (see Fig. P34). It is a much easier method than sequencing larger sequences to distinguish, e.g., phylogenetic differences within taxonomic groups. (See Picard FJ et al 2004 J Clin Microbiol 42:3686).

| Wildtype | Mismatch mutant |
|-----------------|-----------------|
| GGCGTGTGAAC TG | GGCGTGTGTG TCTG |
| | |
| CCGCACACTTGAC | CCGCACAC CAGAC |
| PCR ↓ | PCR ↓ |
| primer TGTGAA → | primer TGTGAA → |
| CCGCACACTTGAC | CCGCACAC CAGAC |
| Product made | No product made |

PCR, DOC (degenerate oligonucleotide-primed polymerase chain reaction and capillary electrophoresis of DNA): A random amplification technique combined with analysis on microchips. ▶capillary electrophoresis, ▶PCR, ▶DOP-PCR; Cheng J et al 1998 Anal Biochem 257:101.

PCR, Electronic: ▶electronic PCR

PCR, Methylation-Specific: ►methylation-specific PCR

PCR, Multiplex: Employs multiple sets of primers for amplification in a single reaction batch. (See Broude NE et al 2001 Proc Natl Acad Sci USA 98:206).

PCR, Nested: The use of two different internal primers to thus identify overlapping transcripts.

PCR, Overlapping: The use of two sets of primers; each has complementary sequences at the 5'-end. Two separate PCRs are carried out and then the products purified by gel to remove the unincorporated primers. A second PCR process uses only the outside primer pairs and the two primary products are joined. ►PCR

PCR, Quantitative: Determine gene expression quantitatively by optimized primers: <http://primerdepot.nci.nih.gov/>; <http://mouseprimerdepot.nci.nih.gov/>.

PCR, Real-Time Reverse Transcription: see Seeger K et al 2001 Cancer Res 61:2517.

PCR, Single Molecule: ►polony

PCR Targeting: ►targeting genes

PCR, Transcriptionally Active (TAP): 1. Specific primers amplify the gene of interest. 2. Mixtures of DNA fragments are equipped with promoter and terminator elements and then can be used for transfection in a suitable plasmid. They can be inserted into plasmids also by homologous recombination. TAP products can be used as DNA vaccines and generate antibodies against the encoded genes. The procedure is suitable for the generation of hundreds or thousands of transcriptionally active genes for genomic/proteomic studies. (Liang X et al 2002 J Biol Chem 277:3593).

PCR-Based Mutagenesis: Any base difference between the amplification primer will be incorporated in the future template through polymerase chain reaction. Actually only half of the new DNA molecules would contain the alteration present in the original amplification primer unless a device is used, e.g., the undesired strand would be made unsuitable for amplification and therefore lost from the reaction mixture. The method may include multiple point mutations, small insertions or deletions too. The amplification may also result in other nucleotide alterations as a result of the error-prone Taq polymerase. ►local mutagenesis, ►primer extension, ►polymerase chain reaction, ►DNA shuffling, ►VENT, ►small-pool PCR; Nelson RM, Long GL 1989 Anal Biochem 180:147.

PCR-LSA (polymerase chain reaction amplification): A method for the localization of SNIPS. ►SNIPS, ►RRS

PCR-Mediated Gene Replacement: The procedure replaces—by mitotic recombination—particular genes with an identifiable marker of a neutral phenotype. A 20 bp unique sequence tract tags each of these lines. On the basis of hybridization of the PCR products to a tag sequence, it is possible to quantitate the altered cell lines in a population. When one of the target genes is deleted in diploid yeast, the other is still expected to be functional. Some of them, however, due to haplo-insufficiency, will display a defective phenotype. These “heterozygotes” may also display increased sensitivity to drugs and may be used for pharmaceutical research. ►haplo-insufficiency; Giaever G et al 1999 Nature Genet 21:279.

PC-TP: phosphatidylcholine transfer protein mediating transfer of phospholipids between organelles within cell.

PD-1: An inhibitory immune receptor (2q37.3) on B, T lymphocytes and natural killer cells.

PDB (Protein Data Bank): <http://www.rcsb.org/pdb/cgi/explore.cgi?pdbld>.

PDECGF: Platelet-derived endothelial cell growth factor.

pDelta: γδ

pDUAL: γδ

PDZ Domains (post-synaptic density, disc-large, zo-1): Approximately 90 amino acid repeats involved in ion-channel and receptor clustering, and linking effectors and receptors. PDZ domain proteins are involved in the regulation of the Jun N-terminal

kinase pathway, in the post-synaptic density (PSD) proteins at glutamatergic synapses, Rho-activated citron protein function, visual signaling, etc. The *Drosophila* gene, *scribble* (*scrib*) encodes a multi PDZ domain protein and in cooperation with a leucine-rich protein controls apical polarization of the embryo. ▶ion channels, ▶tight junction, ▶protein folding, ▶Van Gogh, ▶receptor, ▶effector, ▶signal transduction, ▶AMPA, ▶HOMER, ▶citron, ▶Jun, ▶Rho, ▶NMDAR, ▶mesenchyma, ▶Fraser syndrome; Harris BZ, Lim WA 2001 J Cell Sci 114(pt 18):3219; Hung AY, Sheng M 2002 J Biol Chem 277:5699.

Pea (*Pisum* spp): Several self-pollinating vegetable and feed crops: the Mendel's pea is *P. sativum*, and others are $2n = 2x = 14$ (see Fig. P35). *Pisum*, photograph shows normal Mendelian segregation for smooth and wrinkled within a pod.

Figure P35. Pea

PEA: Death effector domain proteins.

Pea Comb: Comb characteristic of poultry of *rrP(P/p)* genetic constitution. ▶walnut comb

Peach (*Prunus persica*): $x = 7$, the true peaches are diploid.

P

Peacock's Tail: An evolutionary paradigm when a clear disadvantage (like the awkward tail) turns into a mating advantage because of the females' preference for the fancy trait and thus increasing the fitness of the males that display it. ▶fitness, ▶selection, ▶sexual selection

Peanut: ▶groundnut

Pear (*Pyrus* spp): About 15 species; $x = 17$ and mainly diploid, triploid or tetraploids. It is very difficult to hybridize it with apples but can be crossed with some *Sorbus*. ▶apple

Pearson Marrow Pancreas Syndrome: ▶mitochondrial disease in humans

Pearson's Product Moment Correlation Coefficient: ▶correlation

Pebble: ▶scaffolds in genome sequencing

Pectin: The polygalacturonate sequences alternated by rhamnose and may contain galactose, arabinose,

xylose and fucose side chains. Molecular weight varies from 20,000 to 400,000. Its role is intercellular cementing of plant cells. Acids and alkali may cause its depolymerization.

Pedicel: The stalk of flowers in an inflorescence. ▶peduncle

PEDANT (protein extraction, description and analysis tool): See <http://pedant.gsf.de/>.

Pedigree Analysis: Generally carried out by examination of pedigree charts used in human and animal genetics where the family sizes are frequently too small to conduct meaningful direct segregation studies (see Fig. P36). The pedigree chart displays the lines of descent among close natural relatives. Females are represented by circles, males by squares and if the sex is unknown a diamond (◇) is used (see Fig. P37). The same but smaller symbols or by a vertical or slanted line indicates abortion or still birth over the symbol. For spontaneous abortions, triangles (q) may be used. Individuals expressing a particular trait are represented by a shaded or black symbol, and in case they are heterozygous for the trait, half of the symbol is shaded.

Figure P36. Pedigree chart

When an unaffected female is the carrier of a particular gene, there is a dot within the circle. In case segregation for traits needs to be illustrated in the pedigree, the individual displaying both traits may be marked by a horizontal and vertical line within the symbol or only by a horizontal or vertical line, respectively. Horizontal lines connect the parents and if the parents are close relatives, the line is doubled. The progeny is connected to the parental line with a vertical line and the subsequent generations are marked by Roman numerals at the left side of the chart, I (parents), II children, III (grandchildren), and so on. Twins are connected to the same point of the generation line and if they are identical, a horizontal line connects them to each other. The order of birth of the offspring is from left to right and may be numbered accordingly below their symbol. An arrow to a particular symbol indicates the proband, the individual who first became known to the geneticist as expressing the trait. The appropriate symbols of

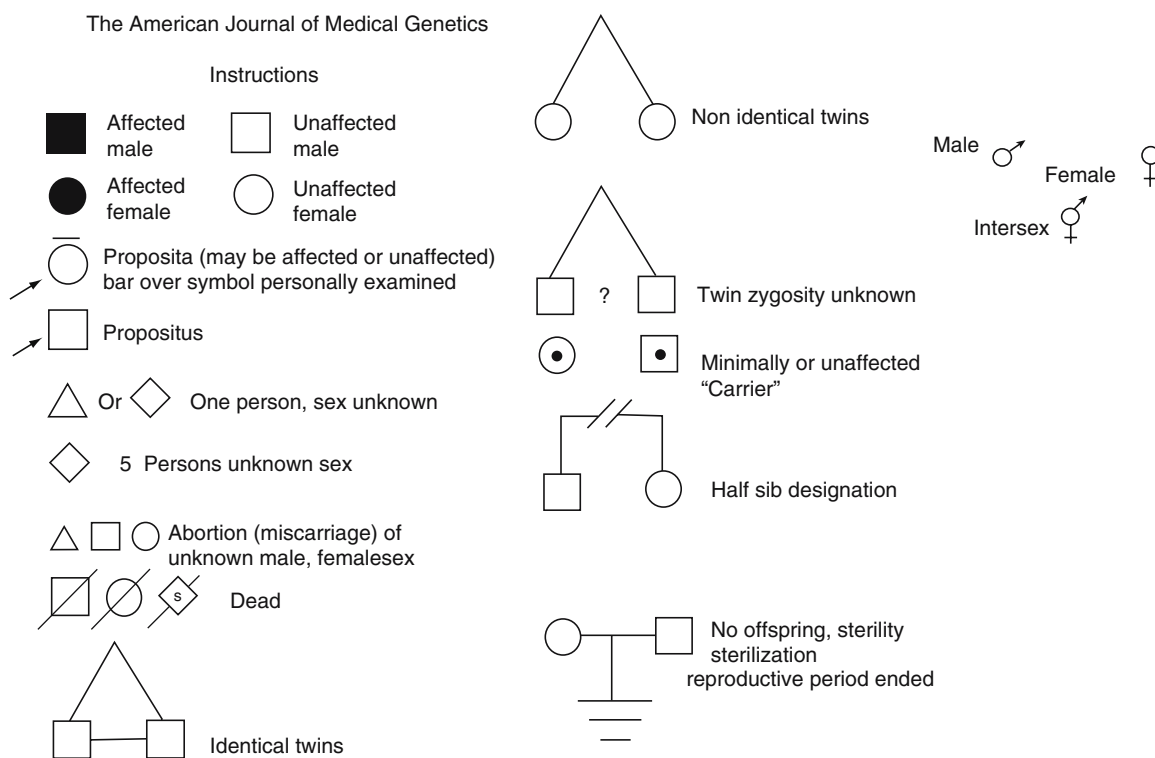

Figure P37. Pedigree symbols

adopted children may be bracketed. If a prospective offspring is considered at risk, broken lines draw the symbol. A horizontal line connected by a vertical line to the "parental" line may indicate lack of offspring by a couple.

Infertility may be represented by doubling a horizontal line under and connected to the male or female symbol, respectively. Egg or sperm donors (in case of assisted reproductive technologies [ART]) are indicated by a D and surrogate mothers by S within the symbols. *Mars shield* represents males and a *Venus mirror* represents females, and the sign in the box shown above at right indicates intersexes. ▶ART; Bennett RL et al 1995 Am J Hum Genet 56:745; Am J Med Genet pedigree chart is reprinted by permission of John Wiley & Sons, Inc.

Pedogenesis: Egg production by immature individuals such as larvae.

PEDro (Proteomics Experiment Data Repository): A model for the collection of information in proteomics. ▶proteomics; Taylor CF et al 2003 Nat Biotechnol 21:247.

Peduncle: The stalk of single standing flowers (→); bundle of nerve cells (see Fig. P38). ▶pedicel

Figure P38. Peduncle

PEG (polyethylene glycol): May be liquid or solid and comes in a range of different viscosities (200, 400, 600, 1500, etc.). It facilitates fusion of protoplasts, uptake of organelles, precipitation of bacteriophages, plasmids and DNA, promoting end-labeling, ligation of linkers, reduction of immunogenicity when attached to humanized antibody, etc.

PEG-3 (progression elevated gene-3): In nude mice up-regulates carcinogenesis in progress via activation of VEGF. It can be blocked by antisense technology. ▶VEGF, ▶antisense technology

PEG (paternally expressed gene): ► [imprinting](#)

PEGylation: Attaches polyethylene glycol (PEG) to the polypeptide backbone of a protein drug, and renders it less liable to clearance from the body, and thus does not have to be supplied so frequently. PEGylated interferons have about 24 h half-life in the plasma whereas native interferons display only 4 h half-life. Interferon- α -2b (a recombinant product) when PEGylated is administered only once a week whereas without PEGylation it needs three dosing per week. ► [interferon](#); Walsh G 2003 Nat Biotechnol 21:865.

PEK: ► [HRI](#)

Pelargonidine: ► [anthocyanin](#)

Pelargonium zonale (geranium): An ornamental plant. Some variegated forms transmit the non-nuclear genes also through the sperm whereas in the majority of plants the plastids are transmitted only through the egg. ► [uniparental inheritance](#), ► [chloroplasts](#), ► [chloroplast genetics](#)

Pelger(-Huet) Anomaly: An autosomal dominant condition in humans as well as in rabbits, cats, etc., characterized by fewer (1.1–1.6) than normal (2.8) nuclear lobes in the granulocytic leukocytes. Mutations may involve the lamin B receptor. It may be a mild anomaly but it may be associated with other more serious ailments. The prevalence varies from 1×10^{-3} to 4×10^{-4} . Similar phenotypes were described also as autosomal recessive or X-linked. ► [laminopathies](#); Shultz LD et al 2003 Hum Mol Genet 12:61.

P

Pelizaeus-Merzbacher Disease: An Xq22 chromosomal recessive leukodystrophy that accumulates a proteolipoprotein (PLP, a 276-amino acid integral membrane protein) of the endoplasmic reticulum and the surface protein DM20 (26.5 kDa). The defect involves alternative splicing of the same mRNA. Duplications and deletion may be responsible for the disorder. The clinical symptoms are defective myelination (dysmyelination) of the nerves and defective interaction between oligodendrocytes and neurons, pathogenesis of the central nervous system and impaired motor development with an onset before age one. Mutation in the same gene encoding PLP is responsible also for X-linked spastic paraplegia type 2 (SPG-2) and the difference is in the degree of hypomyelination and motor dysfunction. Hereditary spastic paraplegia alleles were assigned to 8p, 16p, 15q and 3q27-q28. The corresponding defect in mouse displays *jimpy* and the myelin deficient (*msd*) phenotype. ► [myelin](#), ► [Charcot-Marie-Tooth disease](#), ► [leukodystrophy](#), ► [spastic paraplegia](#)

Pelle: Serine/threonine kinase, involved in dorsal signal transduction. ► [IRAK](#)

Peloric: The circular symmetry of the flower in contrast to the bilateral symmetry of the wild type first described in *Linaria* by Linnaeus. Homologous mutations occur in *Antirrhinum* as shown in Figure P39. This variation of floral symmetry of *Linaria* is due to the different methylation of a gene, *Lcyc* (Cubas P et al 1999 Nature [Lond] 401:157). It is thus an epimutation. The first figure is the wild type *Antirrhinum* flower of bilateral symmetry. The second figure is the *cycloidea* mutant with radial symmetry (pelory). (Illustration is the courtesy of Professor Hans Stubbe; ► [methylation of DNA](#), ► [epigenesis](#), ► [superman](#), ► [snapdragon](#), ► [cycloidea](#))

Figure P39. Normal and peloric snapdragon flowers

pelota: *Drosophila* gene involved in sperm function. ► [azoospermia](#)

Pemphigus: A collection of skin diseases with the general features of developing smaller or larger vesicles of the skin that may or may not heal and in extreme cases may result in death. The autosomal dominant familial pemphigus vulgaris is an autoimmune disease of the skin and mucous membranes. In the majority of cases, HLA-DR4 is involved. This anomaly is particularly common among Jews in Israel. In mice pemphigus vulgaris, inhibitor of MAPK (p38) can reduce the autoimmune blisters (Berkowitz P et al 2006 Proc Natl Acad Sci USA 103:12855). ► [Hailey-Hailey disease](#), ► [HLA](#), ► [skin diseases](#), ► [desmosome](#), ► [autoimmune disease](#)

Pena-Shokeir Syndrome: A fetal akinesia caused by brain malformations; X-chromosomal inheritance is suspected. ► [akinesia](#)

Pendred Syndrome: A recessive (7q31, PDS) thyroid anomaly and neurosensory deafness. The locus encodes *pendrin* an anion transporter, a presumed sulfate transporter localized in the cell membrane and a bicarbonate secretion in the kidney. Recent evidence indicates chloride and iodide transport too. This locus is responsible for about 1–10% of the genetically determined hearing loss. ► [deafness](#), ► [goiter](#); Royaux IE et al 2001 Proc Natl Acad Sci USA 98:4221.

Penetrance: The percentage of individuals in a family that express a trait determined by gene(s) they contain. The genetic basis of this phenomenon is poorly understood, and may cause serious problems in genetic counseling. ► [expressivity](#)

Penicillin: An antibiotic originally obtained from *Penicillium* fungi (see Fig. P40). The arrow points to the reactive bond of the β -lactam ring. ► [antibiotics](#), ► [Penicillium](#), ► [lactam](#), ► [\$\beta\$ -lactamase](#)

Figure P40. Basic structure of penicillins

Penicillin Enrichment: ► [penicillin screen](#)

Penicillin Screen: Used for mass isolation of auxotrophic microbial mutations that failed to grow in basal media (in contrast to the wild type) and the presence of the antibiotic therefore did not lead to their death (in contrast to the wild type). After transfer to complete (or appropriately supplemented) media the auxotrophs grew and thus were selectively isolated. ► [selective medium](#), ► [replica plating](#), ► [mutant isolation](#); Davis BD 1948 J Am Chem Soc 70:4267; Lederberg J, Zinder N 1948 J Am Chem Soc 70:4267.

Penicillinase: β -lactamase

Penicillin Binding Proteins: ► [PBP](#)

Penicillium notatum (fungus): $x = 5$ (see Fig. P41).

Figure P41. *Penicillium* conidiophore with conidia

Penis: The male organ of urinary excretion and insemination (homologous to the female clitoris). It contains the *corpus spongiosum* through which the urethra and sperm passes. Above that are the *corpora cavernosa* that become extended when erection takes place due to enhanced blood supply to this elastic tissue as a consequence of NO (nitrogen-monoxide) gas flows to the muscles of the blood vessel wall, initiated by acetylcholine. The

release of acetylcholine is controlled by steroid hormones. Cyclic GMP-dependent kinase is an essential enzyme for the maintenance of the extended state of the *corpus cavernosum*. Injection of prostaglandin E1 blocks cGMP-degrading phosphodiesterase and facilitates erection. The penis of canines (and most other mammals including primates except humans and spider monkeys) contains a small bone (*baculum* or *os penis*). In all humans, the gulonolactone oxidase (EC 1.1.3.8) gene on chromosome 8p21 is defective and no baculum is formed. The lack of this enzyme also makes humans dependent on dietary ascorbic acid. (It has been suggested that God created Eve not from a rib but from the baculum of Adam.) The baculum of mammals assists quick penetration of the vagina. During sexual intercourse of dogs, the male first penetrates the vulva of the female and erection takes place only in a second phase. At the base of the dog's penis the oval *bulbus glandis* then expands and locks the penis in position and the mating pair cannot separate until the ejaculation is terminated. Some animals (snakes, lizards, crustaceans and insects) have two penises (*virgae*). In *Euborellia plebeja* (Dermaptera) both are functional. ► [animal hormones](#), ► [acetylcholine](#), ► [acetylcholine receptors](#), ► [hypospadias](#), ► [nitric oxide](#), ► [cGMP](#), ► [prostaglandin](#), ► [baculum](#), ► [erectile dysfunction](#), ► [clitoris](#); Kamimura Y, Matsuo Y 2001 Naturwiss 88:447; insect penis evolution review: Palmer AR 2006 Nature [Lond] 444:689.

Pentaglycines: ► [bacteria](#)

Pentaploid: Its cell nucleus contains five genomes (5x). Pentaploids are obtained when hexaploids (6x) are crossed with tetraploids (4x). The pentaploids are generally sterile or semi-fertile because the gametes generally have unbalanced number of chromosomes. ► [polyploids](#), ► [Rosa canina](#)

Pentatrico: A ~35 unit sequence of amino acids, generally repeated several times in some proteins. Pentatricopeptide repeat (PPR) proteins form one of the largest families in higher plants and are believed to be involved in the posttranscriptional processes of gene expression in plant organelles and RNA editing in the chloroplasts (Okuda K et al 2007 Proc Natl Acad Sci USA 104:8178). ► [RNA editing](#), ► [retrograde regulation](#)

Penton: Capsomer with five neighbors in the viral capsid. ► [capsomer](#), ► [hexon](#); Zubieta C et al 2005 Mol Cell 17:121.

Pentose: A sugar with 5-carbon-atom backbone, such as ribose, deoxyribose, arabinose, xylose.

Pentose Phosphate Pathway: glucose-6-phosphate + 2 NADP + H₂O → ribose-5-phosphate + 2 NADPH +

2 H + + CO₂, i.e., the conversion of hexoses to pentoses generates NADPH, a molecule that serves as a hydrogen and electron donor in reductive biosynthesis. ► **Embden-Meyerhof pathway**, ► **Krebs-Szentgyörgyi cycle**

Pentose Shunt: Same as pentose phosphate pathway.

Pentosuria: An autosomal recessive non-debilitating condition characterized by excretion of increased amounts of L-xylulose (1–4 g) in the urine because of a deficiency of the NADP-linked xylitol dehydrogenase enzyme. In Jewish and Lebanese populations, the frequency of the gene was about 0.013–0.03. ► **gene frequency**, ► **allelic frequencies**

PEPCK (phosphoenolpyruvate carboxykinase): A regulator of energy metabolism.

Pepper (*Capsicum* spp): It exists in a great variety of forms but all have 2n = 2x = 24 chromosomes. Some wild species are self-incompatible and the cultivated varieties yield better if they have a chance for xenogamy. ► **self-incompatibility**, ► **xenogamy**

Pepsin: An acid protease, formed from pepsinogens. It has preference for COOH side of phenylalanine and leucine amino acids.

Pepstatin (C₃₄H₆₃N₅O₉): A protease (pepsin, cathepsin D) inhibitor.

Peptamer: The exposed loop on the surface of a carrier protein; it is thus protected from degradation and its conformational stability is improved.

Peptidase (protease): Hydrolyzes peptide bonds. In humans, the peptidase gene PEPA is in chromosome 18q23, PEPB in 12q21, PEPC in 1q42, PEPD in 19cen-q13.11, PEPE in 17q23-qter, PEPS in 4p11-q12, and the tripeptidyl peptidase II (TPP2), a serine exopeptidase is in 13q32-q33. (See <http://merops.sanger.ac.uk>).

Peptide Bond: Amino acids are joined into peptides by their amino and carboxyl ends ↑ (and they lose one molecule of water) (see Fig. P42).

Figure P42. Peptide bond

Peptide Elongation: ► **protein synthesis**, ► **aminoacylation**, ► **aminoacyl-tRNA synthetase**, ► **elongation factors** (eIF), ► **ribosome**, ► **tmRNA**, ► **cycloheximide**

Peptide Initiation: ► **protein synthesis**, ► **pactamycin**

Peptide Mapping: The separation of (in)complete hydrolysates of proteins by two-dimensional paper chromatography or by two-dimensional gel electrophoresis for the purpose of characterization. The distribution pattern is the map or fingerprint, characteristic for each protein.

Peptide Mass Fingerprints: The protein is first cleaved by a sequence-specific protease such as trypsin and analyzed by MALDI-TOF and compared with protein sequences with similar lysyl or arginyl residues of the same mass. On this basis matching proteins even in a mixture can be identified. Modified proteins are detectable on the basis of peptide sequence with an incremental mass due to, e.g., a phosphogroup. ► **proteomics**, ► **MALDI**, ► **trypsin**; Mann M et al 2001 Annu Rev Biochem 70:437; Pratt JM et al 2002 Proteomics 2:157; Giddings MC et al 2003 Proc Natl Acad Sci USA 100:20; <http://www.peptideatlas.org/>.

Peptide Nucleic Acid (PNA): A nucleic acid base (generally thymine) is attached to the nitrogen of a glycine (or other amino acids) by a methylene carboxamide linkage in a backbone of aminoethyl-glycine units (see Fig. P43). Such a structure can displace one of the DNA strands and binds to the other strand.

Figure P43. PNA backbone resembles that of DNA. The letter B stands for nucleic acid bases

They are DNA mimics. This highly stable complex has similar uses as the antisense RNA technology. PNA may be used to inhibit excessive telomerase activity in cancer cells. Homopyrimidine PNA may invade homopurine tracts in double-stranded DNA and may form triplex DNA and interfere with transcription. Peptide nucleic acid can target the polyguanine tract of HIV-1 and can arrest translation elongation (Boutiah-Hamoudi F et al 2007 Nucleic Acids Res 35:3907). PNA may also be used to screen for base mismatches and small deletions or base substitution mutations. Peptide nucleic acid complementary to mutant mtDNA selectively inhibits the replication of mutant mtDNA in vitro. PNA has been suggested to be the first pre-biotic genetic molecule rather than RNA. PNA may be useful for delivering genes to the mitochondria. PNA-DNA hybrids may be identified by binding of the dye 3,3'-diethylthiadicarbocyanine and used for the rapid detection of

mutations of clinical importance. Site-specific recombination may be substantially enhanced by PNA. ▶antisense RNA, ▶antisense DNA, ▶TFO, ▶mtDNA, ▶Hoogsteen pairing, ▶RNA world, ▶mitochondrial gene therapy, ▶acquired immunodeficiency; Corey DR 1997 Trends Biotechnol 15:224; Chinnery PF et al 1999 Gene Ther 6:1909; Wilhelmsson LM et al 2002 Nucleic Acids Res 30(2): e3; Rogers FA et al 2002 Proc Natl Acad Sci USA 99:16695.

Peptide Processing: ▶post-translational processing

Peptide Sequence Tag: ▶electrospray MS

Peptide Transporters: ▶TAP, ▶ABC transporters

Peptide Vaccination: Synthetic polypeptides corresponding to CTL epitopes may result in cytotoxic T cell-mediated immunity but in some instances, it may enhance the elimination of anti-tumor CTL response. ▶vaccination, ▶CTL, ▶epitope, ▶cancer prevention, ▶immunological surveillance; Vandenbark AA et al 2001 Neurochem Res 26:713.

Peptidoglycan: The heteropolysaccharides cross-linked with peptides constituting the bulk of the bacterial cell wall, especially in the Gram-positive strains. ▶Gram negative; see chemical formula in Fig. P44.

Peptidomimetics: These are polymer analogs containing unnatural amino acids. The non-natural amino acids are incorporated by the translation machinery using suppressor amino acid-transfer RNAs or nonsuppressor tRNA in a modified system. Peptidomimetics may facilitate the study of translation, enable directed evolution of small molecules with desirable catalytic and pharmacological properties, and are potential blocking agents of carcinogenesis by promotion of apoptosis. ▶translation, ▶aminoacyl-tRNA synthetase, ▶suppressor tRNA, ▶genetic code, ▶alloproteins; Forster AC et al 2003 Proc Natl Acad Sci USA 100:6353.

Peptidyl Site: ▶P site, ▶ribosome, ▶protein synthesis

Peptidyl Transferase: Generates the peptide bond between the preceding amino acid carboxyl end (at the P ribosomal site) and the amino end of the incoming amino acid (at the A site of the ribosome). It is a ribozyme and the catalytic function resides in the 23S ribosomal RNA. Essential function is attributed to adenine 2451. ▶ribosome, ▶protein synthesis, ▶macrolide

Peptidyl-Prolyl Isomerases (PPI): PPI mediate the interconversion of the cis and trans forms of peptide bonds preceding proline. PPI genes are in human chromosomes 4q31.3, 6p21.1, 7p13 and the mitochondrially located at 10q22-q23. This family includes cyclophilins, FKBs and parvulins. ▶FK506, ▶cyclophilins, ▶parvulin; Shaw PE 2002 EMBO Rep 3:521; Wu X et al 2003 Genetics 165:1687.

Peptoid: A peptide-like molecule that results from the oligomeric assembly of N-substituted glycines. Peptoids have various biological applications.

per (period) locus: In *Drosophila* (map location 1-1.4, 3B1-2), *per* locus controls the circadian and ultradian rhythm, thus affecting eclosion, general locomotor activity, courtship, intercellular communication, etc. The mutations do not seem to affect the viability of the individuals involved, only the behavior is altered. When *per^S* (caused by a base substitution mutation in exon 5) in the brain is transplanted into *per⁰¹* mutants (nonsense mutation in exon 4) causing short ultradian rhythm and multiple periods, some flies may be somewhat normalized. The locus has been cloned and sequenced and seems to code for a proteoglycan. Gene NONO of mammalian cells apparently positively modulates PER and gene WDR5 (involving a histone-methyltransferase subunit) controls methylation/expression of PER (Brown SA et al 2005 Science 308:693). The Per protein forms a heterodimeric complex with the Tim (*timeless* gene) protein

Figure P44. Chemical structure of a segment of peptidoglycan. (NAG): N-acetylglucosamine-N-acetyl muramic acid disaccharide (NAM) and attached pentapeptide. See Meroueh SO et al. 2006 Proc Natl. Acad. Sci. USA 103:4404

and jointly autoregulate transcription. Tim is degraded in the morning in response to light and that results in the disintegration of the complex that is reformed again in dark in a circadian oscillation. In mammals, three *mPer* loci have been identified controlling the circadian clock. ▶circadian, ▶ultradian, ▶proteoglycan

Percent Identity Plot (PIP): A macromolecular sequence map displaying the percentage of identity between two sequences. (See <http://bio.cse.psu.edu>).

Percentile: The percentage of the distribution of variates. More than 50 percentile indicates a value higher than 50% of the variates.

Perdurance: The persistence and expression of the product of the wild type gene even after the gene itself is no longer there.

Perennial: Lasts through more than one year.

Perfect Flower: Has both male and female sexual organs, i.e., it is hermaphroditic (see Fig. P45). ▶hermaphrodite, ▶flower differentiation

Figure P45. Perfect flower

Perforin (encoded at 10q22): Pore-forming protein (homologous to component 9 of the complement) that establishes transmembrane channels; it is stored in vesicles within the CD8⁺ cytotoxic T cells (CTL). These vesicles contain also serine proteases. Perforin mediates apoptosis by permitting killer substances (granzyme) slowly enter the cell. Perforin may have a role in T cell-mediated destruction of pancreatic β -cell in diabetes mellitus type I. ▶apoptosis, ▶complement, ▶T cells, ▶fragmentin-2, ▶granzymes, ▶caspase, ▶histiocytosis, ▶diabetes mellitus; Keefe D et al 2005 Immunity 23:249.

Perfusion: Adding liquid to an organ through its internal vessels in vitro or in vivo.

Perianth: Designates both sepals and petals of the flowers. ▶flower differentiation

Pericarp: The fruit wall (maternal tissue), developed from the ovary wall such as the pea pod, the outer layer of the wheat or maize kernels. The *Arabidopsis* silique, the peel of the citrus, and the skin of apple, the shell of the nuts, etc., are also similar but are exocarps. The outer layer of the common barley “seed” is not part of the fruit wall but it is a bract of the flower.

Pericentric Inversion: ▶inversion pericentric

Pericentromeric Region: A highly redundant tract (<1 kb to ~85 kb), a transition zone, between the genic region of the chromosomes and the satellite heterochromatin. ▶heterochromatin, ▶centromere, ▶satellite DNA; Horvath JE et al 2001 Hum Mol Genet 10:2215.

Perichromatin Fibers: Active genes occupy the surface of specific compartments in the interphase nucleus (chromosome territories) and represent the perichromatin fibers. ▶SR motif, ▶chromatin, ▶chromosome territories; Cmarko D et al 1999 Mol Biol Cell 10:211.

Periclinal Chimera: Contains genetically different tissues in different cell layers. ▶mericlinal chimera, ▶chimera

Pericycle: The (root) tissue between the endodermis and phloem. ▶root, ▶endodermis, ▶phloem

Peridium: The covering of the hymenium or the hard cover of the sporangium of some fungi. ▶hymenium, ▶sporangium

Perinatal: The period after 28 weeks of human gestation⇔four weeks after birth.

Perinuclear Space: A ~20 to 40 nm space between the two layers of the nuclear membrane. ▶nucleus

Periodic Acid-Schiff Reagent (PAP): The tests for glycogen, polysaccharides, mucins, and glycoproteins. It breaks C-C bonds by oxidizing near hydroxyl groups and forms dialdehydes and generates red or purple color.

Periodic Paralysis (PP, KCNE): A group of autosomal dominant human diseases manifested in periodically recurring weakness accompanied by low blood potassium level (hypokalemic periodic paralysis, defect in the α subunits of Ca²⁺ channel) or in other forms with high blood potassium level (hyperkalemic periodic paralysis, paramyotonia). The latter types were attributed to base substitution mutations in a highly conserved region of the α subunit of a transmembrane sodium channel protein. In another type of the disease, the blood potassium level appeared normal and the patients responded favorably to sodium chloride. The MiRP2 potassium

channel defect is also associated with PP. ►ion channel, ►Moebius syndrome, ►myotonia, ►hyperkalemic periodic paralysis; Abbott GW et al 2001 Cell 104:217.

Periodicity: The number of base pairs per turn of the DNA or the number of amino acids per turn of an α -helix of a polypeptide chain. ►protein structure, ►Watson and Crick model

Periodontitis: Several diseases involving inflammation of the gingiva, especially at the base of the teeth and the alveolae, the bone support of the teeth. It is usually associated with keratosis of the palms and soles. About 30% of the human population is affected by it. In the juvenile form (encoded at 4q11-q13) both milk and permanent teeth may be lost in early childhood. The disease is the result of bacterial infections (~500 different species may inhabit the human mouth). The Papillon-Lefèvre syndrome (11q14, prevalence $1-4 \times 10^{-6}$) is based on deficiency of cathepsin C, a dipeptidyl peptidase I. In the similar autosomal recessive periodontitis deficiency of IL-1 is suspected. Similar symptoms may occur also in the Ehlers-Danlos syndrome Type VIII. ►keratosis, ►cathepsin, ►IL-1, ►Ehlers-Danlos syndrome, ►dentinogenesis imperfecta; Travis J et al 2000 Adv Exp Med Biol 477:455.

Peripheral Nervous System: Resides outside the brain and the spinal chord.

Peripheral Proteins: These are bound to the membrane surface by hydrogen bonds or by electrostatic forces. ►membrane proteins

Peripherin (retinal degeneration slow protein): ►retinal dystrophy

Periplasma: The cell compartment between cell wall and cell membrane. In *E. coli* the Sec family of proteins mediate the translocation across the periplasmic and the outer membrane. The extracellular stress response factor σ^E regulates the assembly of the outer membrane. The two-component Cpx seems to be involved in the assembly of the pilus. ►Sec, ►two-component regulatory system, ►pilus; Danese PN, Silhavy TJ 1998 Annu Rev Genet 32:59; Raivio TL, Silhavy TJ 2001 Annu Rev Microbiol 55:591.

Peristalsis: The contraction of muscles of a tubular structures (e.g., intestines) propelling the content.

Peristome: A fringe of teeth at the opening of the sporangium of mosses or the buccal (mouth) area of ciliates.

Perithecium: A fungal fruiting body of disk or flask shape with an opening (ostiole) for releasing the spores (see Fig. P46). A perithecium of *Neurospora*

contains about 200 asci. Its primordium is called protoperithecium. ►ascogonium, ►apothecium, ►cleistothecium, ►gymnothecium, ►*Neurospora*, ►ascus, ►tetrad analysis

Figure P46. Perithecium

Periventricular Heterotopia: A human X-chromosomal mental retardation and seizures caused by anomalies of the brain cortex. The neurons destined for the cerebral cortex fail to migrate. The mutation involves the filamin gene (FLN1, Xq28) encoding an actin-cross-linking phosphoprotein. ►double cortex; Sheen VL et al 2001 Hum Mol Genet 10:1775.

PERK (PKR-like ER kinase): A phosphorylating enzyme in the endoplasmic reticulum, similar to the mammalian RNA-dependent protein kinase (PKR). It is interferon-inducible and activated by double-stranded RNA. PERK and the phosphorylation of eIF2 α inhibit the initiation of translation. ►PKR, ►eIF2 α , ►Ire, ►unfolded protein response, ►S6; Kumar R et al 2001 J Neurochem 77:1418.

Perl Script: Assembles and merges sequences from different DNA libraries. ►DNA library, ►PHRAP

Perlecan: Heparan sulfate proteoglycan that interacts with the extracellular matrix, growth factor receptors and affects signal transduction. ►proteoglycan, ►heparan sulfate, ►Schwartz-Jampel syndrome; Knox S et al 2002 J Biol Chem 277:14657.

Perlegen Sciences: Perlegen sciences have genotyped over 1.5 million unique genetic variants (SNPs), in 71 individuals of European American, African American, or Han Chinese ancestry. In total, more than 112 million individual genotypes were determined, with an average distance between adjacent SNPs of 1871 base pairs. The genotype browser permits accession to virtually all the SNP, linkage disequilibrium, and haplotype data reported in the study. ►SNIPs, ►linkage disequilibrium, ►haplotype;

expanded data: Hinds DA et al 2005 Science 307:1072; <http://genome.perlegen.com/>.

Permafrost: The soil layer in cold regions that remains permanently frozen even when the top may thaw.

Permanent Hybrid: ►complex heterozygote

Permease: The enzymes involved in the transport of substances through cell membranes. ►membrane transport, ►membrane channels, ►membrane potential, ►ion channels; Abramson J et al 2003 Science 301:610.

Permissible Dose: ►radiation hazard assessment

Permissive Condition: The condition at which a conditional mutant can survive or reproduce. ►conditional mutation

Permissive Host: A cell permits (viral) infection and/or development.

Permutation: Generating all possible orders of n numbers, and it can be obtained by the factorial: $n!$, e.g., the factorial of 4, $4! = 4 \times 3 \times 2 \times 1 = 24$. ►combination, ►variation

Permutation Test (randomization test): The test used to assess the association of QTLs with multiple (molecular) markers in a randomized array. ►QTL, Edington ES 1995 Randomization tests, Marcel Dekker, New York.

Permuted Redundancy: At the termini of phage DNA a collection of redundant sequences occur in the phage population that start and end with permuted sequences of the same nucleotide sequence, e.g., 1234...1234, 2341...2341, 3412...3412, etc. This arrangement is characteristic for T-uniform phages, e.g., T1, T3, T5, etc. ►non-permuted redundancy

Perodictus: ►*Lorisidae*

Peroxidase: Heme protein enzymes, which catalyze the oxidation of organic substances by peroxides. Glutathione peroxidase (and selenium) deficiency may cause hemolytic disease. Several peroxidase genes have been located in the human genome: GPX1 in 3q11-q12, GPX2 in 14q24.1, GPX3 in 5q32-q33, GPX4 (in testes) in chromosome 19, a rare eosinophil peroxidase (EPX) may compromise the immune system, a thyroid peroxidase deficiency (2p25) interferes with thyroid function. ►immune system, ►eosinophil, ►hemolytic disease, ►oxidative stress

Peroxidase and Phospholipid Deficiency: An autosomal recessive anomaly of the eosinophils involving the enzyme defects named. ►microbody, ►Refsum disease, ►Zellweger syndrome

Peroxides: They display the — O — O — linkage. Organic peroxides participate in activation and deactivation of promutagens, mutagens, procarcinogens

and carcinogens and in many other physiological reactions. Peroxides are formed by the breakdown of amino acids and fatty material in the cell and may inflict serious damage. According to some views, spontaneous mutation may be caused to a great extent by these regular components of the diet. Therefore, eating rancid food may pose substantial risk. ►environmental mutagens, ►peroxidase, ►catalase peroxisomes, ►promutagen, ►ROS, ►P450

Peroxins: Peroxisome proteins. PEX1 (7q21-q22), PEX10, human chromosome 1) is a peroxisome biogenesis protein, PEX13 (2p15) in another peroxisome biogenesis protein. ►peroxisome, ►PEX, ►Zellweger syndrome, ►Refsum disease, ►microbodies; Walter C et al 2001 Am Hum Genet 69:35.

Peroxiredoxins: Antioxidant enzymes present in prokaryotes and eukaryotes and control signal transduction, apoptosis, tumor formation, HIV infection, etc. (See Wood ZA et al 2003 Science 300:650; Neumann CA et al 2003 Nature [Lond] 424:561).

Peroxisomal 3-Oxoacylcoenzyme A Thiolase Deficiency (pseudo-Zellweger syndrome): Autosomal recessive disease assigned to human chromosome 3p23-p22. ►microbody, ►Zellweger syndrome, ►adrenoleukodystrophy

Peroxisome: Peroxisome are ~0.15–0.5 μm diameter bodies, surrounded by single-layer membrane, in eukaryotic cells containing about 50 proteins, including oxidase and catalase enzymes. The peroxisomes synthesize ether phospholipids by dihydroxyacetonephosphate acetyltransferase (DHAPAT, human chromosome 1q42) and alkyl dihydroxyacetonephosphate synthase (ADHAPS, 2q31). In a human cell, the number of peroxisomes vary from less than 100 to more than 1000. In yeast either over expression or lacking the Inp 1 protein (inheritance of peroxisome protein 1) are detrimental for the right amount and the proper distribution of peroxisome. Inp binds several proteins involved in peroxisome division (Fagarasanu M et al 2005 J Cell Biol 169:765). The peroxisomes have indispensable roles in fatty acid β oxidation, phospholipid and cholesterol metabolism. Fatty acid granules are also named microbodies. The peroxisome biogenesis disorders (PBD) are recessive lethal diseases in variable forms. The extreme form is the Zellweger syndrome, the Refsum disease and the adrenoleukodystrophy are milder and the rhizomelic chondrodysplasia punctata (RCDP) involves bone defects. Peroxisome mutations have been identified also in yeast (PAS). Some rodent carcinogens increase the number of peroxisomes but in humans, these agents did not appear to be carcinogenic. Peroxisomal protein Pex2 controls photomorphogenesis in *Arabidopsis*. ►glyoxisome,

►microbodies, ►PPAR, ►peroxin, ►Zellweger syndrome, ►Refsum disease, ►adrenoleukodystrophy, ►chondrodysplasia, ►oxalosis, ►peroxidase and phospholipid deficiency, ►peroxisomal 3-oxo-acyl-coenzyme A thiolase deficiency, ►PPAR, ►micro-pexophagy, ►pexophagy, ►PEX; Gould SJ, Valle D 2000 Trends Genet 16:340; Sacksteder KA, Gould SJ 2000 Annu Rev Genet 34:623; Titorenko VI, Rachubinski RA 2001 Trends Cell Biol 11:22; Thai T-P et al 2001 Hum Mol Genet 10:127; Titorenko VI, Rachubinski RA 2001 Nat Rev Mol Cell Biol 2:357; Purdue PE, Lazarow PB 2001 Annu Rev Cell Dev Biol 17:701; Hu J et al 2002 Science 297:405; Matsumoto N et al 2003 Am J Hum Genet 73:233; Weller S et al 2003 Annu Rev Genomics Hum Genet 4:165; Wanders RJA, Waterham HR 2006 Annu Rev Biochem 75:295; <http://www.peroxisomeDB.org>.

Peroxynitrite (ONOO⁻/ONOOH): The diffusion-limited product of nitric oxide with superoxide. It is strongly oxidizing and toxic. ►nitric oxide, ►super-oxide, ►peroxides; García-Nogales P et al 2003 J Biol Chem 278:864.

Perp: ►p63

Persistence, Bacterial: A phenocopy-like phenomenon in bacteria. When the culture is exposed to strong stress (e.g., antibiotics), the majority of the cells die but a small fraction survives although without a heritable resistance. When they re grow the population become sensitive to the antibiotic. ►phenocopy; Balaban NQ et al 2004 Science 305:1622.

Personal Genomics: ►DNA fingerprinting, ►DNA sequencing

Personality: Can be characterized by five main groups of features: (1) *extraversion* (being outgoing) or the lack of it, ability to lead and sell their ideas versus reticent and avoiding company [heritability about 0.71]; (2) *neuroticism* (emotional versus stable) worrisome or self-assured, [heritability about 0.21]; (3) *conscientiousness* (well-organized versus impulsive) responsible or irresponsible, reliable or undependable, [heritability 0.38–0.32]; (4) *agreeableness* (empathic or unfriendly) warm versus cold, cooperative versus quarrelsome, forgiving versus vindictive, [heritability about 0.49], and (5) *openness* (insightful or lacking intelligence) imaginative versus imitative, inquisitive or superficial). These heritability estimates vary a great deal, however, and may be very different in some populations. Based on twin studies, several investigators concluded that overall close to 50% of the variance could be attributed to additive or non-additive genetic determination. ►behavior in humans, ►behavior genetics, ►human intelligence, ►affective disorders, ►heritability in humans

Person/Year: Used as, for e.g., incidence of an event a (symptoms of a disease) per person per year.

Persyn: ►synuclein-γ

Perturbogen: Short peptides or protein fragments that can disrupt specific biochemical function in the cell.

Pertussis Toxin: Produced by the Gram-negative *Bordetella* bacteria, responsible for whooping cough. The toxin stimulates ADP-ribosylation of the Gα_i subunit of a G-protein in the presence of ARF and thus GDP stays bound to the G-protein and adenylate cyclase is not inhibited and K⁺ ion channels do not open. As a consequence, histamine hypersensitivity and reduction of blood glucose level follows. ►whooping cough, ►signal transduction, ►ARF, ►G-protein, ►ADP, ►GDP, ►cholera toxin, ►adenylate cyclase; Alonso S et al 2001 Infect Immun 69:6038.

PERV (porcine endogenous retrovirus): Exists in >50 copies/pig chromosome complement and has been feared to endanger humans with xenotransplantation of pig organs. So far, the limited information indicates minimal risk relative to the potential benefits. PERVs can be transferred to mice by xenotransplantation. ►xenograft, ►xenotransplantation, ►nuclear transplantation; Specke V et al 2001 Virology 285:177.

PEST (proline [P]-glutamate [E]-serine [S]-threonine [T]-rich motif): PEST in the carboxyl domain of IκB and other proteins (Ubc) is involved in the stimulation of proteolysis. ►IκB, ►NF-κB, ►proteasome, ►Ubc, ►ubiquitin

Pest Eradication by Genetic Means: ►genetic sterilization, ►*Bacillus thuringiensis*, ►host–pathogen relations (see Fig. P47).

Figure P47. *Bacillus thuringiensis* toxin transgene is lethal to worms (right) but the wild type plants (left) were destroyed. (Courtesy of Professor Marc Van Montagu, Rijksuniversiteit, Gent)

Pesticide Mutagens: ►environmental mutagens

Pesticin: The toxin of *Pasteurella* bacteria

Pestilence: An infectious epidemic of disease.

PET: ►tomography

PET: ►transcriptome, ►paired-end diTAG

Petaflop Computer: An extremely powerful supercomputer. “Peta” comes from the Latin word *peto* (I move forward) and in computer jargon, “flops” designate floating operations. This new hardware may be capable of performing one quadrillion flops/second, that are more than 10^6 times the efficiency of the best desktop computers.

Petals: Generally the second whorl of modified leaves from the bottom of the flower (see Fig. P48).

Figure P48. Petals of *Arabidopsis* are shown at left. At right: The adaxial ridge of the petal as viewed by scanning electronmicrography and reveal the beauty, which the naked eye cannot see. (From Bowman JL, Smyth DR 1994 In: Bowman JL (ed) *Arabidopsis: An Atlas of Morphology and Development*. By permission of Springer-Verlag, New York)

Frequently, they are quite showy because of their anthocyanin or flavonoid pigmentation. The petal number is a taxonomic characteristic, although petal number may be altered by homeotic mutations converting the anthers and/or pistils into petals and appearing as sterile double flowers of floricultural advantage. MicroRNA may have a role in the regulation of petal number (Baker CC et al 2005 *Curr Biol* 15:303). ►flower differentiation, ►flower pigments, ►homeotic mutants; Roeder AHK, Yanofsky MF 2001 *Dev Cell* 1:4.

PETCM (α -[trichloromethyl]-4-pyridineethanol): Stimulates caspase-3 activity and thereby apoptosis. ►caspase, ►apoptosis; Jiuang X et al 2003 *Science* 299:223.

Petiole: The stalk of a leaf (see Fig. P49).

Figure P49. Petiole

Petite Colony Mutants: Petite colony mutants of yeast forms small colonies because they are deficient in respiration (OXPHOS minus) and lethal under aerobic conditions. The *vegetative petites* (ρ^-) are caused by (large) deletions in the mitochondrial DNA, the *segregational petites* are controlled by nuclear genes at over 200 loci. The mitochondrial mutations occur at high (0.1 to 10%) frequency and using ethidium bromide as a mutagen their frequency may become as high as 100%. The mitochondrial petites fail to transmit this character in crosses with the wild type except one special group the *suppressive petites* that may be transmitted at a low frequency in outcrosses with the wild type. In yeast, the A + T content of the normal mitochondrial DNA is about 83%, in some of the mitochondrial mutants the A + T content may reach 96% because the coding sequences were lost and only the redundant A + T sequences were retained and amplified so the mtDNA content is not reduced. The *hypersuppressive petite* mutants have short (400–900 bp) repeats that share 300 bp (*ori* and *rep*) sequences with the wild type, necessary for replication. *Neutral petites* produce wild type progeny when outcrossed to the wild type. Yeast cells that have normal mitochondrial function make large colonies and are called *grande*. Cells that can dispense with mitochondrial functions are sometimes called petite-positive whereas that absolutely need mitochondria are called petite-negative. Inactivation of an ATP and metal-dependent protease (Yme1p) associated with the inner membrane of the mitochondrion can convert the “positives” to “negatives” and the presence of the Yme1p function may have the opposite effect. Yme is not universally present in all yeasts. ►mitochondria, ►mtDNA, ►mitochondrial mutations, ►oxidative phosphorylation; Sager R 1972 *Cytoplasmic Genes and Organelles*, Academic Press, New York; MacAlpine DM et al 2001 *EMBO J* 20:1807; Chen XJ, Clark-Walker GD 2000 *Int Rev Cytol* 194:197.

Petri Plate: A (flat) glass or disposable plastic culture dish for microbes or eukaryotic cells (see Fig. P50).

Figure P50. Petri plate

Petunia hybrida (2n = 28): *Solanaceae*; predominantly self-pollinating but allogamy also occurs. It has been used extensively for cell, protoplast and embryo culture, intergeneric and inter-specific cell fusion, genetic transformation and the genetic control of pigment biosynthesis. It has a good number of related species.

Peutz-Jeghers Syndrome: ▶polyposis hamartomatous

PEV (position effect variegation): ▶position effect, ▶heterochromatin, ▶RPD3

PEX: Proteins import the peroxisome-targeting signals (PTS) to the peroxisomes. The various PEXs play roles in peroxisome biogenesis. ▶peroxisome; Braverman N et al 1988 Hum Mol Genet 7:1195.

Pexophagy: Sequestration to and engulfing peroxisomes into vesicles and their destruction. ▶peroxisome

Peyer's Patches: Aggregated lymphatic nodes. The Peyer's patches mediate the uptake of macromolecules, antigens and microorganisms through the epithelium of the gut. These plaques are instruments of mucosal immunity. B cells are required for the normal functions of the Peyer's patches. *Salmonella typhi* infection may cause perforation of the Peyer's patches. Tyrosine kinase receptor RET is a regulator of Peyer's patch formation (Veiga-Fernandes H et al 2007 Nature [Lond] 446:547). ▶mucosal immunity, ▶RET oncogene

Peyronie Disease: An apparently dominant autosomal disorder, it may be caused by a variety of acquired and genetic conditions. Its exact prevalence has not been determined but it may occur at ~1 to 8% of the human males. It involves fibrous, thickened collagen plaques on most commonly on the dorsal part of the penis and causes its curvature under painful conditions of erection. The condition may be transient. It occurs generally after age 40. Several drugs and in severe conditions surgical intervention have been used for treatment. (See Usta MF, Hellstrom WJG 2004 In: Seftel AD et al (Eds.) Male and Female Sexual Dysfunction, Mosby, St. Louis, Missouri, p 191).

PFAM: A database of over 3000 protein families and domains, multiple sequence alignments and profile hidden Markov models. ▶alignment; Bateman A et al

2002 Nucleic Acids Res 30:276; <http://pfam.wustl.edu>; <http://www.sanger.ac.uk/Software/Pfam/>; <http://pfam.jouy.inra.fr>; <http://pfam.cgb.ki.se/>.

Pfeiffer Syndrome: The syndrome includes autosomal dominant bone malformation affecting the head, thumbs and toes (acrocephalosyndactyly) (see Fig. P51), the autosomal recessive head-bone (craniostosis) and heart disease. The origin is primarily paternal. The latter type seems to co-segregate with fibroblast growth factor receptor 1 (FGFR1) in human chromosome 8p11.2-p11.1.

Figure P51. Short and broad thumb in Pfeiffer syndrome

Another locus in chromosome 10q26 represents also a fibroblast growth factor receptor, FGFR2. FGFR3 is located in chromosome 4p16.3 and its mutation is concerned with hypo-chondroplasia. Mutations in all three genes involve Pro→Arg replacements at identical sites, 253. This syndrome is allelic to the Crouzon and to the Jackson-Weiss syndromes. Some of the mutations represent gain-of-functions. ▶fibroblast growth factor, ▶Alpert's syndrome, ▶Crouzon syndrome, ▶Jackson-Weiss syndrome, ▶craniosynostosis syndromes, ▶hypo-chondroplasia, ▶achondroplasia, ▶gain-of-function, ▶receptor tyrosine kinase

PfEMP1: A group of *Plasmodium falciparum* protein ligands expressed on the surface of infected red blood cells and mediate cell adhesion (virulence factors) but may incite host immune reaction. PfEMP displays antigenic variation to evade this response. Other pathogenesis proteins of the parasite are rifins. ▶Plasmodium, ▶antigenic variation, ▶rifin; Flick K et al 2001 Science 293:2009.

PFGE (pulsed field gel electrophoresis): PFGE separates very large nucleic acid fragments or even small chromosomes. The megabase size fragments can be used for physical mapping of large chromosomal domains (PFG mapping). ▶pulsed field gel electrophoresis

pfu (p.f.u.): The plaque forming unit. The number of phage particles/mL that can invade a bacterial lawn and then after reaching about 10^7 particle numbers

a clear spot appears on the Petri plate where the bacterial cells had been lysed. ► **plaque**, ► **pu**, ► **CFU**

PG: ► **prostaglandins**

PGA: Phosphoglyceric acid, a 3-carbon product of photosynthesis. ► **photosynthesis**, ► **Calvin cycle**, ► **C3 plants**

PGC (primordial germ cells): Gynogenetic/parthenogenetic cell, the primordial cell of female gonads. ► **gonad**, ► **gynogenesis**, ► **parthenogenesis**

PGC1 (PPAR- γ -coactivator): A regulator of transcription, body heat production, mitochondrial biogenesis and other processes. PGC-1 β is a transcriptional coactivator for the production of cholesterol and triglycerides. PGC1 α regulates both the gluconeogenic and glycolytic pathways during fasting. PGC1 α is also a regulator of the expression of several transcription factors required for the biogenesis of mitochondria and it is down regulated in Huntington disease (McGill JK, Beal MF 2006 Cell 127:465). Sirtuin interacts with and deacetylates PGC in a NAD-dependent manner as part of energy homeostasis, diabetes and lifespan (Rodgers JT et al 2005 Nature [Lond] 434:113). ► **PPAR**, ► **nuclear receptor**, ► **sirtuin**, ► **gluconeogenesis**, ► **glycolysis**, ► **aging**, ► **resveratrol**, ► **Huntington's chorea**; Tsukiyama-Kohara K et al 2001 Nature Med 7:1102.

PGD (preimplantation genetic diagnosis): PGD can be carried out for some human genetic disorders, for e.g., PCR or FISH (for fragile X, aneuploidy, etc.) examining polar bodies or blastomeres at the stage of a few cells in the embryo. The disorders that have been identified by PCR included cystic fibrosis, Tay-Sachs disease, Lesh-Nyhan syndrome, Huntington chorea, Marfan syndrome, ornithine transcarbamylase deficiency, Fanconi anemia, etc. The diagnosis may permit—by using in vitro fertilization—to develop a human offspring of a certain (disease-free) genetic constitution. Misdiagnosis is rare but varies somewhat in different laboratories. It seems likely that all cells in a single eight-cell embryo may not be identical. (See diseases mentioned under separate entries, ► **PCR**, ► **FISH**, ► **ART**; Bickerstaff H et al 2001 Hum Fert 4(1):24; Simpson JL 2001 Mol

Cell Endocrinol 183(Suppl. 1):S69; Findlay I et al 2001 Mol Cell Endocrinol 183(Suppl. 1):S5; PGD tests carried out according to international survey: Sermon K et al 2005 Hum Reprod 20:19).

PGK-neo: A commonly used transformation cassette for gene knockout where the neomycinophosphotransferase gene (*neo*) is fused to the phosphoglycerate kinase (PGK) promoter. ► **knockout**, ► **vector cassette**; Scacheri PC et al 2001 Genesis 30(4):259.

P-Glycoprotein: The 170 kDa product of the human multidrug resistance gene (MDR-1, 7q21.1) that exports different (mainly hydrophobic) toxic substances from the cells in an ATP-dependent manner. ► **multidrug resistance**

PGM: ► **phosphoglucomutase**

PGRS (polymorphic GC-rich repetitive sequences): Mycobacterium tuberculosis proteins (~70) with glycine-glycine doublets that have few charged amino acids and essentially contain no cysteine. These proteins are apparently involved in pathogenesis. ► **Mycobacteria**; Karlin S 2001 Trends Microbiol 9:335.

PgtB: Bacterial kinase that phosphorylates regulator protein PgtA. ► **kinase**, ► **protein kinases**

PH: Pleckstrin homology domain. ► **pleckstrin**

pH: = $-\log(\text{H}_3\text{O}^+)$, negative logarithm of the hydrogen ion concentration; pure water at 25°C contains 10^{-7} mole hydrogen ions; solutions of acids could contain 1 mole and solution of bases 10^{-13} moles per liter.

The pH meters measure the electrical property of solutions which is proportional to pH; pH 7 is neutral and below it is acidic above it is alkaline (basic) (see Fig. P52). The pH of body fluids and tissues is regulated by the function of the ion channels.

The pH of plant tissues is generally below 7 because of the presence of organic acids and the majority of plant tissues can be cultured best in media around pH 6. Most animal tissues display neutral pH (~7). In the human blood, the pH is normally within the narrow range of 7.3 to 7.5. If the blood pH approaches 7, acidosis may result causing coma and at about pH 7.8 alkalosis may cause tetany

Figure P52. pH scale

(dangerous spasms) but the stomach secretions may be pH 0.9. The pH optima of enzymes vary a great deal but most commonly, it is in the range of 6 to 9. The preferred pH of microbes is also variable; the euryarchaeon bacterium, *Picrophilus torridus* thrives well at pH 0.7 and 60°C. (Fütterer O et al 2004 Proc Natl Acad Sci USA 101:9091). ▶ion channels, ▶buffer

Ph1 Chromosome: ▶Philadelphia chromosome

PhGene (pairing high): An approximately 700 Mb sequence that controls selective pairing in hexaploid wheat. In its presence, homoeologous chromosomes do not pair. It is in chromosome 5B. Plants nullisomic for this chromosome display multivalent associations in meiosis. A similar gene *Ph2* is in chromosome 3D. A *Ph* gene is present also in the A genome. Additional less powerful genes regulate chromosome pairing also. The *Ph* gene is absent from the genome of diploids but it is present in the B and G genomes in tetraploids. This observation indicates that *Ph* originated after polyploidization. ▶Triticum, ▶homoeologous, ▶nullisomic; Sears ER 1969 Annu Rev Genet 3:451; Martinez-Perez E 2001 Nature 411:204; Griffith S et al 2006 Nature [Lond] 439:749; Dvorak J et al 2006 Genetics 174:17.

PHA (phytohemagglutinin): A lectin of bean (*Phaseolus vulgaris*) plants; agglutinates erythrocytes and activates T lymphocytes. ▶lectins, ▶agglutination, ▶erythrocyte, ▶lymphocytes

Phaeochromocytoma (pheochromocytoma): A bladder-kidney carcinoma, over-producing adrenaline and noradrenaline. The disease may be caused by mutation in the von Hippel-Lindau gene or the neurofibromatosis 1 or the RET protooncogenes or by the multiple endocrine neoplasia gene MEN2. Mutations in the subunits of mitochondrial succinate dehydrogenase in the long arm of human chromosome 11 also may be involved. ▶animal hormones, ▶von Hippel-Lindau syndrome, ▶neurofibromatosis, ▶MEN, ▶RET, ▶succinate dehydrogenase; Astuti D et al 2001 Am Hum Genet 69:49; Maher ER, Eng C 2002 Hum Mol Genet 11:2347.

Phaeomelanin: A mammalian pigment. ▶pigmentation of animals

Phage (bacteriophage): A virus of bacteria. ▶bacteriophages, ▶development, ▶phage life cycle

Phage Conversion: The acquisition of new properties by the bacterial cell after infection by a temperate phage. ▶temperate phage

Phage Cross: ▶rounds of matings

Phage Display: Filamentous bacteriophages (M13, fd) have a few copies (3–5) of protein III gene at the end of the particles (see Fig. P53). This protein controls phage assembly and adsorption to the bacterial pilus. When short DNA sequences are inserted into gene III (g3p), the protein encoded may be displayed on the surface of the particles. In case variable region fragments of antibody genes are inserted into the protein III coding sequences, specific antigens may be screened. The peptides can be separated with antibody affinity chromatography (panning). By repeated screening enormous arrays of recombinant libraries become available. The g3p product and the Fvs (fragments of variability) can be separated proteolytically or by inserting a stop codon between g3p and Fv. By the insertion of a large array of nucleotide sequences, a huge combinatorial library of soluble epitopes may be generated. The specificity of the antibodies can be further manipulated by mutation (random or targeted), by error-prone polymerase chain reactions, recombination, by chain shuffling, i.e., trying out various light and heavy chain combinations, synthetic CDR sequences, etc. Similarly, a variety of different antigens may be displayed on the surface of protein III and can be used to screen for cognate antibody. Phage display may be of applied significance for the pharmaceutical industry because extremely large number of variants (up to 10^8 to 10^{10}) of monoclonal antibodies can be selectively isolated and tested. For in vitro testing the two-hybrid method may be employed. The protein-protein interaction may then be studied in mammalian cells and screening techniques can be developed to isolate the cells that can neutralize the cytotoxic virus. The use of phagemid vectors may enhance the efficiency of the procedure. This procedure may facilitate the isolation of novel receptors, ligands, antibodies, anti-cancer reagents, transport proteins, signal transduction molecules, transcription factors, etc. Phage display technique may substitute for the construction of hybridomas (see Fig. P54). It can be used also for typing blood, for various diagnostic procedures, etc. A T7 phage display system permits the selection of RNA-binding regulatory proteins.

By screening large phage libraries for select tissue-specific organ antibodies, luminal endothelial cell

Figure P53. Protein III recognition

Figure P54. Phage display. (Note that the filamentous phage is represented as 'globular' only for the convenience of drawing).

plasma membranes were enriched from the bloodstream. The phage-displayed antibodies were converted Fv-Fc fusion proteins and monitored target selection by whole-body γ -scintigraphic imaging. Mass spectrometry identified the antigen targets. The procedure permits monitoring the vascular route of specific substances (Valadon P et al 2006 Proc Natl Acad Sci USA 103:407). ▶filamentous phages, ▶affinity chromatography, ▶epitope screening, ▶combinatorial library, ▶pilus, ▶antibody engineering, ▶CDR, ▶monoclonal antibody, ▶mRNA display, ▶two-hybrid method, ▶monoclonal antibody, ▶hybridoma, ▶phagemid, ▶anchored periplasmic expression; Smith GP, Petrenko VA 1997 Chem Rev 97:391; Danner S, Belasco JG 2001 Proc Natl Acad Sci USA 98:12954; Arap W et al 2002 Nature Med 8:121.

Phage Ghost: The empty protein shell of the virus.

Phage Immunity: A lysogenic bacterium carrying a prophage cannot be infected by another phage of the same type. ▶prophage, ▶zygotic induction

Phage Induction: Stimulates the prophage to leave a site in the bacterial chromosome and become vegetative. Physical and chemical agents may be inductive (UV light, mutagens, zygotic induction).

Phage Lifecycle: See Fig. P55, Böhm J et al 2001 Curr Biol 11:1168.

Figure P55. Phage lifecycle. (Redrawn after the illustration provided by Drs. Simon LD, Anderson TF Institute of Cancer Research, Philadelphia, PA, USA)

Phage Morphogenesis: ▶one-step growth, ▶development, ▶phage life cycle

Phage Mosaic: May be generated by phage display, expressing different molecular structures on the surface of a filamentous phage. ▶phage display

Phage Therapy: The bacteriophages are bacteria-eating systems. D'Hérelle, the discoverer of phages, already attempted their therapeutic use in poultry as well as for humans with considerable success. With the discovery of antibiotics, the interest in phage therapy ebbed. Another cause for the decline of interest was the discovery of phage resistance in bacteria.

Also, bacteria encode restriction/modification systems of defense. The human body may also react immunologically against the phages. Recent studies, despite some technical problems indicate feasibility of this type of therapy. (See Summers WC 2001 Annu Rev Microbiol 55:437; Schuch B et al 2002 Nature [Lond] 418:884).

Phagemids: Genetic vectors that generally contain the ColE1 origin of replication and one or more selectable markers from a plasmid and a major intergenic copy of a filamentous phage (M13, fd1). When cells carrying such a combination are superinfected by a filamentous phage, it triggers a rolling

circle type replication of the vector DNA. This single-stranded product is used then for sequencing by the Sanger type DNA sequencing system, for oligonucleotide-directed mutagenesis and as strand-specific probes. The phagemids can carry up to 10 kb passenger DNA. Their replication is fast (in the presence of a helper), and they can produce up to 10^{11} plaque-forming units (pfu)/mL bacterial culture. Their stability is comparable to conventional plasmids. They obviate subcloning the DNA fragments from plasmid to filamentous phage. The most widely used phagemids contain parts of phage M13 and pUC, π VX^c, and pBR322 vectors. ▶**phasmid**, ▶**vectors**, ▶**plasmovirus**, ▶**vectors**, ▶**pfu**, ▶**pUC**, ▶**DNA sequencing**; Sambrook J et al 1989 Molecular Cloning, Cold Spring Harbor Laboratory Press, Cold Spring Harbor, New York; O'Connell D et al 2002 J Mol Biol 321:49.

Phagocytosis: A special cell (phagocyte) engulfs a foreign particle (microorganism, cell debris) and eventually exposes it to lysosomal enzymes for the purpose of destroying it. Dendritic cells and macrophages have important roles. In lower animals, this mechanism substitutes for the immune system. Phagocytosis pathway is controlled by a battery of *Ced* genes (and homologs, e.g., Dock180 in humans) during apoptosis. The CD14 human glycoprotein on the surface of macrophages recognizes and clears apoptotic cells (see Fig. P56). The major phagocyte receptors are CR3 (binds opsonized C3b complement fraction) and the Fc gamma receptor, FcγR (binds immunoglobulin G). Both processes require the reorganization of the cytoskeleton under the control of RAC or RHO G proteins, respectively. ▶**pinocytosis**, ▶**apoptosis**, ▶**macrophage**, ▶**complement**, ▶**antibody**, ▶**opsonins**, ▶**RAC**, ▶**RHO**, ▶**lysosomes**, ▶**cross presentation**, ▶**cell fusion**; Underhill DM, Ozinsky A 2002 Annu Rev Immunol 20:825; Stuart LM, Ezekowitz RAB 2005 Immunity 22:539.

Figure P56. Phagocytosis

Phagosome: A body (vesicle) surrounded by plasma membrane of a phagocyte. They are fused with endosomes and lysosomal compartments to become

degradative organelles (Touret N et al 2005 Cell 123:157). In *Drosophila* phagosomes 617 interactive proteins have been detected that are involved in immune reactions (Stuart LM et al 2007 Nature [Lond] 445:95). ▶**phagocytosis**, ▶**endocytosis**, ▶**endosome**, ▶**lysosomes**, ▶**macrophage**

Phakomatoses (neurocutane syndromes): Hereditary and congenital diseases, which are of ectodermal origin and display spots on the body, such as neurofibromatosis, epiloia/tuberous sclerosis, FAP, von Hippel-Lindau syndrome, nevoid basal cell carcinoma, Cowden disease, Peutz-Jeghers syndrome, polyposis. (See separate entries; Tucker M et al 2000 J Natl Cancer Inst 92:530).

Phalange(s): The three bones in fingers and toes (at left) with the metacarpal bone (at right) (see Fig. P57).

Figure P57. Phalange

Phalloidin: An amanotoxin, similar to, but faster in action than amanitin. When labeled with fluorescent coumarin phenyl isothiocyanate it is suitable to identify filamentous actin in the cells. It is extremely toxic. ▶**amatoxins**, ▶**α-amanitin**; Vetter J 1998 Toxicon 36:13.

Phallus: The penis, a symbol of generative power, also the fetal anlage of the penis and clitoris. ▶**penis**, ▶**clitoris**, ▶**anlage**

Phantom Mutation: Artifacts of the DNA sequencing. They can be filtered out by statistical procedures. (Bandelt, H-J et al 2002 Am J Hum Genet 71:1150).

Pharate: The larva/adult emerging from the puparium.

Pharmaceuticals: The chemical agents used for medical purposes. Data collected on 352 marketed drugs (excluding anti-cancer agents, nucleosides, steroids and peptide-based formulations, which are known to affect DNA); 101 (28.7%) had at least one positive indication for genotoxicity. Four types of tests were used: bacterial mutagenesis, in vitro cytogenetics, in vivo cytogenetics and mouse lymphoma assay. One must keep in mind that carcinogenicity may involve routes that are not testable by these methods. Also, the laboratory assays are not 100% reliable. ▶**genotoxic chemicals**, ▶**combinatorial chemistry**, ▶**bioassays in genetic toxicology**; Snyder RD, Green JW 2001 Mutat Res 488:151.

Pharmacogenetics: The study of the reaction of individuals of different genetic constitution to various drugs and medicines. Most of the differences are monogenic. Polymorphic genes frequently determine drug metabolism, drug transporters and drug responses of the body. Pharmacogenetics studies also study simultaneous drug responses by many genes. Based on these responses drugs with special, selective effect can be developed. Certain drugs have special side effects for individuals of particular genetic constitution ►cytochromes, ►SADR; Roses AD 2001 Hum Mol Genet 10:2261; Kuehl P et al 2001 Nature Genet 27:383; Roses AD 2002 Nature Rev Drug Discov 1:541; Goldstein DB et al 2003 Nature Rev Genet 4:937; Evans WE, Relling MV 2004 Nature [Lond] 429:464; problems and goals in pharmacogenetics/genomics: Need AC et al 2005 Nature Genet 37:671; variation in human genes and drug responses: <http://www.PharmGKB.org>; key therapeutic targets in proteins and nucleic acids: <http://xin.cz3.nus.edu.sg/group/ttd/ttd.asp>; pharmacogenetic substances [proteins, drugs]: <http://bidd.cz3.nus.edu.sg/phg/>.

Pharmacogenomics: The study of drug response of the entire genome of an organism. ►pharmacogenetics, ►SADR

Pharmacokinetics (pharmacodynamics): The study of absorption, tissue distribution, metabolism, and elimination (ADAME) as a function of time of biologically relevant molecules.

Pharmacoproteomics: The study of the proteins in sera or urine as a consequence of disease and/or drug therapy.

Pharmacodynamics: ►pharmacokinetics

Pharming: The production of pharmacologically useful compounds by transgenic organisms. ►transgenic, ►biopharming, ►molecular breeding, ►plantibody

PHAS-1: A heat stable protein ($M_r \approx 12,400$); when it is not phosphorylated it binds to peptide initiation factor eIF-4E and inhibits protein synthesis. Its Ser⁶⁴ site is readily phosphorylated by MAP and then no longer binds to eIF-4E and protein synthesis may be stimulated. ►eIF-4E, ►MAP

Phase Diagram: A graphic representation of the equilibrium between/among components of a system. The phase is an identifiable part of a system. Phase diagrams are used in several scientific fields for the elucidation of the behavior of the phases of the components under dynamic conditions. In biology, phase diagrams can shed light on the mechanisms of interaction within a system, e.g., in a genetic network. Figure P58 represents three hypothetical internal (metabolic) components of the cell and two external

factors (e.g., temperature and light) that determine in an interactive manner the node (red dot). ►networks, ►genetic networks; Park J, Barabási A-L 2007 Proc Natl Acad Sci 104:17916.

Figure P58. Phase diagram

Phase Variation: A programmed rearrangement in several genetic systems. The flagellin genes of the bacterium *Salmonella* display it at frequencies of 10^{-5} to 10^{-3} . The flagellar protein has two forms, H1 and H2. The *H1* gene is a passive element. When *H2* is expressed no H1 protein is made. When *H2* is switched off the H1 antigen is made. The expression of *H2* is regulated by the expression of the *rhI* repressor (repressing the synthesis of the H1 protein) and the promoter of *H2*. This promoter is about 100 bp upstream from the gene and it is liable to inversion, and then *H2* and *rhI* are turned off. Such an event then switches on the synthesis of H1 protein. Reversing the inversion flip switches back to H2. The *Hin* recombinase that is very similar to the invertases or recombinases of phage Mu or *Cin* from phage P1 catalyze the inversions. They can functionally substitute for each other. *Hin* binds to the *hixL* and *hixR* recombination sites. Additional genes are also involved in the fine-tuning. Defect in type III methyltransferase in restriction modification systems can cause phase variation of different genes in several bacterial species (Srihanta YN et al 2005 Proc Natl Acad Sci USA 102:5547).

Somewhat similar mechanisms control the host-specificity genes of phage Mu and the mating type of budding yeast. ►cassette model, ►regulation of gene activity, ►antigenic variation, ►mating type determination in yeasts, ►Trypanosoma, ►flagellin, ►DNA uptake sequences, ►SSR; Hughes KT et al 1988 Genes Dev 2:937; Snyder LA et al 2001 Microbiology 147:2321.

Phase-Contrast Microscope: It alters the phase of light passing through and around the objects and this permits its visualization without fixation and/or

staining. ►Nomarski, ►fluorescence microscopy, ►microscopy light, ►confocal microscopy, ►electron microscopy

Phaseolin ($C_{20}H_{18}O_4$): An antifungal globulin in bean (*Phaseolus*).

Phasing Codon: Initiates translation (such as AUG) and determines the reading frame. ►genetic code, ►reading frame

Phasmid (phage-plasmid): A plasmid vector equipped with the *att* site of the lambda phage and thus, enables the plasmid to participate in site-specific recombination with the λ genome resulting in incorporation of plasmid sequences into the phage (*lifting*). Because it contains both λ and plasmid origins of replication it may be replicated either as a plasmid or as λ . ►lambda phage, ►phagemid, ►vectors; Briani F et al 2001 Plasmid 45:1.

Phenacetin ($C_{10}H_{13}NO_2$): An analgesic and antipyretic drug and a carcinogen.

Phene: An observable trait that may or may not have direct genetic determination. ►gene

Phenetics: The taxonomic classification based on phenotypes.

Phenocopy: The phenotypic change that mimics the expression of a mutation. ►phenotype, ►epigenetic, ►epimutation, ►morphosis, ►genocopy

Phenodeviate: An individual of unknown genetic constitution displaying a phenotype attributed to various genic combinations within the population.

Phenogenetics: The attempts to correlate the function of genes with phenotypes.

Phenogram: ►character matrix

Phenolics: Compounds containing a phenol ring such as acetosyringone, hydroxyacetosyringone, chalcone derivatives, phenylpropanoids, and some phytoalexins. The mentioned compounds may excite or suppress the *vir* gene cascade of *Agrobacterium* and may affect the response to plant pathogenic agents. Capsaicin, ginger, resveratrol may be anticarcinogens due to their antioxidative properties and may promote apoptosis. Phenylpropenes such as chavicol, *t*-anol, eugenol and isoeugenol repel animals and micro-organism but may attract some pollinators (see Fig. P59). Humans use these compounds as spices, food preservatives and medicine. Coniferyl acetate and NADPH may form as a precursor for enzymatic synthesis of eugenols (Koeduka T et al 2006 Proc Natl Acad Sci USA 103:10128). ►*Agrobacterium*, ►virulence genes of *Agrobacterium*, ►phytoalexins, ►chalcones, ►acetosyringone, ►resveratrol,

►ginger, ►capsaicin, ►apoptosis, ►wound response; Nicholson RL, Hammerschmidt RE 1992 Annu Rev Plant Path 30:369.

Figure P59. Phenylpropene backbone

Phenology: The study of the effects of the environment on live organisms.

Phenome: The collection of phenotypes; a group of organisms with shared phenotypes. (See Freimer N, Sabatti C 2003 Nature Genet 34:15; ►SNIPs; <http://www.jax.org/phenome>; <http://www.phenomicdb.de>.)

Phenome Analysis: The attempts to determine the expression of genes at the RNA and protein level under different conditions, involving the environment and/or the prevailing genetic system (network). This may be an extremely difficult undertaking because gene expression may vary from complete silence to very variable and great complexity. ►phenotype, ►phenotype MicroArray; Bochner BR 2003 Nature Rev Genet 4:309.

Phenomenology: The description of facts as observed without metaphysical interpretation. The concept that behavior depends on how a person interprets reality rather than what is the objective reality.

Phenoptosis: An apoptosis-like phenomenon in unicellular organisms. ►apoptosis

Phenotype: The appearance of an organism that may or may not represent the genetic constitution. The proteins encoded by the DNA (the genotype) represent the phenotype. The 1014 human (disease) genes displayed 1429 distinguishable phenotypes (~141%). Microarray hybridization data can provide most comprehensive information on phenotype. In budding yeast, similar morphology indicates functional similarity of the coding genes. Triple-stained mutants facilitate the analysis of the morphology as a quantitative trait and can attribute function to many genes with previously unknown function (Ohya Y et al 2005 Proc Natl Acad Sci USA 102:19015). Mutation in the DNA is largely responsible for altered phenotypes. Alterations in transcription and translation also affect the phenotype and generally, as shown, there are more phenotypes than the number of

genes (Bürger R et al 2006 Genetics 172:197). ► [gene ontology](#), ► [microarray hybridization](#), ► [cell comparisons](#), ► [endophenotype](#); Phenomic Data Base facilitates the identification of genes involved in a phenotype or gives the phenotype caused by genes in major organisms: <http://www.phenomicDB.de>; muse phenotypes and relevance to human disease: <http://www.eumorphia.org/>

Phenotype MicroArrays: An automated analysis of phenotypic expression of hundreds of genes on microplates and can be used to monitor the consequences of knockouts or other genetic alterations. ► [microarray hybridization](#), ► [knockout](#); Bochner BR et al 2001 Genome Res 11:1246.

Phenotypic Assortment: ► [macronucleus](#)

Phenotypic Knockout: It means somatic gene therapy that neutralizes intracellular harmful mechanisms. ► [gene therapy](#), ► [knockout](#)

Phenotypic Lag: A period of time may be required for gene expression after transformation or mutagenic treatment. ► [transformation genetic](#), ► [premutation](#); Ryan FJ 1955 Am Nat 89:159.

Phenotypic Mixing: The mixed assembly of viral nucleic acids and proteins upon simultaneous infections by different types of viruses. Therefore, the coat protein properties of the virions do not match the viral genotype by serological or other tests. (See Hayes W 1965 The genetics of bacteria and their viruses. Wiley, New York).

Phenotypic Plasticity: An adaptive property of an organism enabling it to take advantage of local conditions without evolving a particular function and at the expense of another function. ► [homeostasis genetic](#), ► [canalization](#), ► [plasticity](#)

Phenotypic Reversion: An apparent restoration of the normal expression of a mutant gene; it is not, however, inherited. Aminoglycoside antibiotics (paromomycin, geneticin, etc.) may successfully compete with the translation termination factors in eukaryotes in cases when the mRNA carries a stop codon mutation. As a result, some of the polypeptide chains are not terminated/truncated but completed in the presence of the drug. Transposable elements may also alter gene function without causing mutation in the gene. Phenotypic reversion may be exploited for correcting the genetic defects in some diseases. ► [phenocopy](#), ► [amino-glycosides](#), ► [G418](#), ► [paromomycin](#), ► [suppressor tRNA](#), ► [translation termination](#); Gause M et al 1996 Mol Gen Genet 253:370; Franzoni MG, De Castro-Prado MA 2000 Biol Res 33:11; Biedler JL et al 1975 J Natl Cancer Inst 55:671.

Phenotypic Sex: It may not reflect the expectation based on the sex-chromosomal constitution. ► [testicular feminization](#), ► [hermaphrodite](#)

Phenotypic Stability Factor: A measure of developmental homeostasis; it is calculated by the ratios of the quantitative expression of a parameter (gene) under two different environmental conditions. ► [homeostasis](#), ► [logarithmic stability factor](#); Lewis D 1954 Heredity 8:334.

Phenotypic Suppression: An apparently normal but non-hereditary phenotype brought about by translational error due to environmental effects and/or drugs. ► [error in translation](#)

Phenotypic Switch: Alters phenotypes more frequently than expected by point mutation and may be caused by epigenetic methylation or by protein folding. (See Lim HN, van Oudenaarden A 2007 Nature Genet 39:269).

Phenotypic Value: In quantitative genetics, it is defined as the mean value of a population regarding the trait under study and it is generally represented as P value. ► [breeding value](#)

Phenotypic Variance: ► [genetic variance](#)

Phenylalanine (C₉H₁₁NO₂): An essential water-soluble, aromatic amino acid (MW 165.19). Its biosynthetic path (*with enzymes involved in parenthesis*): Chorismate → (*chorismate mutase*) → Prephenate → (*prephenate dihydratase*) → Phenylpyruvate → (*aminotransferase*, glutamate NH₃ donor) → Phenylalanine. ► [chorismate](#), ► [tyrosine](#), ► [phenylketonuria](#)

Phenylalanine Ammonia Lyase (PAL): PAL deaminates phenylalanine into cinnamic acid and it is thus involved in the synthesis of plant phenolics. ► [phenolics](#)

Phenylalanine Hydroxylase (PAH, 12q24.1): The deficiency of PAH leads to phenylketonuria.

Phenylhydrazine (C₆H₉ClN₂): A hemolytic compound but it is also used as a reagent for sugars, aldehydes, ketones and a number of industrial purposes (stabilizing explosives, dyes, etc.). ► [hemolysis](#)

Phenylketonuria (PKU, PAH, Fölling disease): This gene was located to human chromosome 12q24.1. It is a recessive disorder that has a prevalence of about 1×10^{-4} (carrier frequency is about 0.02) in white populations. Thus, an affected person has about 0.01 chance to have an affected child in case of a random mate but the recurrence rate in a family where one of the partners is affected and the other is a carrier it is nearly 0.5 (see Fig. P60).

Figure P60. Mentally retarded heterozygous children of a phenylketonuric mother (indirect epistasis). Courtesy of Dr. C. Charlton Mabry 1963; by permission of the New England Journal of Medicine 269:1404

Its incidence is substantially lower among Asian and black people (one-third of that in whites). PKU is more frequent in European populations of Celtic origin than in the other Europeans. This has been interpreted as the result of natural selection because PKU heterozygosity conveys some tolerance to the mycotoxin, ochratoxin A, produced by *Aspergillus* and *Penicillium* fungi, common in humid northern regions. Before the nature of this disorder and the method of treatment were identified, about 0.5 to 1% of the patients in mental asylums were afflicted by PKU. A deficiency of the enzyme phenylalanine hydroxylase and consequently the accumulation of phenyl pyruvic acid and a deficiency of tyrosine cause the disease:

For the identification of the condition the Guthrie test has been used to cultures of *Bacillus subtilis* containing blood of the patients, β -2-thienylalanine was added. This phenylalanine analog is a competitive inhibitor of tyrosine synthesis. In the presence of excess amounts of phenylalanine, the bacterial growth does not stop. Since in the different families the genetically determined defect in the enzyme varies, so does the severity of the clinical symptoms. The accumulation of phenyl pyruvic acid is apparently responsible for the mental retardation and the musty odor of the urine of the patients.

The reduced amount of tyrosine prevents normal pigmentation (melanin) and thus results in pale color. The good aspect of this condition is that relative normalcy can be established if it is diagnosed early and dietary restrictions for phenylalanine are implemented. The restriction of phenylalanine must

start as early as possible (before birth if feasible), and continue at least until age 10. Restriction should be observed before pregnancy, during pregnancy and during breast-feeding or during the entire life to avoid harm to the nervous system. Phenylketonuria of the mother may damage the nervous system of genetically normal fetus through placental transfer (indirect epistasis). Because of the multiple metabolic pathways involving phenylpyruvic acid, besides the deficiency of phenylalanine hydroxylase, other genes and conditions may cause similar clinical symptoms. Phenylalanine hydroxylase activity requires the availability of the reduced form of the co-factor 5,6,7,8-tetrahydrobiopterin that is made by the enzyme *dihydrobiopterin reductase* from 7,8-dihydrobiopterin. The dihydrobiopterin reductase enzyme is coded in human chromosome 4p15.1-p16.1. Defect in this enzyme also causes phenylketonuria symptoms but lowering the level phenylalanine in the diet does not alleviate the problems. Another form of phenylketonuria is based on a deficiency in dihydrobiopterin synthesis. Using the ϕ BT1 integrating phage vector (containing a site-specific recombinase), equipped with the murine phenylalanine hydroxylase cDNA, PKU could be completely and persistently cured after three injections to the mouse liver (Chen L, Woo SLC et al 2005 Proc Natl Acad Sci USA 102:15581).

Prenatal diagnosis can be carried out by several methods. Mutations at various related metabolic sites in the mouse may serve as a model for studying phenylketonuria. ►epistasis, ►mental retardation, ►one gene-one-enzyme theorem, ►genetic screening, ►Guthrie test, ►tyrosinemia, ►alkaptonuria, ►phenylalanine, ►hyperphenylalaninemia, ►amino acid metabolism, ►prenatal diagnosis, ►enzyme replacement therapy, ►integrase, ►targeting genes; Ledley FD et al 1986 N Engl J Med 314:1276; Gjetting T et al 2001 Am J Hum Genet 68:1353.

Phenylpropanoid: ►phenolics, ►phytoalexins

Phenylthiocarbamide Tasting (PTC): A major incompletely dominant gene appears to be in human chromosome 7q35-q36 (Conneally PM et al 1976 Hum Hered 26(4):276). A major bitter testing locus is assigned to human chromosome 5p15 (Reed DR et al 1999 Am J Hum Genet 64:1478). The TAS2R10 PTC receptor appears to be in the short arm of chromosome 12. A single G protein coupled receptor with allelic variants may account for the taste perception (Bufo B et al 2005 Curr Biol 15:322). In humans and chimpanzees, two alleles at the TAS2R38 locus control bitter tasting but the human and chimpanzee alleles are different (Wooding S et al. 2006 Nature [Lond] 440:930). About 30% of North-American Whites and about 8–10% of Blacks cannot taste the

bitterness of this compound. Persons affected by thyroid-deficiency (athyreotic) cretinism (mental deficiency) are non-tasters. Phenylthiocarbamide (syn. phenylthiourea) has been used for classroom demonstration of human diversity but it should be kept in mind that it is a toxic compound (LD₅₀ oral dose for rats 3 mg/kg and for mice 10 mg/kg). ►taste, ►LD₅₀; Guo SW, Reed DR 2001 Ann Hum Biol 28(2):111; Kim U-K et al 2003 Science 299:1221.

Phenylthiourea: ►phenylthiocarbamide tasting (see Fig. P61).

Figure P61. Phenylthiourea

Pheochromocytoma (phaeochromocytoma): An adrenal tumor induced by the SHC oncogene. ►paraganglion, ►SHC, ►adenomatosis endocrine multiple, ►endocrine neoplasian neuroendocrine cancer

Pheresis (apheresis): The medical procedure of withdrawal of blood; after fractionation, some fraction(s) are reintroduced. Such a protocol may use stem cells, transfect them with a vector or apply to them chemotherapy, and eventually place them back in the body of the same individual.

Pheromones: Various chemical substances secreted by animals and cells for the purpose of signaling and generating certain responses by members of the species, such as sex-attractants, stimulants, territorial markers, or other behavioral signals and cues. The male pheromone of Asian elephants, frontalin (exists in two enantiomorphs) is secreted during musth (annual period of increased sexual activity and aggression) by the temporal gland on the face. The proportion of the two forms and the extent of secretion of frontalin are sensed primarily by the ovulating females (Greenwood DR et al 2005 Nature [Lond] 438:1097). About 100 genes control the pheromones and their receptors in rodents and the signals are transmitted through G protein-associated signal transduction pathways. The mouse sex pheromones in the male urine includes several compounds, among them the strongest response is evoked by (methylthio) methanethiol for females. Apparently, only a small number of cells at the olfactory bulb responded to this compound, which for humans had a garlic-like odor (Lin DY et al 2005 Nature [Lond]

434:470). The lacrimal glands of adult male mice secrete a 7 kDa peptide to which the vomeronasal receptors of the sensory neurons of the female animals respond (Kimoto H et al. 2005 Nature [Lond] 437:898). The role of pheromones in humans may not be generally agreed upon. The steroid compounds 4,16-androstadien-3-one (AND) present in the sweat of human males and estra-1,3,5(10)-tetraen-3-ol (EST) present in the female urine appear to have pheromone-like properties. Their smelling causes sex-differentiated activation of the anterior hypothalamus of the brain. Male homosexuals respond to AND but not to EST in contrast to heterosexuals (Savic I et al 2005 Proc Natl Acad Sci USA 102:7356). Heterosexual men were found to respond to AND; lesbian women processed AND (unlike heterosexual women), not by the anterior pituitary but by the olfactory network (Berglund H et al 2006 Proc Natl Acad Sci USA 103:8269).

The pheromone receptor genes in rodents include *V1r* and *V2r*; apparently there are no human homologs. The sexually deceptive orchid plant *Chiloglottis* attracts the *Neozeleboria* insect pollinator males by secreting a volatile compound (2-ethyl-5-propylcyclohexan-1,3-dione), which is chemically identical with the insect female sex pheromone (Schiestl FP et al 2003 Science 302:437). RNA interference technique revealed that in silkworm, for sex pheromone production pheromone activating neuropeptide receptor (*PBANR*), pheromone gland-specific (PG) fatty acyl reductase (*pgFAR*), PGZ11/ Δ 10,12 desaturase (*Bmpgdesat1*), PG acyl CoA-binding protein (*pgACBP*) genes are essential (Ohnishi A et al 2006 Proc Natl Acad Sci USA 103:4398). In *Drosophila*, the male-specific pheromone 1-*cis*-vaccenyl acetate (cVA) acts through olfactory receptor Or67d. The *fruitless* (*fru*) gene controls three classes of olfactory receptors, one of which is Or67d. This single receptor controls both male and female mating behavior. Mutant males display homosexual tendencies whereas mutant females are less receptive to courting indicating that cVA has opposite effects for the two sexes, i.e., inhibiting males' mating behavior but stimulating that in females (Kurtovic A et al 2007 Nature [Lond] 446:542). Male flies show less interest in females, which have mated before, apparently by sensing cVA (Ejima A et al 2007 Curr Biol 17:599). The trichoid sensilla on the antennae has three olfactory receptors; receptor T1 responds primarily to male odor in the cuticular extracts whereas to the odor of virgin females receptors T2 and T3 respond (van der Goes van Naters W, Carlson JR 2007 Curr Biol 17:606). In male *Drosophila*, the synthesis of octopamine (a norepinephrine related substance) mediates aggressive behavior toward other males. In flies defective

for tyramine β -hydroxylase (the enzyme that converts octopamine from its precursor), courtship is observed (Cartel SJ et al 2007 Proc Natl Acad Sci USA 104:4706). Pheromone hydrocarbon chains are longer in females than in males. The transformer gene (*tra*) feminizes males and makes them produce longer (female type) hydrocarbon pheromones (Chertemps T et al 2007 Proc Natl Acad Sci USA 104:4273). ▶mating type determination in yeast, ▶sex determination, ▶*fru*, ▶olfactogenetics, ▶vomeronasal organ, ▶signal transduction, ▶homosexual, ▶RNAi, ▶silkworm, ▶kairomones, ▶mimicry, ▶Bruce effect; Kohl JV et al 2001 Neuroendocrinol Lett 22(5):309; Luo M et al 2003 Science 299:1196; Prestwich GD, Blomquist GJ 1987 Pheromone Biochemistry, Academic Press, Orlando, Florida; Wang Y, Dohlman HG 2004 Science 306:1508; Dulac C, Torello AT 2003 Nature Rev Neurosci 4:531; mini-review: Stowers L, Marton TF 2005 Neuron 46:699; review of vertebrate pheromone communication: Brennanm PA, Zufall F 2006 Nature [Lond] 444:308; pheromone signaling circuits: Dulac C, Wagner S 2006 Annu Rev Genet 40:449; insect pheromones: <http://www.pherobase.com>.

Phialide: Fungal stem cells from which conidia are budded.

Philadelphia Chromosome: In the Philadelphia chromosome, the long arm (q34) of human chromosome 9, carrying the *c-abl* oncogene is translocated to the long arm (q11) of chromosome 22 carrying site *bcr* (breakpoint cluster region). The *bcr-abl* gene fusion is then responsible for 85% of myelogenous (Abelson) and acute leukemia as a consequence of the translocation and fusion. In the acute form, a 7.5 kb mRNA is translated into protein p190, and in the myelogenous form an 8.5 kb mRNA is translated into a chimeric protein p210. The fusion protein is a deregulated tyrosine kinase acting on hematopoietic cells and causes leukemia-like oncogenic transformation in mice. Synthetic antisense phosphorothioate oligonucleotides ([S]ODN) complementary to the 2nd exon of BCR or to the 3rd exon of the ABL of the fused genes block temporarily the proliferation of the chronic leukemic cells, without harming the normal cells, in a mouse model. The outcome of such a therapy could be improved by simultaneously targeting also the *c-Myc* oncogene with an antisense construct. Further effectiveness was observed by exposing the cells to a low concentration of mafosfamide, an antineoplastic drug that promotes apoptosis, or to cyclophosphamide. ▶ABL, ▶BCR, ▶leukemia, ▶hematopoiesis, ▶cancer gene therapy, ▶apoptosis, ▶cyclophosphamide, ▶antisense technologies, ▶transresponder, ▶Knudson's two mutation theory; Saglio G et al

2002 Proc Natl Acad Sci USA 99:9882; Goldman JM et al 2003 N Engl J Med 349:1451.

Phlebotomous: A blood-sucking (insect), or phlebotomy bloodletting surgical procedure.

Phloem: A plant tissue involved in the transport of nutrients; it contains sieve tubes and companion cells, phloem parenchyma, and fibers. ▶sieve tube, ▶parenchyma, ▶xylem, ▶root, ▶proteoglycan; Bonke M et al 2003 Nature [Lond] 426:181.

Phlorizin: A dihalcone in the bark of trees (*Rosaceae*); it blocks the reabsorption of glucose by the tubules of the kidney and causes glucosuria. ▶disaccharide intolerance, ▶chalcones

PHO81: A yeast CDK inhibitor homologous to p16^{INK4}. ▶CDK, ▶p16^{INK4}

PHO85: A cyclin-dependent kinase of *Saccharomyces cerevisiae*. ▶CDK, ▶KIN28, ▶CDC28, ▶PHO81

phoA: A gene for alkaline phosphatase.

Phobias: Phobias exist in different forms, all characterized by unreasonable avoidance of objects, events, or people. A phobia may amount to serious, morbid mental illness. Apparently, duplication in human chromosome 15q24-q26 is associated with one form and also with laxity of the joints. ▶panic disorder, ▶panic obsessive disorder, ▶anxiety; Gratacós M et al 2001 Cell 106:367.

Phocomelia: The absence of some bones of the limbs proximal to the trunk. It may occur as a teratological effect of various recessive and dominant human genetic defects or as a consequence of teratogenic drugs, e.g., thalidomide use during human or primate pregnancy. ▶limb defects in humans, ▶Roberts syndrome, ▶thalidomide

PHOGE (pulsed homogeneous orthogonal field electrophoresis): A type of pulsed field gel electrophoresis, within the range of 50 kb to 1 Mb DNA, permitting straight tracks of large number of samples. ▶pulsed field gel electrophoresis

PhoQ: *Salmonella* kinase, affecting regulator of virulence PhoP. ▶virulence, ▶*Salmonella*

PhoR: Phosphate assimilation regulated by PhoR kinase upon phosphorylation of regulator PhoB.

Phorbol Esters: Facilitators of tumorous growth that work by activating protein kinase C. ▶TPA, ▶protein kinases, ▶procarcinogen, ▶carcinogen, ▶PMA, see formula at ▶PMA

Phorbol 12-Myristate-13-Acetate (PMA): ▶phorbol esters, ▶PMA (see Fig. P62).

Figure P62. Myristoylphorbol acetate (ester)

Phosphatases: In animals, both acid and alkaline phosphatases are common, in plants acid phosphatases are found. Some of the phosphatases have high specificities and have indispensable role in energy release in the cells. A series of non-specific phosphatases carry out only digestive tasks. In humans, the erythrocyte and fibroblast expressed acid phosphatase (ACP1) isozymes are coded in chromosomes 2 and 4. It has been suggested that these enzymes split flavin mononucleotide phosphates. In megaloblastic anemia, ACP1 level is increased. The tartrate-resistant acid phosphatase type 5 (TR-AP) is an iron-glycoprotein of 34 kDa (human chromosome 15q22-q26), and it is increased in the spleen in case of Gaucher disease. Lysosomal acid phosphatase (ACP2) is located in human chromosome 11p12-p11. Alkaline phosphatase (ALPL) is present in the liver, bone, kidney, and fibroblasts, is often called the non-tissue-specific phosphatase (human chromosome 1p36-p34), and is deficient in hypophosphatasias. The alkaline phosphatase ALPP is located in the placenta (human chromosome 2q37) and several allelic forms have been identified. A similar alkaline phosphatase is present also in the testes and the thymus and the gene occurs at the same chromosomal location, but its expression is highly tissue-specific. Protein phosphatase 2A (PP2A) catalytic subunit, encoded at human chromosome 9q34, is involved in the control of many cellular processes, including the mitotic spindle (Sclaitz A-L et al 2007 Cell 128:115). The structure of the holoenzyme is known (Xu Y et al 2006 Cell 127:1239). ▶serine/threonine and tyrosine protein phosphatases, ▶hypophosphatasia, ▶hypophosphatemia, ▶dual-specificity phosphatase, ▶megaloblastic anemia, ▶Gaucher's disease

Phosphate Response of Plants: The inorganic phosphate level is frequently growth-limiting in plants.

Arabidopsis is an extremely sensitive indicator of P in soils. The photograph illustrates *Arabidopsis* growth on a Missouri soil sample, without and with PO_4 addition (see Fig. P63) (Rédei GP 1966 unpublished).

Figure P63. *Arabidopsis* growth with and without PO_4 addition

The physical contact of the *Arabidopsis thaliana* primary root tip with low-phosphate medium arrests root growth. Loss-of-function mutations in *Low Phosphate Root1 (LPR1)* and its close paralog *LPR2* strongly (encoding multicopper oxidases) reduce this inhibition (Svistonoff S et al 2007 Nature Genet 39:792). The non-protein coding gene *IPS1* (Induced by phosphate starvation1) contains a motif with sequence complementarity to the phosphate (Pi) starvation-induced miRNA miR-399. When the pairing is interrupted by a mismatched loop at the expected miRNA cleavage site, IPS1 RNA is not cleaved but instead sequesters miR-399. Thus, IPS1 overexpression results in increased accumulation of the miR-399 target PHO2 mRNA (phosphate-starvation) and, concomitantly, in reduced shoot Pi content (Franco-Zorilla JM et al 2007 Nature Genet 39:1033).

Microarray hybridization of transcript abundance among 22,810 *Arabidopsis* genes indicated that 612 were coordinately induced, whereas 254 genes were suppressed by inorganic phosphate. These genes are involved with metabolic pathways, ion transport, signal transduction, transcriptional regulation and other cellular processes (Misson J et al 2005 Proc Natl Acad Sci USA 102:11).

Phosphatidate: A precursor of diacylglycerol (see Fig. P64). ▶diacylglycerol, formula at right.

Figure P64. Phosphatidate

Phosphatidylinositol (1,2-diacyl-sn-glycero-3-phospho [1-o-myoinositol]): A cell membrane phospholipid. Phosphatidylinositol-transfer protein is required for vesicle budding from the Golgi complex. Phosphatidylinositol-3,4,5-trisphosphate activates protein kinase B. Phosphatidylinositol-kinase-3 mutations are oncogenic (Kang S et al 2005 Proc Natl Acad Sci USA 102:802). ▶PIK, ▶pleckstrin domain, ▶PKB, ▶Golgi apparatus, ▶PTEN, ▶phosphoinositides, ▶wortmannin; Bourette RP et al 1997 EMBO J 16:5880; Abel K et al 2001 J Cell Sci 114:2207.

3'-Phosphoadenosine-5'-Phosphosulfate: ▶PAPS

Phosphodegron: SCF β -TRCP promotes Chk1-dependent Cdc25A ubiquitination, and this involves serine 76, a known Chk1 phosphorylation site, but other sites of phosphorylated amino acids may make a protein liable to degradation by ubiquitination. ▶SCF, ▶Chk-1, ▶CDC25, ▶ubiquitin

Phosphodiester Bond: A phosphodiester bond attaches the nucleotides into a chain by hooking up the incoming 5'-phosphate ends to the 3'-hydroxy tail of the preceding nucleotide: R¹ and R² represent nucleosides, O: oxygen, H: hydrogen, P: phosphorus (see Fig. P65). ▶Watson-Crick model, formula.

Figure P65. Phosphodiester bond

Phosphodiesterases: Exonucleases. The snake venom phosphodiesterase starts at the 3'-OH ends of a nucleotide chain and splits off the nucleoside-5'-phosphate. The 3'-phosphate terminus does not lend the nucleotide chain for its action. The spleen phosphodiesterase, on the other hand, generates nucleoside-3'-phosphate molecules by splitting on the other side of the nucleotides. Phosphodiesterase converts cyclic AMP into AMP or cGMP into GMP. Phosphodiesterase 5 inhibitors are therapeutics for erectile dysfunction and several other diseases. The sensitivity of RNA phosphodiesterases is affected by the secondary and tertiary structure of the RNA as well by the adjacent nucleotides. ▶phosphodiester bond, ▶nitric oxide, ▶priapism, ▶stroke; structure: Sung BJ et al 2003 Nature [Lond] 425:98; catalytic domains for different inhibitors: Card GL et al 2004 Structure 12:2233.

Phosphoenolpyruvate: Phosphoenolpyruvate is efficient in transferring phosphate group to ADP to form ADP (see Fig. P66).

Figure P66. Phosphoenolpyruvate

Phosphofructokinase M (glycogen storage disease VII, 12q13.3): A phospho-fructokinase in the muscles (PFKM). It deficiency may cause muscle cramps and myoglobinuria. Lactate production is reduced and fatigue develops after exertion. ▶glycogen storage diseases, ▶myoglobin, ▶fructose-2,6-bisphosphatase

Phosphofructokinase Platelet Type (PFKP, 10p15.3-p15.2): PFKP is expressed in the platelet but it displays 71% identity of amino acid sequence of the muscle type and 63% identity with the liver enzyme.

Phosphofructokinase X (PFKX): A chromosome 2-encoded enzyme, which is expressed in the fibroblasts and the brain.

Phosphofructo-2-Kinase/Fructose-2,6-Bisphosphatase (PFKFB, PFRX, Xp11.21): A bifunctional enzyme encoded in the X chromosome of humans and rodents. The PFKFB3 locus is in 10p15-p14. The PFKFB4 enzyme is in 3p22-p21.

Phosphofructose Kinase 1 (PFK-1, PFKL, phosphofructokinase): PFK-1 enzyme catalyzes the formation of fructose-1,6-bisphosphate from fructose-6-phosphate in the presence of ATP and Mg²⁺. PFKL (liver enzyme) is encoded in human chromosome 21q22.3. The tetrameric enzyme may exist in five different forms due to the random association of the products of two different loci.

Phosphofructose Kinase 2 (PFK-2): PFK-2 mediates the formation of fructose-2,6-bisphosphate from fructose-6-phosphate. It enhances the activity of fructosephosphate 1 enzyme by binding to it, and also inhibits fructose-2,6-bisphosphatase and therefore enhances glycolysis. ▶glycolysis

Phosphoglucomutase (PGM): The enzyme that catalyzes the reaction:

Phosphoglucomutase proteins are homologous in structure through the animal kingdom. In humans, there are several PGM enzymes and some with multiple allelic forms with characteristic patterns and are reasonably stable. Therefore, PGM is used in forensic

genetics for personal identification on samples up to 6 months old. Their human chromosomal locations are: PGM1 (1p31), PGM2 (4p14-q12), PGM3 (6q12), and PGM5 (9p12-q12). ►forensic genetics

Phosphogluconate Oxidative Pathway: Same as pentose phosphate pathway.

3-Phosphoglycerate Dehydrogenase Deficiency (PHGDH, 1q12): PHGDH results in recessive serine biosynthetic defect, microcephaly, and neurological defects and seizures. ►serine

Phosphoglyceratemutase Deficiency: ►myopathy, ►glycerophospholipid

Phosphoglyceride: ►glycerophospholipid

Phosphohexose Isomerase (PHI): PHI catalyzes the glucose-6-phosphate⇌fructose-6-phosphate conversions. It is encoded in human chromosome 19cen-q12. Its defects result in dominant hemolytic anemia. ►anemia, ►hemolytic anemia

Phosphoinositide-3-Kinases: ►PIK, ►phosphoinositides

Phosphoinositides: Inositol-containing phospholipids. They play an important role as second messengers, and in phosphorylated/dephosphorylated forms they participate in the regulation of traffic through membranes, growth, differentiation, oncogenesis, neurotransmission, hormone action, cytoskeletal organization, platelet function, and sensory perception. The signals converge on phospholipase C (PLC, 20q12-q13.1). It hydrolyzes phosphatidylinositol-4,5-bisphosphate (PtdInsP₂) into inositol trisphosphate (InsP₃) and diacylglycerol (DAG). PtdInsP₂ segregation is mediated by PTEN, and CDC42 control apical morphogenesis (Martin-Belmonte F et al 2007 Cell 128:383). InsP₃ regulates Ca²⁺ household and DAG activates PLC. InsP₃ levels also regulate pronuclear migration, nuclear envelope breakdown, metaphase-anaphase transitions, and cytokinesis. Cytidine diphosphate-diacylglycerol synthase (CDS) is required for the regeneration of PtdInsP₂ from phosphatidic acid. CDS is a key regulator in the G-protein-coupled photo-transduction pathway. Pleckstrin homology domains selectively bind phosphoinositides. ►inositol, ►phospholipase, ►stoma, ►DAG, ►signal transduction, ►IP₂ [InsP₂ for formula], ►IP₃ [InsP₃ for formula], ►phosphatidylinositol, ►myoinositol, ►PIK, ►pleckstrin, ►PTEN, ►CDC42; Czech MP 2000 Cell 100:603; Vanhaesebroeck B et al 2001 Annu Rev Biochem 70:535; Sato TK et al 2001 Science 294:1881; De Matteis MA et al 2002 Curr Opin Cell Biol 14:434; review: Di Paolo G, Di Camilli P 2006 Nature [Lond] 443:651.

Phosphoinositide-Specific Phospholipase Cδ: Cδ signal transducers and generates the second messengers inositol-1,4,5-triphosphate and diacylglycerol. ►signal transduction, ►second messenger

Phospholamban (phosphorylated pholamban, PLN, 6q22.1): A regulator of sarcoplasmic reticulum Ca²⁺-ATPase (SERCA); it is a kinetic regulator of heart muscle function. Mutation in PLN leads to hereditary cardiomyopathy and premature death (Haghighi K et al 2006 Proc Natl Acad Sci USA 103:1388). ►cardiomyopathy

Phospholipase (PL) A, D, C: Each split specific bond in phospholipids. PLC-β generates diacylglycerol and phosphatidylinositol 2,4,5-triphosphate from phosphatidylinositol 4,5-bis-phosphate. These second messenger molecules play roles in signal transduction. PLC-γ is activated by receptor tyrosine kinases and one of its homologs is the SRC oncoprotein. PLC-γ1 with VEGF—through the FLT-1 receptor—controls the strength of the heartbeat by regulating calcium signaling in the myocytes (Rottbauer W et al 2005 Genes Dev 19:1624). PLA is present in mammalian inflammatory exudates. Form A2 is coded by human chromosome 12, the other PLA2B by chromosome 1. Phospholipase C is coded in human chromosomes at the following locations: PLCB3 (11q11), PLCB4 (20p12), and PLCG2 (16q24.1). ►serine/threonine phosphoprotein phosphatases, ►SRC, ►signal transduction, ►phosphoinositides, ►Ipk1, ►Ipk2, ►VEGF, ►stoma; Rhee SG 2001 Annu Rev Biochem 70:281; Wang X 2001 Annu Rev Plant Physiol Mol Biol 52:211.

Phospholipid: A lipid with phosphate group(s). ►liposome, ►lipids

Phosphomannomutase Deficiency: A rare defect of glycosylation displaying large differences in expressivity. It involves inverted nipples, fat pads, strabismus, hyporeflexia (sluggish responses), mental retardation, hypogonadism, and early death. (See Grünwald S et al 2001 Am J Hum Genet 68:347).

Phosphomannose Isomerase (MPI, 15q22-qter): The defects of MPI affect many glycosylation reactions in the cell. MPI is involved in the conversion of fructose-6-phosphate into mannose-6-phosphate. Clinically, it may cause diarrhea, enlarged liver, hypoglycemia with convulsions, coma, etc. The 5 kb gene includes 8 exons.

Phosphomonoesterase: A phosphatase digesting phosphomonoesters, such as nucleotide chains. ►phosphodiester bond

Phosphonitricin (Basta): ►herbicides

Phosphoramidates: Phosphoramidates are used in antisense technologies by the modification of the sugar-phosphate backbone of oligonucleotides (see Fig. P67). ▶antisense technologies, ▶trinucleotide-directed mutagenesis; Jin Y et al 2001 Bioorg Med Chem Lett 11:2057; Faria M et al 2001 Nature Biotechnol 19:40.

Figure P67. Phosphoramidate

Phosphoramidite/Ink Jotting: A rapid method of DNA analysis. (See Cooley P et al 2001 Methods Mol Biol 170:117).

Phosphorelay: ▶two-component regulatory system

Phosphorescence: ▶fluorescence, ▶luminescence

Phosphoribosylglycinamide Formyltransferase: Phosphoribosylglycinamide formyltransferase is human chromosome 21q22.1 dominant and it controls purine, pyrimidine biosynthesis, and folate metabolism.

Phosphoribosylpyrophosphate Synthetase (PRPS1, Xq22-q24): An enzyme of the purine/pyrimidine salvage pathway. Its deficiency may cause hyperuricemia (excessive amounts of uric acid in the urine), deafness, and neurological disorder.

Phosphorimaging: The detection of radioactive labels in tissues by phosphorescence.

Phosphorolysis: In phosphorolysis, glycosidic linkage holding two sugars together is attacked by inorganic phosphate and the terminal glucose is removed (from glycogen) as α -D-glucose-1-phosphate.

Phosphorothioates: Analogs of oligodeoxynucleotides; they are used in antisense technology. Their attachment to the 3'-end inhibits the activity of nucleases that attacks RNA from that end. They can bind to proteins, but do not stimulate the activity of RNase H (phosphoro-dithioate modified heteroduplexes may stimulate RNase H), inhibit translation, and are relatively easily taken up by cells. Some of the truncated mRNAs can, however, be translated into truncated proteins (Hasselblatt P et al 2005 Nucleic Acids Res 33:114). Some of the effects of these molecules are not based on their anti-sense properties (e.g., binding to CD4, NF- κ B, inhibition of cell adhesion, inhibition of receptors, etc.). Phosphorothioate-modified nucleotides (one of the oxygen attached to P is replaced by S) are used also in vitro mutagenesis to protect

the template strand from nucleases, while the strand to be modified is excised before re-synthesis in a mutant form. ▶antisense technologies, ▶antisense RNA, ▶antisense DNA, ▶OL(1)p53, ▶ribonuclease H, ▶CD4, ▶NF- κ B; Sazani P et al 2001 Nucleic Acids Res 29:3965; ▶quenched autoligation probe

Phosphorylase b Kinase: An enzyme that phosphorylates two specific serine residues in *phosphorylase b*, thus converting it into *phosphorylase a* upon the action of cAMP-dependent protein kinase (synonym protein kinase A). Phosphorylase b kinase mediates glycogen breakdown. This enzyme is a tetramer and for activation the two regulatory subunits (R) must be separated from the two catalytic subunits to be able to function. The dissociation is mediated by cAMP through A-kinase. The δ subunit is calmodulin. ▶epinephrine, ▶cAMP-dependent protein kinase, ▶cAMP, ▶A-kinases, ▶calmodulin; Brushia RJ, Walsh DA 1999 Front Biosci 4:D618.

Phosphorylases (kinases): ▶serine/threonine kinases, ▶tyrosine protein kinase, ▶Jak kinase, ▶phosphorylase B, ▶A-kinases, ▶signal transduction, ▶serine/threonine phosphoprotein phosphatases, ▶phospholipase C, ▶signal transduction, ▶calmodulin, ▶phosphorylase b kinase

Phosphorylation: Adding phosphate to a molecule. It may play an important role in signal transduction, and depending on which of the potentially several sites is phosphorylated, the function of some transcription factors may be altered. In the proteins serine and threonine, residues are frequently phosphorylated. If phosphoserine and phosphothreonine residues are replaced by the lysine analog aminoethylcysteine or β -methylaminoethylcysteine, the lysine-specific proteases cleave at these sites and thus these phosphorylation sites can be revealed (Knight ZA et al 2003 Nature Biotechnol 21:1047). Phosphorylation sites are detectable also by tandem mass spectrometry. The mouse genome contains more than 500 kinases. The nerve synapse system alone operates with 650 phosphorylation events involving 331 sites. Some proteins, like MAP1B, have 33 such sites. The bioinformatics information indicates that a small number of kinases phosphorylate many proteins and some substrates are phosphorylated by many kinases. These phosphorylations form elaborate interacting networks (Collins MO et al 2005 J Biol Chem 280:5972). ▶oxidative phosphorylation, ▶kinase, ▶phosphorylases, ▶tandem mass spectrometry, ▶unstructured proteins; Whitmarsh AJ, Davis RJ 2000 Cell Mol Life Sci 57:1172; protein phosphorylation site prediction (DISPHOS): <http://core.ist.temple.edu/pred/pred.html>; PHOSIDA phosphorylation site database: <http://www.phosida.com/>; protein

three-dimensional phosphorylation sites: <http://cbm.bio.uniroma2.it/phospho3d>.

Phosphorylation Potential (ΔG_p): The change in free energy within the cell after hydrolysis of ATP.

Phosphoserinephosphatase: Phosphoserinephosphatase hydrolyzes O-phosphoserine into serine; it is encoded in human chromosome 7p15.1-p15.1.

Photoactivated Localization Microscopy: Photoactivated localization microscopy can detect activable fluorescent proteins within cells and cellular organelles at nanometer resolution (Betzig E et al 2006 Science 313:1642). ►microscopy

Photoaffinity Tagging: In photoaffinity tagging, the labels may be radioactive or fluorescent and bind to certain compounds by non-covalent bonds upon illumination. (See Knorre DG et al 1998 FEBS Lett 433:9).

Photoaging: In photoaging, skin collagens and elastin are damaged by the ultraviolet light induced metalloproteinases and this results in wrinkling of the skin similar to what occurs during aging. These enzymes are upregulated by AP-1 and NF- κ B transcription factors. ►aging, ►collagen, ►elastin, ►AP-1, ►NF- κ B

Photoallergy: Immunological response to a substance activated by light.

Photoautotroph: An organism that can synthesize in light all its required organic substances and energy from inorganic compounds. The majority of green plants are photoautotrophic. By introducing a glucose transporter gene into obligate photoautotrophic alga, the organism could be converted to light-independent growth on glucose. (See Zaslavskaja LA et al 2001 Science 292:2073).

Photochemical Reaction Center: The site of photon absorption and initiation of electron transfer in the photosynthetic system. ►photosynthesis

Photodynamic Effect: Photosensitivation, photodestruction. A dye or pigment absorbs light and converts the energy to a higher state and exerts specific effects. Photodynamic effects may have various therapeutic applications. Phenothiazines, phthalocyanines, porphyrines, and other molecules with photoactive properties have been successfully tested as photoinactivating agents against Gram-positive and Gram-negative bacteria. After absorption of light, singlet oxygen (1O_2) may be generated and the oxidative damage to proteins and lipids may kill the bacteria even if they are resistant to antibiotics. ►ROS, ►singlet oxygen; Langmack K et al 2001 J Photochem Photobiol B 60:37; Maisch T et al 2007 Proc Natl Acad Sci USA 104:7223.

Photoelectric Effect: The photoelectric effect has very wide applications of modern technology (television, computers and other electronic instruments). Atoms may emit electrons when light hits a suitable target. When X-rays hit a target, very high energy photoelectrons may be generated.

Photogenes: Chloroplast DNA-encoded proteins involved in photosynthesis. One of the most studied is *photogene 32* (*psbA*), which codes for a 32 kDa thylakoid protein involved in electron transport in photosystem II. Also, it binds the herbicide atrazine and by removing or altering this binding site, one can obtain plants resistant to the weed killer through molecular genetic manipulations. ►photosynthesis, ►herbicides; Roderick SR, Bogorad L 1985 J Cell Biol 100:463.

Photography: Photography, in the laboratory, has special requirements depending on the objects. Cell cultures in Petri plates can be best photographed through macrolenses (for extreme close ups, use extension rings or teleconverter) and through using highly sensitive color films, such as Kodak Gold 400. To eliminate reflection, the blue photoflood lamps should be adjusted at an angle of about 45°. Agarose gels can be photographed with a polaroid camera mounted on a copying stand and using high speed (ASA 3000) films. Ultraviolet light sources of the longer wavelength are less likely to damage the DNA. The contrast can be enhanced by the use of orange filters on the camera (such as Kodak Wratten 22A). Note that ultraviolet light is dangerous to the skin and particularly to the eyes. Use gloves, goggles, and wear a long-sleeved shirt. For photomicrography, built-in automatic exposure meters are very advantageous, if frequently used. Otherwise, numerous exposures, at the proper color temperature, are necessary. For photocopying and editing, halftone image computers with (color) scanners can be used. The resolution now provided by digital cameras is satisfactory for most biological applications; they are very convenient and the high pixel (up to 8–10 megapixel [picture elements]) units are very powerful.

Photolabeling: Adding photoactivatable groups to proteins, membranes, or other cellular constituents in order to detect their reaction path. The labels are generally small molecules, stable in the dark and highly susceptible to light. They work without causing photolytic damage to the target and are stable enough to permit analytical manipulations of the sample. Synthetic peptides containing substances, such as 4'-(trifluoromethyl-diaziriny)-phenylalanine or 4'-benzoyl-phenylalanine, etc., have been used to analyze biological structures (membranes, proteins, etc.). ►green fluorescent protein, ►luciferase

Photolithography: A modification of a more-than-a-century-old printing process. A solid plate is coated with a light-sensitive emulsion, overlaid by a photographic film, and then, illuminated. An image is formed after the plate is exposed to light. A similar principle has been adapted now to visualize DNA sequences for the purpose of large scale mapping, fingerprinting, and diagnostics. The process is also used for the synthesis of nucleotide probes. ► [DNA chips](#), ► [microarray hybridization](#); Barone AD et al 2001 *Nucleosides Nucleotides Nucleic Acids* 20 (4–7):525; review of techniques: Truskett VN, Watts MP 2006 *Trends Biotechnol* 24:312.

Photolyase: A flavoprotein repair enzyme (M_r 54,000) that splits cyclobutane pyrimidine dimers (Pyr < > Pyr) into monomers upon absorption of blue light. A photolyase-like 42-nucleotide deoxyribozyme is also capable of repairing thymine dimers optimally at 300 nm light (Chinnapen DJ-F, Sen D 2004 *Proc Natl Acad Sci USA* 101:65). In *E. coli*, two chromophores assist the process of photolyase action; 5,10-methenyltetrahydrofolate absorbs the photo-reactivating light and 8-hydroxy-5-deazariboflavin, and the energy is then transferred to FADH₂, although the latter too absorbs some energy. The excited FADH₂* then transfers the energy to the dimer and while FADH₂ is regenerated, the dimer splits up, the recipient member of the dimer breaks down, and monomeric pyrimidines are formed. A second cofactor, 5,10-methenyl-tetrahydrofolylpolyglutamate (MTHF), may be the light harvester. It is interesting that the blue light photoreceptor cryptochromes of plants bear substantial similarities to the bacterial photolyase and its cofactors are also the same, yet the exact role of photolyases in plant DNA repair is unclear. Cyclobutane photolyase does not split the pyrimidine-pyrimidinone (6-4) photoproducts. The 6-4 photolyases are under the control of two different genes. Topical application of photolyase and light to sunburnt human skin may alleviate the symptoms by repair of the DNA damage. ► [DNA repair](#), ► [direct repair](#), ► [photo-reactivation](#), ► [pyrimidine dimer](#), ► [cyclobutane ring](#), ► [cryptochrome](#), ► [base flipping](#), ► [pyrimidinone](#); Tanaka M et al 2001 *Mutagenesis* 16:1; Komori H et al. 2001 *Proc Natl Acad Sci USA* 98:13560; crystal structure: Mees A et al 2004 *Science* 306:1789; repair process: Kao Y-T et al 2005 *Proc Natl Acad Sci USA* 102:16128.

Photolysis: Degradation of chemicals or cells by light.

Photomixotrophic: An organism that can synthesize some of its organic requirements with the aid of light energy, while for others it depends on supplied organic substances.

Photomorphogenesis: Light-dependent morphogenesis. Light affects the growth and differentiation of plant meristems (photoperiodism), plastid differentiation, and directly or indirectly many processes of plant metabolism. Certain stages in photomorphogenesis can be reached at low intensity (fluence) illumination (or even in darkness), such as the formation of proplastids and etioplasts. Other steps such as the full differentiation of the thylakoid system and photosynthesis-dependent processes require high fluence rate and critical spectral regimes (red and blue). Several genes involved in the control of plastid development have been identified in *Arabidopsis* and other plants. The *lu* mutation is normal green at low light intensity but it is entirely bleached and dies at high light levels. Wild type plants can make etioplasts in the dark but the *deetiololed* (*det1*), *constitutive photomorphogenesis* (*cop1* and *cop9*) mutants develop chloroplasts in darkness. The Cop9 complex includes eight subunits, forming a signalosome in plants and a homolog is found also in animals. The *gun* (*genome uncoupled*) mutants grow normally in the dark but do not allow the development of etioplasts into chloroplasts. Various pale *hy* (*high-hypocotyl*) mutants, deficient in phytochrome, make light green plastids indicating that phytochrome is not a requisite for plastid differentiation to an advanced stage. The *blu* (*blue light uninhibited*) class of mutants is inhibited in hypocotyl elongation by far red light. The *HY4* locus of *Arabidopsis* encodes a protein, homologous to photolyases, and the recessive mutations are insensitive to blue light for hypocotyl elongation. Mutants were identified, some of which showed no response to blue light and others displayed very high blue light requirement for curvature. Most of these light responses appear to be mediated by signal transduction pathways. The chlorophyll-b free, yellow green mutants (*ch*) display chloroplast structure appearing almost normal by electronmicroscopy. Several mutations defective in fatty acid biosynthesis and/or photosynthesis are rather normal in photomorphogenesis. Some mutants are resistant to high CO₂ atmosphere, and normal chloroplast differentiation requires high CO₂. Other mutants can be protected from bleaching only at 2% CO₂ atmosphere. The *Arabidopsis* nuclear mutants of the *im* (*immutans*) type display variegation under average greenhouse illumination, but they are almost normal green under low light intensity and short daily light cycles whereas at high intensity continuous illumination they are almost entirely free of leaf pigments. Under the latter condition, by continuous feeding of an inhibitor or repressor of the de novo pyrimidine pathway, the leaf pigment content may increase twenty-fold. In these variegated plants, the green cells have entirely normal chloroplasts

whereas the white cells lack thylakoid structure. The azauracil-treated plants display fully functional, although morphologically altered thylakoids. An insertional mutation at the *ch-42 locus* (*cs*) identified a thylakoid protein, essential for normal greening of the plants without abolishing cell viability. The *PRF* (*pleiotropic regulatory factor*) locus, tagged by a T-DNA insertion, controls several loci involved in photomorphogenesis. The product of the gene is a subunit of the G-protein family. The *det2*, *cyp90*, *cop*, *fus*, *dim* *axr2*, and the *cbb* dwarf mutations develop their characteristic phenotypes because of defects in the brassinosteroid pathway. The nuclear gene *chm* (*chloroplast mutator*) induces a wide variety of plastid morphological changes, due to extranuclear mutation. ▶[photoperiodism](#), ▶[florigen](#), ▶[phototropism](#), ▶[phytochrome](#), ▶[circadian rhythm](#), ▶[signal transduction](#), ▶[brassinosteroids](#), ▶[COP](#), ▶[proteasome](#), ▶[dominance reversal](#); Wada M, Kadota A 1989 Annu Rev Plant Physiol Plant Mol Biol 40:169; von Arnim A, Deng X-W 1996 Annu Rev Plant Physiol Plant Mol Biol 47:215; Quail PH 2002 Nature Rev Mol Cell Biol 3:85.

Photon: A quantum of electromagnetic radiation, which has zero rest mass and an energy h times the frequency of the radiation. Photons are generated by collisions between atomic nuclei and electrons and other processes when electrically charged particles change momentum. ▶[measurement units](#)

Photoperiodism: The response of some species of plants to the relative length of the daily light and dark periods.

P

Besides the length of these cycles, the spectral properties and the intensity of the light are also important. Responses of plants include, the onset of flowering, vegetative growth, elongation of the internodes, seed germination, leaf abscission, etc. *Short-day*, *long-day* and *day-neutral* plants are commonly distinguished on the basis of the critical daylength or, in the latter category, by the lack of it (see Fig. P68). The geographic distribution of plants is correlated with their photoperiodic response. In the near equatorial regions, short-day species predominate whereas in the regions extending toward the poles long-day plants are common. The onset of flowering of short-day plants is promoted by 15–16 h of dark periods whereas in long-day plants, the flowering is accelerated by continuous illumination or by longer light than dark daily cycles. The critical day-length is not an absolute term; it varies in different species. Usually, there is a minimum number of cycles to evoke the photoperiodic response. Mutants of *Arabidopsis* (*gi*, *co*, *ld*; Rédei GP 1962 Genetics 47:443) and others shed light on some of the basic mechanisms involved (Schultz TF, Kay SA

Figure P68. Henbane (*Hyoscyamus niger*) Long-day plants flower only under long daily light periods (after appropriate cold treatment). Courtesy of Professor G. Melchers

2003 Science 301:326). The most important photoreceptor chromoprotein is *phytochrome*. The effect of phytochrome is affected by different plant hormones. Typical long-day plants are henbane (*Hyoscyamus*), spinach, *Arabidopsis* [without a critical daylength], the majority of the grasses and cereal crops (wheat, barley, oats), lettuce, radish, etc. Typical short day plants are Biloxi soybean, cocklebur, aster, chrysanthemum, poinsettia, dahlia, etc. In the majority of species, the photoperiodic response is controlled by one or a few genes. Some processes in animals are also under photoperiodic control. In the Japanese quail, the gene encoding type 2 iodothyronine deiodinase, which catalyzes the conversion of the prohormone into the active 3,5,3'-triiodothyronine is induced by light. The anatomical location of the response center is in the hypothalamus, while the target site is the differentiation of the gonads (Yoshimura T et al 2003 Nature [Lond] 426:178). ▶[phytochrome](#), ▶[florigen](#), ▶[cryptochromes](#), ▶[photomorphogenesis](#), ▶[circadian rhythm](#), ▶[phototropism](#), ▶[vernalization](#), ▶[flower evocation](#), ▶[floral induction](#), ▶[dominance reversal](#); Jackson SD, Prat S 1996 Plant Physiol 98:407; Amador V et al 2001 Cell 106:343; Quail PH 2002 Curr Opin Cell Biol 2002 14:180; Mockler T et al 2003 Proc Natl Acad Sci USA 100:2140S; Yanofsky MJ, Kay SA 2003 Nature Rev Mol Cell Biol 4:265; Chen M et al 2004 Annu Rev Genet 38:87.

Photophosphorylation: ATP formation from ADP in photosynthetic cells.

Photoreactivation: Elimination of the harmful effects of ultraviolet irradiation by subsequent exposure to visible light (that activates enzymes splitting up the pyrimidine dimers in the DNA). With a few exceptions, e.g., *Haemophilus influenzae*, most organisms

possess light-activated repair enzymes. The majority of mammals do not have efficient photoreactivation system, except the marsupials. ►light repair, ►photolyase dark repair, ►excision repair, ►glycosylases, ►error-prone repair, ►DNA repair; Kelner A 1949 J Bacteriol 48:5111; Tuteja N et al 2001 Crit Rev Biochem Mol Biol 36(4):337; Sancar GB 2000 Mutation Res 451:25.

Photoreceptors: Humans have, in the eye, the very sensitive rod cells, mediating black and white vision and the less sensitive cone cells for color vision. ►phytochrome, ►rhodopsin, ►CRX, ►metalloproteinases, ►phototropism, ►sevenless, ►S-cone disease; Calvert PD et al 2006 Trends Cell Biol 16:560.

Photoreduction: In photosynthetic cells, light induced reduction of an electron acceptor.

Photorespiration: Oxygen consumption in illuminated plants used primarily for the oxidation of the photosynthetic product phosphoglycolate; it also protects C3 plants from photooxidation. Step-wise nuclear transformation of *Arabidopsis* with five chloroplast-targeted bacterial genes encoding glycolate dehydrogenase, glyoxylate carboligase, and tartronic semialdehyde reductase converted chloroplast glycolate directly to glycerate. Transgenic plants grew faster, produced more shoot and root biomass, and contained more soluble sugars, reflecting reduced photorespiration and enhanced photosynthesis that correlated with an increased chloroplast CO₂ concentration (Kabeish R et al 2007 Nature Biotechnol 25:593). ►respiration, ►Calvin cycle, ►C3 plants; Wingler A et al 2000 Philos Trans R Soc Lond B Biol Sci 355:1517.

Photorhabdus luminescens: A gram-negative enterobacterium that maintains a mutualistic association with insect-feeding Heterorhabditis species of nematodes. When the nematodes invade the insects, the bacteria are released, kill the host with the help of the toxin, emit light, and make the cadaver luminescent. The toxins (tca and tcd) are potential insecticide, fungicide, and antibacterial agents, somewhat similarly to that of *Bacillus thuringiensis*. *Arabidopsis* plants, transgenic for the *TcdA* gene driven by the constitutive cassava vein mosaic virus promoter and equipped with the 5' and 3' untranslated sequences of the tobacco *osmotin* gene, were especially resistant to feeding insects (Liu D et al 2003 Nature Biotechnol 21:1038). The *osmotin* gene sequences increased the mRNA stability. The activity of the transgene was affected significantly by the position of the insertion site in the plant chromosome. Strain TT01 genome contains 5,688,987 bp and encodes presumably 4839 proteins (Duchaud E et al 2003 Nature Biotechnol 21:1307). ►*Bacillus thuringiensis*; Ehlers RU 2001

Appl Microbiol Biotechnol 56:623; Szállás E et al 1997 Int J Syst Bacteriol 47:402; Bowen D et al 1998 Science 280:2129.

Photosensitizers: Photosensitizers may increase the oxidative damage to DNA. Their action may involve initial electron or hydrogen transfer to the DNA by the excited photosensitizer, followed by the generation of free radicals. Alternatively, they generate singlet oxygen that interacts with the DNA and then produces peroxidic intermediates. Most commonly, guanine suffers lesions. ►oxidative DNA damages

Photosynthesis: Using light energy for the conversion of CO₂ into carbohydrates with the assistance of a reducing agent such as water. The photosynthetic system appears to have evolved from the core of the cyanobacterial genome (Mulikidjanian AY et al 2006 Proc Natl Acad Sci USA 103:13126). ►photosystems, ►Z scheme, ►chlorophyll binding proteins, ►thermotolerance, ►C3 plants, ►C4 plants, ►Calvin cycle; Matsuoka M et al 2001 Annu Rev Plant Physiol Mol Biol 52:297; Xiong J, Bauer CE 2002 Annu Rev Plant Biol 53:503.

Photosystems: In photosynthesis, photosystem I is excited by far red light (~700 nm) while photosystem II requires higher energy red light (~650–680 nm). In the thylakoids of the chloroplast of plants, the immunophilin FKB20-2, an FK-506 binding protein, is required for the assembly of the photosystem II complex (Lima A et al 2006 Proc Natl Acad Sci USA 103:12631). Photosynthesis in bacteria that does not evolve oxygen uses only photosystem I. Upon absorption of photons, photosystem I liberates electrons that are carried through a cascade of carriers to NADP⁺, which is reduced to NADPH. The departure of electrons generates a “void” in the P700 photoreaction center of photosystem I and that is filled then by electrons produced through splitting of water molecules in photosystem II. The overall reaction flow is:

Mutants of *Chlamydomonas* alga lacking photosystem I survive as long as the actinic light (beyond violet) reaches 200 microeinsteins per m²/second. The photosystem II of cyanobacteria (similar to that of plants and algae) is a complex of 20 proteins and 77 cofactors including 14 integrally bound lipids and their crystal structure has been determined at 3.0 Å resolution (Loll B et al 2005 Nature [Lond] 438:1040). Photosystem I has 17 protein subunits and the crystal structure of the supercomplex has been determined at 3.4 Å resolution (Amunts A et al 2007 Nature [Lond] 447:58). ►CAB, ►LHCP, ►antenna, ►chloroplast, ►thylakoid, ►Z scheme, ►immunophilins; Annu Rev

Genet 29:755; Guergova-Kuras M et al 2001 Proc Natl Acad Sci USA 98:4437; Jordan P et al 2001 Nature [Lond] 411:909; Chitnis PR 2001 Annu Rev Plant Physiol Plant Mol Biol 52:593; Szabó I et al 2001 J Biol Chem 276:13784; Rhe K-H 2001 Annu Rev Biophys Biomol Struct 30:307; Saenger W et al 2002 Curr Opin Struct Biol 12:244; Munekage Y et al 2004 Nature [Lond] 429:579; structure of photosystems: Nelson N, Yocum CE 2006 Annu Rev Plant Biol 57:521.

Phototaxis: A movement of organisms (plants, animals and microbes) in response to light.

Phototransduction: The transmission of light signals mediating gene expression. A scaffold protein (InaD in *Drosophila*) assembles the components of the light transduction pathway. ► [signal transduction](#), ► [rhodopsin](#), ► [retinal dystrophy](#)

Phototroph: An organism that uses light to generate energy and uses this energy to synthesize its nutrients from inorganic compounds.

Phototropin: Flavoprotein photoreceptors for plant phototropism. They have two flavin mononucleotide-binding domains (LOV1 and LOV2) and a serine-threonine kinase domain at the carboxyl end. Phototropins 1 and 2 are blue light-activated kinases for low and high intensity light. ► [flavoprotein](#); Harper SM et al 2003 Science 301:1541.

Phototropism: The reaction of an organ or organism to light, involving apparently more than a single photoreceptor (see Fig. P69). In *Arabidopsis*, the phytochromes and two complementary cryptochrome mutations (*CRY1*, *CRY2*) have been identified. Inactivation of both is required to eliminate phototropic response. It was suggested that one of the receptors is a membrane protein with autophosphorylating ability. Additional genes (*NPH1*, *NPH2*, *NPH3*, *RPT*, *NPL1*) are required for processing the responses after perception of the signals. Phototropin (phot1) detects low fluence blue light. Phytochromes

modulate phototropism by phytochrome A signaling components. Phytochrome kinase substrate proteins (Pks1, Pks2 and Pks4), in a complex with phot1 and NPH3 (non-phototropic hypocotyl), are involved in the signaling to phototropism (Lariguet P et al 2006 Proc Natl Acad Sci USA 103:10134). ► [photoreceptors](#), ► [gravitropism](#), ► [phytochromes](#), ► [cryptochromes](#), ► [phototropin](#); Briggs WR, Liscum E 1997 Plant Cell Environ 20:768; Quail PH 2002 Curr Opin Cell Biol 2002 14:180; Chen M et al 2004 Annu Rev Genet 38:87.

Phox: An oxidation subunit of proteins that is activated by phosphorylation. (Hoyal CR et al 2003 Proc Natl Acad Sci USA 100:5130).

Phragmoplast: A hollow-looking ring- or barrel-like structure formed near the end of mitosis in the middle plane of plant cells before the *cell plate* appears, separating the two daughter cells. ► [mitosis](#); Gu X, Verma DP 1996 EMBO J 15:695; Zhang Z et al 2000 J Biol Chem 275:8779.

PHRAP: One of the frequently used DNA sequence alignment programs. A quality score of $10^{X/10} \approx 30$ corresponds to an accuracy of 99.9% regarding the base sequence. ► [PHRED](#), ► [CONSED](#), ► [base-call](#); Harmsen D et al 2002 Nucleic Acids Res 30:416; <http://www.phrap.org>.

PHRED: An automated base-calling computer program. ► [PHRAP](#), ► [PolyPhred](#), ► [base-call](#)

Phycobilins: Highly fluorescent photoreceptor pigments in blue-green, red, and some other algae. They contain a linear tetrapyrrole prosthetic group for light harvesting. They also contain bile pigments and an apoprotein. This family of pigments includes the blue phycocyanins, the red phycoerythrins, and the pale blue allophycocyanins. These pigments may form phycobilisome, attached to the photosynthetic membrane. Phytochromes are also related pigments. ► [light-harvesting protein](#), ► [phytochrome](#); Wu SH et al 1997 J Biol Chem 272:25700.

Phycocyanin: The pigment of blue-green algae. ► [phycobilins](#)

Phycoerythrin: The red pigment of red algae. ► [phycobilins](#), ► [phycocyanin](#)

Phycomycetes: Fungi with some algal characteristics. *Ph. blakesleeana* is easy to grow with four-days-long asexual cycle and about two-months-long sexual cycle. It forms heterokaryons ($n = 14$) and can be subjected to formal genetic analyses, although the tetrads may be irregularly amplified. Transformation is feasible. It is well suited for physiological and developmental studies.

Figure P69. Phototropism

Phyletic Evolution: Gradual emergence of a species in a line of descent. The gaps in the fossil records are supposed to be due to accidents in the preservation of the intermediate forms.

Phyllody: Developmental anomaly of conversion of floral parts into leaves, generally after infection by pathogens.

Phylloquinone: Phylloquinone is composed of a p-naphthokinone and a phytol radical and it catalyzes oxydation-reduction reactions in plants. ▶ [vitamin K](#)

Phyllotaxy (phyllotaxis): In phyllotaxy, the consecutive leaves of plants do not occur above each other. Quite commonly, single leaves are at opposite positions (unless they occur in whorls) (see Fig. P70). This arrangement makes sense for the optimal utilization of light. In many plants, the leaves may not alternate in 180° but they may be arranged in any other determined pattern. This pattern is called phyllotaxy. If the leaves are opposite to each other, the phyllotaxy is 1/2. A common phyllotactic index is 2/5 (144°). This means that if the leaves are positioned by this index, leaf #1 will be followed by #2 at 144°, then #3 will take the place in a spiral at 288°, i.e., it will be above #1 (because $288:144 = 0.5$ and $0.5 \times 360 = 180$), and so on. The arrangement of the fruits on the stem may also be caused by such an obliquity, following either clockwise or counterclockwise directions. The phyllotactic arrangement is determined by the flow of auxin, and it may be negatively regulated by cytokinins in the shoot meristem (Giulini A et al 2004 Nature [Lond] 430:1031). ▶ [embryogenesis in plants](#), ▶ [Fibonacci series](#), ▶ [decussate](#); Hake S, Jackson D 1995 ASGSB Bull 8 (2):29; Kuhlemeier C, Reinhardt D 2001 Trends Plant Sci 6:187; Reinhardt D et al 2003 Nature [Lond] 426:255; Jönsson H et al 2006 Proc Natl Acad Sci USA 103:1633; Smith RS et al 2006 Proc Natl Acad Sci USA 103:1301.

Figure P70. Phyllotaxy

Phylogenetic Analysis: Phylogenetic analysis in forensic science uses pathogen strain DNA comparisons for identifying the source of infection, e.g., the retroviral DNA in case of HIV. ▶ [acquired immunodeficiency](#), ▶ [DNA finger printing](#), ▶ [forensic genetics](#)

Phylogenetic Depth: The total number of genetic changes, which separate an organism from its ancestors.

Phylogenetic Profile Method: The phylogenetic profile method studies the correlations of inheritance of pairs of proteins among various species. These proteins are not necessarily homologous but they appear to be linked functionally. ▶ [rosetta stone sequences](#); <http://dip.doe-mbi.ucla.edu>.

Phylogenetic Tree: The phylogenetic tree graphically represents the phylogeny of organisms. Trees have been constructed in the past on the basis of morphology, the sequences of single genes, or sequences of entire genomes. Similarity between two organisms can also be determined by dividing their total number of genes by the number of genes they have in common. Phylogenetic analysis based on molecular information greatly increases the precision of map construction. Although insights into the various genomes greatly facilitate the elucidation of phylogenetic relationships, none of the molecular methods are completely free of problems because duplications, deletions, horizontal gene transfer, and the evolution of new genes from various sequences may create problems in interpretation. ▶ [evolutionary tree](#), ▶ [BAMBE](#); Madsen O et al 2001 Nature [Lond] 409:610; Murphy WJ et al. 2001 Nature [Lond] 409:614; Kristian H et al 2007 Bioinformatics 23:793; <http://www.treefam.org/>.

Phylogenetic Weighting: As per phylogenetic weighting, DNA sequence information from various taxa is included in the phylogenetic tree in decreasing order of relationship. Thus, alignment from distant relatives should not precede alignment of closer relatives. This procedure prevents confounding similarity and descent. ▶ [evolutionary tree](#), ▶ [maximum parsimony](#), ▶ [homology](#), ▶ [DNA sequence alignment](#), ▶ [homology](#); Robinson M et al 1998 Mol Biol Evol 15:1091.

Phylogenomics: Phylogenomics uses evolutionary information to infer function of genes or the reconstruction of phylogenetic history on the basis of genomes. (See Delsuc F et al 2005 Nature Rev Genet 6:361; metabolic networks from protein structure: Caetano-Anollés G et al 2007 Proc Natl Acad Sci USA 104: 9358; phylogeny of protein domains: <http://www.bioinformatics.nl/tools/treedom/>; Berkeley phylogenomics: <http://phylogenomics.berkeley.edu>; search several gene families

simultaneously: <http://www.cs.nuim.ie/distributed/multiphyl.php>; distributed computing: <http://distributed.cs.nuim.ie/multiphylOnlineManual.php>; prokaryotic phylogenomics: <http://genetrees.vbi.vt.edu>).

Phylogeny: The evolutionary descent of a species or other taxonomic groups. ▶evolution, ▶ontology, ▶speciation, ▶genome conservation; Huelsenbeck JP et al 2001 Science 294:2310; information at the web site: <http://beta.tolweb.org/tree/>; <http://mrbayes.csit.fsu.edu/>.

Phylo type (phylogenetic type): A species representing a branch of a phylogenetic tree on the basis of shared similarity of nucleotide sequences. ▶phylogenetic tree

Phylum: The first main category of the plant and animal, and other kingdoms.

Physarum polycephalum: A single-cell slime mold that displays physiological dioecy. The cell forms a plasmodium, i.e., the nuclei divide without cell division and thus, the cell becomes multinucleate. In the early embryos, only the S and M phases of the cell cycle are detectable.

Physcomitrella patens: A moss with a principal life phase as a haploid gametophyte. It can be used for the production of various mutants, for parasexual research, transformation, study of plant hormones on developmental processes, and various tropisms. Sequencing of the genome is nearly complete by 2005. The estimated genome size ($n = 27$) ~511 Mb (~0.53 pg). The chloroplast genome is 122890 bp encoding 83 proteins. (See Schaefer DG 2002 Annu Rev Plant Biol 53:477; Cove D 2005 Annu Rev Genet 39:339).

Physical Containment: ▶containment

Physical Map: A map where the genome is ordered in DNA fragments or nucleotide sequences rather than in units of recombination. The first physical maps were constructed in bac-terio phages with small genomes. The DNA of phage P4 was cleaved completely by restriction endonuclease EcoRI into four fragments, which could be separated by electrophoresis according to size:

| | | | |
|---|---|---|---|
| v | ζ | ζ | ψ |
| A | C | B | D |

After incomplete digestion for 5 min, larger fragments were also detected that contained fragments A + B + C, C + B, and the combined size of C + D appeared but no fragment appeared with the size B + D. The cause of the absence of B + D must have been that B and D were not adjacent in the circular DNA. Therefore, the sequence of the fragments in the chromosome could only have been: A – B – C – D.

The much larger polyoma genome was mapped by a different procedure. With a single EcoRI cut, the circular DNA was linearized and that cut was designated as the zero coordinate of the map. HindIII cut the circle into two fragments: A = 55% and B = 45% (see Fig. P71). HpaII produced eight fragments: a = 27%, b = 21%, c = 17%, d = 13%, e = 8%, f = 7%, g = 5%, and h = 2% of the total genome. When EcoRI and HpaII cleaved the DNA, fragment b (21%) was not detected by electrophoresis, but instead, two new fragments of 1% and 20% were found. Obviously, the EcoRI cut was 1% from one end and 20% from the other end of fragment b. In the following step, the HindIII is shown to generate a fragment that was digested by HpaII. Fragments c, d, e, g, and h were found again ($17 + 13 + 8 + 5 + 2 = 45$) and two pieces of 3% and 7% were also obtained. When the HindIII fragment of 45% length was exposed to HpaII fragment, f remained intact but two other fragments of 18% and 20% were recovered. Therefore, the fragments could be pieced together as follows:

| | | | | | |
|------------|-----------|---|-----|-----------|-----|
| HindIII A: | 7% | - | 45% | - | 3% |
| | part of a | | | part of b | |
| HindIII B: | 18% | - | 7% | - | 20% |
| | part of b | | f | part of a | |

Figure P71. Fitting the positions of hypothetical double digest fragments

Incomplete digestion of A by HpaII produced fragments: a + c, c + e, e + d, h + g, and g + b, therefore the polyoma DNA appeared as: b – f – a – c – e – d – h – g, with the zero coordinate in b and g near the 100 coordinate.

Larger genomes such as *E coli*, yeast, or those of higher eukaryotes are generally pieced together by a chromosome walking like procedure, using overlapping fragments generated by several restriction endonucleases, e.g.:

Fragments generated by enzyme A :

| | | |
|-------|-----------|-----------|
| 1 | 2 | 3 |
| abcde | fghijklmn | oprstuvwz |

Fragments generated by enzyme B :

| | |
|---------|------------|
| 4 | 5 |
| cdefghi | jklmnoprst |

will be tied into the order 1, 2, 3 on the basis of the hybridization of 4 with 1 and 2, and hybridization of 5 with 2 and 3, but not 5 with 1 or 4 with 3. In the initial steps, generally YAC clones are used because they cover large segments of the genomes. Cosmid clones usually follow this and eventually large

continuities (contigs) are established without gaps. By the employment of anchors, fragments with genetically or functionally known sites, the physical map can be correlated with the genetic map determined by recombination frequencies, and thus *integrated maps* are generated. The individual fragments can then be sequenced and thus maps of ultimate physical resolution can be obtained. ▶RFLP, ▶chromosome walking, ▶FISH, ▶SAGE, ▶integrated map, ▶dynamic molecular combing, ▶anchoring, ▶contigs, ▶cosmids, ▶restriction enzymes, ▶EcoRI, ▶HindIII, ▶HpaII, ▶genomic screening, ▶electronic PCR, ▶PCR; Bhandarkar SM et al 2001 Genetics 157:1021.

Physical Mutagens: The most widely used forms of physical mutagens are *electromagnetic*, ionizing radiations such as X rays and γ rays emitted by radioisotopes. The most commonly used radiation sources for the induction of mutation by γ rays are cobalt⁶⁰ (Co⁶⁰) and cesium¹³⁷ (Cs¹³⁷). *Particulate radiations* such as produced by atomic fission are also ionizing. Ionization is the dislodging of orbital electrons of the atoms. The particulate (corpuscular) radiation source is uranium²³⁵, which releases neutrons, uncharged particles (slightly heavier than that the hydrogen atom) with very high penetrating power and the ability to release about 15 times as much energy along their path as the hard X rays (of short wave length and high energy). The *fast neutrons* have energies between 0.5 and 2.0 MeV (million electron volt). The *thermal neutrons* have much lower level of energy (about 0.025 eV) because they have been “moderated” by carbon and hydrogen atoms. Radioactive isotopes emit also β particles (electrons). Their level of energy and penetrating power depend a great deal on the source; H³ (tritium) has very short path (about 0.5 μ m) and P³² is much more energetic (2600 μ m). Beta emitters are rarely used for mutation induction. They can, however, be incorporated directly into the genetic material by using radioactively labeled precursors or building blocks of nucleic acids, and thus are capable of inducing localized damage, the degree of localization depends on the effective path length. Uranium238 emits α particles (helium nuclei) releasing thousands of times more energy per unit track than X rays. Because of the very low penetrating power, it can be stopped by a couple of sheets of cells in contrast to X rays and gamma rays which require heavy concrete or lead shielding. Alpha radiation, because of its high energy per short path, can very effectively destroy chromosomes. The most common genetic effect of all ionizing radiations is chromosome breakage and particularly deletions.

Another physical mutagen is *ultraviolet (UV)* radiation. The latter causes excitation, rather than

ionization, in the biological material. Excitation may raise the orbital electrons to a higher level of energy, from which they return to the ground state very shortly. UV radiation sources are commonly mercury or cadmium lamps (black light, germicidal, and sun lamps). Natural light also includes UV radiation, especially in the clean air of the higher mountains. Near ultraviolet light, UV-B (290–400 nm) may be present in the emission of fluorescent light tubes and in the presence of sensitizers it may be genetically effective on a few layers of cells. The most common genetic effect of UV light is the production of pyrimidine dimers.

The effect of radiation on cells and organisms may be *direct*, i.e., the radiation actually hits the target molecules or it may be *indirect*, i.e., the radiation produces reactive molecules in the intra- or extra-cellular environment, and these in turn cause the genetic and/or physiological damage. Exposure to high temperature may enhance mutability. If radiation is received during DNA replication, damage is more likely than in the dormant state. Generally, hydrated cells and tissues are more sensitive to ionizing radiation than dry or non-metabolizing cells. ▶X-rays, ▶radioisotopes, ▶radiation effects, ▶ultraviolet light, ▶chemical mutagens, ▶maximal permissive dose, ▶carcinogens, ▶LET, ▶chromosomal mutation, ▶DNA repair, ▶genetic sterilization, ▶cosmic radiation, ▶genomic subtraction, ▶nuclear reactors, ▶atomic radiations, ▶electromagnetic radiation, ▶pyrimidine dimer, ▶cycloputane ring; Hollaender A (ed) 1954–56 Radiation Biology, McGraw-Hill, New York.

Physiology: The discipline dealing with the functions of living cells and organisms.

Phytanic Acid: A 20-carbon, branched chain fatty acid is formed from the phytol alcohol ester of chlorophylls and it degraded by β -oxidation into propionyl-, acetyl-, and isobutyryl-CoA. Deficiency of this oxidation leads to Refsum disease in humans. ▶Refsum diseases, ▶peroxisome

Phytic Acid (inositol hexaphosphoric acid, IP⁶): Phytic acid combined with Ca²⁺ and Mg²⁺ salts are called phytins and are commonly present in plant tissues. Phytate also ties up iron in the plant tissues and limits its availability for human nutrition, unless it is degraded by phytase. ▶myoinositol, ▶phosphoinositides; engineered phytate-free seeds: Stevenson-Paulik J et al 2005 Proc Natl Acad Sci USA 102:12612.

Phytoalexins: Generally relatively low molecular weight, yet diverse, compounds synthesized through the phenylpropanoid pathway. They were attributed to defense systems against various plant pathogens. Currently, they are considered to be mainly consequences of infection rather than active defense

molecules. ►host-pathogen relation, ►phenolics; Hammerschmidt R 1999 Annu Rev Phytopath 37:285.

Phytochromes: Five regulatory proteins with alternating absorbance peaks in red and far-red light (see Fig. P72). Through their absorbance peaks (red [R] 660 nm and far-red [FR] 730), they control various photomorphogenic processes, such as short- and long-day onset of flowering, hypocotyl elongation, apical hooks, pigmentation, etc. These chromoproteins are homodimers of 124 kDa subunits and a tetrapyrrole complex, joined covalently through a cysteinyl residue at about 1/3 distance from the NH₂ end. The molecule exists in two conformations corresponding to the R and FR absorption states. The interconversion between these states is mediated very rapidly by light of R and FR emission peaks. In etiolated plant tissue, the inactive P_r conformation may constitute up to 0.5% of the protein. The transition from the P_r conformation into the active P_{fr} form also entails the degradation of this receptor. The apoprotein, coded by different genes (*PHYA* and *PHYB*) in *Arabidopsis* may have only about 50% homology in amino acid sequences, although they bind the same chromophore. The specificity of PhyA (far-red) and PhyB (red) resides in the N-termini. The C-terminal domain of phytochrome B attenuates the transducing signals (Matsushita T et al 2003 Nature [Lond] 424:571). Phytochromes can induce and silence the expression of genes in a specific selective manner. The transcription of the phytochrome genes is also light regulated; R light reduces the transcription more effectively than FR. Phy-A perceives continuous FR, whereas phy-B responds to continuous red light.

Phytochrome B is also a photoreceptor in the circadian rhythm. Phytochrome A appears to be

serine/threonine kinase. Phytochrome C is a light-stable molecule. SPA1 (suppressor of phy-A), a WD-protein with sequence similarity to protein kinases, mediates, among other factors, the photomorphogenic reactions. The phytochrome responses are under complex genetic regulatory systems involving light response elements, transcription factors, and components of the signal transduction circuits. PIF3 (phytochrome-inducing factor) is a basic helix-loop-helix protein that attaches to the non-photoactive C-terminus of phytochromes A and B and mediates their conversion into active forms. PIF3 also binds to a G-box in the promoter and thus regulates transcription. Nucleoside diphosphate kinase 2 (NDPK2) preferentially binds to the red light activated form of phytochrome and appears to play a role in eliciting light responses. In photomorphogenic responses, phytochromes interact with cryptochromes. Although phytochrome is known as a ubiquitous plant product, the yeast *Pichia* also synthesizes phytochromobilin (PΦB), a precursor of this plant chromophore. PΦB deficient plants can be complemented by the insertion of the algal phycocyanobilin gene (Kami C et al 2004 Proc Natl Acad Sci USA 101:1099). Also, a phytochrome-like protein (Ppr) has been identified in non-photosynthetic prokaryotes (*Deinococcus radiodurans*, *Pseudomonas aeruginosa*). In the *Rhodospirillum rubrum*, a purple photosynthetic bacterium, a photoreactive yellow (PYP) pigment has been identified with a central domain resembling phytochromes.

In cyanobacteria, the circadian input kinase (CikA), a bacteriophytochrome, mediates the circadian oscillations. ►photoperiodism, ►photomorphogenesis, ►signal transduction, ►phycobilins, ►cryptochromes, ►brassinosteroids, ►WD-40, ►G box; Neff MM et al 2000 Genes Dev 14:257; Martinez-Garcia JF et al 2000 Science 288:859; Smith H 2000

Phytoplankton: Aquatic, free-flowing plants. ▶[bacterioplankton](#)

Phytoplasmas (Mollicutes, 530–1350 kbp circular DNA): Minute, round (200–800 μm or filamentous) bacteria without cell wall, infecting the phloem cells of plants and causing disease. The symptoms vary from yellowing to sterility, stunting, and heavy branching. Phytoplasmas resemble somewhat mycoplasmas of animals but cannot be cultured in cell-free media. They are propagated by sucking insects that cause economic loss in vegetables and trees. Phytoplasma infection may be exploited for gain by floriculture to obtain bushier Poinsettias (Lee I-M

et al 1997 Nature Biotechnol 15:178). Phytoplasmas may be identified by DNA-DNA hybridization and serological means. ▶[mycoplasma](#), ▶[phyllody](#); Lee IM et al 2000 Annu Rev Microbiol 54:221.

Phytoremediation: ▶[bioremediation](#)

Phytosulfokines (PSK): PSK- α , a sulfated pentapeptide, and PSK- β , a tetrapeptide, are cell proliferation promoting compounds of plants.

Phytotron: A plant growth chamber system with maximal physical regulation facilities.

Pi: Inorganic phosphate.

pI (pH_I): Isoelectric point. ▶[isoelectric focusing](#)

PI 3 Kinase: ▶[phosphoinositide 3 kinase](#)

PI Vector: The PI vector contains packaging site (*pac*) and allows about 115 kb to be packaged, and it infects *E. coli* at a pair of *lox P* recombination sites, at which the *Cre* recombinase circularizes DNA inside the host cell. ▶[vectors](#)

Pibids: ▶[trichothiodystrophy](#)

PIC (preinitiation complex): Proteins associated with RNA polymerase before transcription. During pre-initiation, the carboxyterminal domain (CTD) is hypophosphorylated but during initiation, the movement four kinases in a step-wise manner phosphorylate the RNA polymerase. Phosphorylation regulates the attachment of additional proteins. ▶[transcription factors](#), ▶[open promoter complex](#), ▶[TBP](#), ▶[transcript elongation](#), ▶[chromatin remodeling](#), ▶[mediator complex](#); He S, Weintraub SJ 1998 Mol Cell Biol 18:2876; Tsai FT, Sigler PB 2000 EMBO J 19:25; Soutoglou E, Talianidis I 2002 Science 295:1901; Wilcox CB et al 2004 Genetics 167:93; Chen H-T, Hahn S 2004 Cell 119:169.

PIC: ▶[polymorphic information content](#)

Pick Disease (FTDP-17, frontotemporal dementia and parkinsonism): A chromosome 17q21.11 dominant behavioral, cognitive, and motor disease involving variable loss and atrophy of the frontal and temporal part of the brain, caused by defects in the splicing of the Tau microtubule-associated protein. The mutations responsible for the conditions occur in exon 10 of Tau or in its 5'-splicing site, resulting in duplications in Tau mRNA (14q24.3). Frontotemporal dementia (FTD) may be tau-negative in case of mutation/loss of progranulin, a 68.5 kDa regulatory protein encoded at 17q21.31 (Baker M et al 2006 Nature [Lond] 442:916; Cruts M et al 2006 Nature

[Lond] 442:920). ►dementia, ►Parkinsonism, ►tau, ►RNAi

Picornaviruses: The single-stranded RNA genomes of picornaviruses, measuring about 7.2 to 8.4 kb (ca. 2.5 to 2.9×10^6 Da), are transcribed into four major polypeptides. Their RNA transcript lacks the 5' cap in the mRNA, characteristic for other eukaryotic viruses. A functional picornavirus IRES in a dicistronic mRNA may support the activity, not only of the downstream, but also of the upstream reporter gene at high salt concentrations in *cis*. Analysis of different experimental parameters influencing this effect shows that the enhanced availability of the initiation factor eIF4F provided by a functional picornavirus IRES on the same RNA molecule in *cis* causes this translation enhancement effect (Jünemann C et al 2007 J Biol Chem 282:132). They include *enteroviruses* (a group of mostly asymptomatic intestinal viruses. The paralytic *poliovirus* may also belong to this group). *Cardioviruses* (responsible for myocarditis [causing inflammation of the heart muscles] and encephalomyelitis [inflammation of the brain and heart]), *rhinoviruses* (in over 100 variants responsible for the common cold and other respiratory problems in humans and animals), and *aphthoviruses* (causing foot-and-mouth disease in cattle, sheep and pigs and occasionally infecting also people) are other types of picornaviruses. The *hepatitis virus* may also be classified among the picornaviruses. ►papovaviruses, ►animal viruses, ►coxsackie virus, ►polio virus, ►IRES, ►eIF-4F; Knipe DM et al (Eds.) 2001 Fundamentals of Virology, Lippincott Williams & Wilkins, Philadelphia, Pennsylvania.

PIDD: A p53-inducible death domain protein, which promotes apoptosis. ►death domain, ►apoptosis, ►p53

PIE: Polyadenylation inhibition element. ►polyadenylation signal

Piebaldism: Piebaldism in animals is the result of hypomelanosis (low melanin), it is generally restricted to spots on the body; white spots occur on a black background. It may be a mutation of the KIT oncogene (4q12), or may be due to other factors. ►albinism, ►nevus, ►vitilego, ►melanin, ►Himalayan rabbit, ►mouse, ►pigmentation in animals, ►KIT oncogene, ►spotting, ►Hirschsprung disease, see Fig. P74.

Figure P74. Piebald rat

Pierre-Robin Syndrome: An autosomal recessive defect, involving the tongue (glossoptosis), small jaws (micrognathia), and sometimes cleft palate and syndactyly of toes. In an autosomal dominant form, reduced digit number (oligodactyly) is also found. There is also an X-linked form involving clubfoot and heart defect. Another X-linked form shows and increase in the number of the bones in the digits (hyperphalangy). (See terms under separate entries).

Piezoelectric Mechanism: By piezoelectric mechanism, crystalline material, under pressure, may generate electricity. Also, expansion and contraction may take place in matter in response to alternative electric current mechanical stress. This latter property has been exploited for insertion of cell nuclei into eggs after the destruction of its original egg nucleus. This type of nuclear transplantation may help achieve cloning of higher animals. ►nuclear transplantation

PIF: Proteolysis inducing factor.

PIG (*Sus crofa*): $2n = 38$. The domesticated breeds are the descendants of the crosses between the European wild boar and the Chinese pigs and they can still interbreed with the wild forms of similar chromosome number. The wild European pig is $2n = 36$. The Caribbean pig-like peccaries (*Tayassuidae*) are $2n = 30$. There are about 300 breeds of the domesticated pig. The various breeds of minipigs weigh generally less than 50 pounds as adults and are used for biomedical research. Sexual maturity sets in by about five to six months and the gestation period is about 114 days. It is a multiparous species with a litter size of 4–12. By adult somatic cell nuclear transplantation, live clones can be produced. ►animal genetics; Polejaeva IA et al 2000 Nature [Lond] 407:86; dispersal in Southeast Asia: Larson G et al 2007 Proc Natl Acad Sci USA 104: 4834; nuclear transplantation: <http://www.toulouse.inra.fr/lgc/pig/hybrid.htm>; <http://www.animalgenome.org/QTldb/>; <http://www.piggenome.org/>; <http://ascswine.rnet.missouri.edu/Description.html>; <http://www.piggis.org/>; <http://pig.genomics.org.cn/>.

Pigeon: *Columbia livia*, $2n = 80$. Great morphological variations among the various breeds of pigeons had already caught Darwin's attention, who made a few crosses between "pure races" and observed some "mendelian" patterns (see Fig. P75). Homing pigeons follow important landmarks such as railway tracks and highways as guided by their learned memory (Lipp H-P et al 2004 Curr Biol 14:1239). The "homing" ability, i.e., pigeons can return from great distances, is probably based on magnetoreception of the earth magnetic field facilitated by the upper beak

area and may be aided also by olfactory nerves (Mora CV et al 2004 Nature [Lond] 432:508).

Figure P75. Variations in pigeons

PiggyBac: A cabbage moth (*Trichoplusia ni*) transposon-derived transformation vector of several different insect species. It is 2.5 kb with 13 bp inverted terminal repeats and contains a 2.1 kb open reading frame. Its specific target is TTAA. PiggyBac is particularly useful for large-scale and general disruption of *Drosophila* genes (Thibault S et al 2004 Nature Genet 36:283). PiggyBac efficiently transposes also in human and mouse cells (Ding S et al 2005 Cell 122:473). The high transposition activity of *piggyBac* and the flexibility for molecular modification of its transposase suggest the possibility of using it routinely for mammalian transgenesis (Wu SC-Y et al 2006 Proc Natl Acad Sci USA 103:15008). Frequently green fluorescent protein marker is used for its easy detection. ▶transposon, ▶open reading frame, ▶transposon vector, ▶sleeping beauty, ▶GFP; Handler AM et al 1998 Proc Natl Acad Sci USA 95:7520; Horn C et al 2003 Genetics 163:647; inducible piggyBac: Cadiñanos J, Bradley A 2007 Nucleic Acids Res 35(12):e87.

Pigment Epithelium-Derived Factor (PEDF): A potent inhibitor of angiogenesis of the retina. Its defect leads to opacity of vision and blindness. ▶angiostatin, ▶endostatin, ▶thrombospondin, ▶angiogenesis

Pigmentation Defects: ▶albinism, ▶piebaldism, ▶hypomelanosis, ▶incontinentia pigmenti, ▶pigmentation in animals, ▶LEOPARD syndrome, ▶Fanconi anemia, ▶hematochromatosis, ▶neurofibromatosis, ▶tuberous sclerosis, ▶Waardenburg syndrome, ▶Hermansky-Pudlak syndrome, ▶polyposis hamartomatous, ▶Addison disease, ▶focal dermal hypoplasia, ▶erythralgia, ▶skin diseases

Pigmentation of Animals: In mammals, tyrosine is the primary precursor of the complex black pigment

melanin. The enzyme tyrosinase (located in the melanosomes) hastens the oxidation of dihydroxyphenylalanine (DOPA) into dopaquinone, which is changed by non-enzymatic process into leukodopachrome. Leukodopachrome is an indole-derivative that is oxidized also by tyrosinase into an intermediate of 5,6-dihydroxyindole. After another step of oxidation, indole-5,6-quinone is formed. Coupling the latter to 5,6-dihydroxyindole is the first step in the addition of further dihydroxyindole units in the process of polymerization to melanin. When cysteine is combined with dopaquinone, through a series of steps, reddish pigments are formed in hair and feathers. The different pigments may have also other adducts at one or more positions to yield various colors. In the formation of the eye color of insects, tryptophan is a precursor to the formation of formylkynurenine → kynurenine → hydroxykynurenine → ommin, ommatin. The catabolic pathway of amino acids contributes to the formation of guanine and through the latter to pteridines that contribute to the coloration of insects, amphibians, and fishes, and serves also as a light receptor. The Xanthopterin and leucopterin account for the yellow and white pigmentation of butterflies, sepiapterin, is found in the eyes of *Drosophila* and biopterin is found in the urine and liver of mammals. The degradation of the heme group yields a linear tetrapyrrole from which the bile pigment biliverdin and ultimately bilirubin diglucuronide is synthesized. Bilirubin diglucuronide is secreted into the intestines and may accumulate in the eyes and other organs causing jaundice when the liver does not function normally. Oxidized derivatives of bilirubin, urobilin, and stercobilin color the urine. Mutations were detected already during the early years of genetics that block the biosynthetic paths of these pigments and thus contribute to understanding how genes affect the phenotype. The color of the skin in humans is determined by its melanin content. Pheomelanin is a reddish pigment and eumelanin is black. The former is responsible for the light skin and red hair color and it also potentially generates free radicals and thus may make the individual susceptible to UV damage. Eumelanin provides protection against UV. The melanocyte-stimulating hormone (MSH) and its receptor (MC1R) regulate the relative proportion of these two melanins. A putative cation exchanger (SLC24A5, human chromosome 15q21) has modulatory effect on the formation of melanosomes and due to different single nucleotide polymorphisms has impact on the determination of pigmentation, depending also on the climatic regions and exposure to sunlight (Lamson RL et al 2005 Science 310:1782). In mice, about 100 genes are known that control pigmentation. Differences in the pigmentation of the

human skin in various geographic areas of the world seem to be correlated with the degree of exposure to ultraviolet radiation. ▶chorismate, ▶tryptophan, ▶tyrosine, ▶phenylalanine, ▶albinism, ▶melanin, ▶eye color in humans, ▶Himalayan rabbit, ▶Siamese cat, ▶pigmentation in plants, ▶agouti, ▶melanocyte-stimulating hormone, ▶hair color, ▶tanning, ▶opiocortin; hair and skin color: Rees JL 2003 Annu Rev Genet 37:67; Price T Borntrager A 2001 Curr Biol 11:R405; evolution, genetics, physiology [folate, vitamin D, UV light exposure] and variation in human skin color: Jablonski NG 2004 Annu Rev Anthropol 33:585; Sturm RA 2006 Trends Genet 22:464; Lin JY, Fisher DE 2007 Nature [Lond] 445:843.

plgR (polymeric immunoglobulin receptor): ▶antibody polymers

P_{II}: P_{II} proteins (are involved in bacterial glutamine synthesis) accelerate hydrolysis of NtrC in the presence of NtrB and ATP in limited N supply and low levels of 2-ketoglutarate. P_{II} uridylylation permits the increase of NtrC-phosphate level and increases transcription from the glnAp2 promoter. In excess N supply, P_{II} is not altered resulting in no NtrC build-up and glnA2 activation ceases. ▶NtrB, ▶NtrC, ▶glnAp

PI3K (PI(3)K): ▶PIK

PIK/PI(3)K (phosphatidylinositol kinases): PI(3)K preferentially phosphorylates the 3 and 4 positions on the inositol ring. PIK-catalyzed reaction products (PtdIns) are second messengers. They participate in meiotic recombination, immunoglobulin V(D)J switches, chromosome maintenance and repair, progression of the cell cycle, etc. The mouse Pik3r1 regulatory gene encodes proteins p85 α , p55 α , and p50 α . p55/p50 are essential for viability. Their defect may lead to immunological disorders and cancer. In ovarian cancer, increase of PIK3CA and increased PIK activity were detected. In different types of human cancers, mutations in the catalytic subunit is high (Samuels Y et al 2004 Science 304:554). PIK inactivation of its γ -subunit may lead to invasive colorectal cancer in mice. PI3K γ may signal to phosphokinase B or to MAPK. PI3K is negatively controlled by PTEN. PIK related kinases are TOR, FRAP, TEL, MEI, and DNA-PK. Their inhibitor is wortmannin. ATM, ATR, DNA-P-related protein kinases, ATRIP, and Ku80 share a terminal amino acid sequence motif (734 AKEESLADDLFRYN-PYLKRRR) of the Nijmegen breakage syndrome (Nbs1) protein that recruits these kinases to the site of DNA damage and cell cycle checkpoint control and repair (Falck J et al 2005 Nature [Lond] 434:605). The nuclear GTPase PIKE enhances PIK activity and

is regulated by protein 4.1N. ▶phosphatidylinositol, ▶second messenger, ▶immunoglobulins, ▶DNA repair, ▶ATM, ▶ATR, ▶DNA-PK, ▶Ku, ▶ATRIP, ▶Nijmegen breakage syndrome, ▶cell cycle, ▶wortmannin, ▶MEC1, ▶phosphoinositides, ▶PTEN, ▶protein 4.1N, ▶colorectal cancer, ▶chemotaxis, ▶Langerhans islets; Kuruvilla FG, Schreiber SL 1999 Chem Biol 6:R129; Katso R et al 2001 Annu Rev Cell Dev Biol 17:615.

Pileus: The umbrella-shaped fleshy mushroom fruiting body. Also, it is a membrane that may be present on the head of newborns.

Pilin: The protein material of the pilus. ▶pilus

Pilomatricoma: Usually benign, calcifying skin tumors, densely packed by basophilic cells and developing into hair follicle-like structures. Their origin is attributed to mutation in LEF/ β -catenin. ▶LEF, ▶catenins, ▶basophil, ▶follicle

PILR α : Inhibitory receptor of myeloid cell encoded at human chromosome 7q22. ▶ITIM

Pilus: A bacterial appendage, which may be converted into a conjugation tube through which the entire or part of the replicated chromosome is transferred from a donor to a recipient cell (see Fig. P76). It may also serve as protein conduit. In pathogenic enterobacteria (*Neisseria gonorrhoea*, *Vibrio cholerae*) and in some types of *E. coli*, the so-called pilus type IV may be formed. It facilitates bacterial aggregation (bundle-forming pilus, BFP, encoded by a 14-gene operon), and the expression of the LEE (enterocyte effacement) element enhances the association of the bacteria with the mucous intestinal membranes and triggers diarrhea. The pilin protein may undergo antigenic variation to escape host defenses. The pilus may also form an attachment to the invaded eukaryotic cell. ▶conjugation, ▶conjugation mapping, ▶PapD, ▶pilin, ▶antigenic variation, ▶mating bacterial, ▶shoufflon, ▶pseudopilus [ψ -pilus]; Jin Q, He S-Y 2001 Science 294:2556.

Figure P76. Pilus

PIM Oncogene: The PIM oncogene is located in human chromosome 6p21-p12 and in mouse chromosome 17. The gene is highly expressed in blood-forming (hematopoietic) cells and myeloid cells and over-expressed in myeloid malignancies and some leukemias. The human protein is a serine/threonine kinase. ▶[oncogenes](#), ▶[serine/threonine kinases](#)

Pimento (*Pimento dioica*): Also called allspice. Tropical dioecious spice tree; $2n = 2x = 22$.

PIN1: A peptidyl-prolyl cis/trans isomerase in human cells. It is important for protein folding assembly and/or transport. Its deficiency leads to mitotic arrest, while its overproduction may block the cell cycle in G2 phase. It interacts with NIMA kinase. PIN1 membrane protein of plants regulates auxin transport. ▶[cell cycle](#), ▶[NIMA](#), ▶[parvulin](#)

PIN⁺: The prion form of the yeast protein Rnq1. ▶[prion](#); Bradley ME, Liebman SW 2003 Genetics 165:1675.

pin: The promoter of the transposase gene of a transposon. There are two GATC sites involved in *dam* methylation within pin. ▶[RNA-IN](#), ▶[dam](#)

Pinch: A group of proteins with LIM and additional domain(s). ▶[CRP](#), ▶[LMO](#), ▶[LIM domain](#)

Pineal Gland: The site of melatonin synthesis and photoreception in the brain. ▶[melatonin](#), ▶[opsins](#), ▶[Rabson-Mendenhall syndrome](#), ▶[brain](#)

Pineapple (*Ananas comosus*): A monocotyledonous tropical or subtropical plant ($2n = 50, 75, 100$). The flowers and bracts sit on a central axis and form fleshy fruits. The lack of seeds is caused by self-incompatibility of the commercial varieties but they develop seeds if allowed to cross-pollinate with other varieties. ▶[seedless fruits](#)

Pines (*Pinus* spp): Trees, all 94 species are $2n = 2x = 24$. ▶[spruce](#)

Ping-Pong Kinetics: The property of some dimeric or multimeric enzymes catalyzing two “half reactions.” First, they release the first product and form an enzyme intermediate before binding of the second substrate. After the second reaction and release of the product, the enzyme returns to the initial state. (See Frank RAW et al 2004 Science 306:872).

Pinna: The ear lobe, the lobe of a compound leaf or frond. ▶[hairy ear](#)

Pinning: Pinning uses a floating replication tool with about 100 or more pinheads to test yeast colonies on different culture media. ▶[replica plating](#)

Pinocytosis: The formation of ingestion vesicles for fluids and solutes by the invagination of membranes of eukaryotic cells. ▶[phagocytosis](#), ▶[endocytosis](#)

Pinosome: A small cytoplasmic vesicle originating by invagination of the cell membrane. ▶[endocytosis](#)

PinPoint Assay: The PinPoint assay identifies single nucleotide polymorphism (SNIP). The polymorphic DNA site is extended by a single nucleotide with the aid of a primer annealed immediately upstream to the site. The extension products are analyzed by MALDI-TOF mass spectrophotometry. ▶[SNIP](#), ▶[primer extension](#), ▶[MALDI-TOF](#); Haff LA, Smirnov IP 1997 Genome Res 4:378.

PIN*POINT (protein position identification with a nuclease tail): An in vivo method to ascertain the position of the critical promoter-binding proteins involved in the LCR. Fusion proteins with an unspecific nuclease tail are studied for how the cleavage position affects the expression of the gene (s). ▶[LCR](#); Lee J-S et al. 1998 Proc Natl Acad USA 95:969.

PIP: Phosphatidylinositol phosphate. ▶[phosphoinositides](#), ▶[PIP2\[PIP₂\]](#), ▶[PIP3](#)

PIP2: Phosphatidylinositol (4,5)-bisphosphate is involved (with PIP3) in mediating the inositol phospholipid signaling pathway and in the activation of phospholipase C (PLC). PIP₂ also controls the ATP-regulated potassium ion channel (K_{ATP}) by binding to the intracellular C-domain of the channel protein and interfering with the binding of ATP. Since K_{ATP} channels affect pancreatic β cells and vascular and cardiac muscle tone, they may have relevance for human diseases, e.g., diabetes. Pleckstrin homology domains selectively bind phosphoinositides. ▶[phosphoinositides](#), ▶[PITP](#), ▶[ion channels](#), ▶[diabetes](#), ▶[InsP](#), ▶[pleckstrin](#), ▶[TIRAP](#); Martin TF 2001 Curr Opin Cell Biol 13:493.

PIP3 (phosphoinositol-3,4,5-trisphosphate): An intracellular messenger and stimulator of insulin, epidermal growth factor, etc., that works by adding another phosphate to PIP2 and activating PKB. ▶[PKB](#), ▶[PTEN](#), ▶[chemotaxis](#), ▶[InsP](#); Hinchliffe KA 2001 Curr Biol 11:R371.

Pipecolic Acid (homoproline): An intermediate in lysine catabolism (see Fig. P77). Increase of pipecolic acid (hyperpipecolathemia/hyperpipecolicacidemia) in the blood plasma and urine leads to increase in the size of the liver (hepatomegaly), resulting in growth retardation, vision defects, and demyelination of the nervous system.

Figure P77. Pipecolic acid

Pipes (piperazine-*N,N'*-bis(2-ethanesulfonic acid): A buffer within the pH range of 6.2–7.3.

PIR (protein information resource): ►MIPS; <http://pir.georgetown.edu/>.

PIR-A, PIR-B: Immunoglobulin-like regulatory molecules (activator/inhibitor) on murine B cells, dendritic cells, and myeloid cells. A single gene encodes Pir-B whereas a multigene family encodes the six Pir-A proteins. ►ITIM; Dennis G Jr et al 1999 J Immunol 163:6371.

Piriformospora indica: Root endophytic fungus that may associate with both dicotyledonous and monocotyledonous plants and convey resistance to fungal disease, salt tolerance, improved nitrogen metabolism, and lead consequently to higher yield. ►symbiont, ►host–pathogen relationship, ►salt-tolerance; Waller F et al 2005 Proc Natl Acad Sci USA 102:13386.

piRNA (Piwi interacting RNA): 26-31-nucleotide-long RNA regulating germ and stem cell development when bound to Argonaute family proteins (Aubergine, Piwi, Ago3). In mouse, the MIWI/Piwi RNA associates with the polysomes and chromatoid body during spermatogenesis (Grivna ST et al 2006 Proc Natl Acad Sci USA 103: 13415). It is involved also in regulating transposons activity (Brennecke J et al 2007 Cell 128:1089). ►RNAi, ►Argonaute, ►chromatoid body, ►Slicer; Aravin A et al 2006 Nature [Lond] 442:203; Girard A et al 2006 Nature [Lond] 442:199; review: O'Donnell KA, Boeke JD 2007 Cell 129:37.

PISA (protein in situ assay): In the PISA assay, PCR-generated DNA fragments are transcribed and translated in a cell-free protein expression system on a coated microtiter plate where the protein was immobilized. Single chain antibody fragments and luciferase have been successfully arrayed. ►PCR; He M, Taussig MJ 2001 Nucleic Acids Res 29(15):E73.

Pistil: A central structure of flowers (gynecium) consisting of the stigma, style, and ovary. ►gametophyte female, ►gametophyte male, ►flower differentiation

Pistillate: Flower or plants that carries the female sexual organs. A female parent in plants.

Pisum sativum (pea): A legume ($2n = 14$). It played an important role in establishing the Mendelian principles of heredity and contributed further information on genetics. Curiously, the famous “wrinkled” gene of Mendel turned out to be an insertional mutation. ►pea

Pit: An indentation. Also, the stony endocarp of some fruits, e.g., plums, apricot, cherry.

Pitalre (cdk9): ►acquired immunodeficiency, ►TEFb; Darbinian N et al 2001 J Neuroimmunol 121:3

Pitch: The length of a complete turn of a spiral (helix) and the translation per residue is the pitch divided by the number of the residues per turn. In a keratin alpha helix, it is $0.54 \text{ nm}/3.6 = 0.15 \text{ nm}$. Also, a dark black residue after distillation. The auditory pitch is the physiological response of the ear to sound depending on the frequency of vibration of the air. Pitch-selective neurons are located in the auditory cortex of the brain in monkeys and humans (Bendor D, Wang X 2005 Nature [Lond] 436:1161). Perfect/absolute pitch is ability for recognizing musical notes by talented artists. ►musical talent, ►prosody

Pith: The parenchyma tissue in the core of plant stems, e.g., in elderberry (*Sambucus*).

Pithecia (saki monkey): ►Cebidae

PITP (phosphatidylinositol transfer proteins, 35 and 36 kDa): PITP is required by for the hydrolysis of PIP₂ (phosphatidyl-inositol bis-phosphate) by PLC (phospholipase C). In a GTP-dependent signal pathway, PITP is required also by epidermal growth factor (EGF) signaling. ►PIP, ►PIP₂, ►EGF, ►GTP, ►phosphoinositides; Cockcroft S 1999 Chem Phys Lipids 98:23.

PI-TR: Phosphatidylinositol transfer protein involved in transfer of lipids among organelles within cells.

PITSRE: Members a cyclin-dependent protein kinase family involved in RNA transcription or processing. They are associated with ELL2, TFIIF, TFIIS, and FACT. ►ELL, ►transcription factors, ►TFIIS, ►protein 14-3-3; Trembley JH et al 2002 J Biol Chem 277:2589.

Pituitary (hypophysis): The hypophysis is located at the base of the brain and is connected also to the hypothalamus (a ventral part of the brain). The anterior part secretes the pituitary hormones and the posterior part stores and releases them. ►brain human, ►gonads, ►septo-optic dysplasia; Fauquier T et al 2001 Proc Natl Acad Sci USA 98:8891; Scully KM, Rosenfeld MG 2002 Science 295:2231.

Pituitary Dwarfism: Pituitary dwarfism is due to recessive mutation, deletion, or unequal crossing over in the gene cluster containing somatotropin and homologs in human chromosome 17q22-q24. Administration of somatotropin may restore growth. The defect may also be in the hormone receptor (human chromosome 5p13.1-p12, mouse chromosome 15) and in these cases, the growth hormone

level may be high (Laron types of dwarfisms). The level of somatomedin (insulin-like growth factors) may also be low. Somatomedin is a peptide facilitating the binding of proteins and in addition shows insulin-like activity. In either case, dwarfism may result. Dominant-negative mutations in IGHD2 (isolated growth hormone deficiency) are also known. ►dwarfism, ►GH, ►insulin-like growth factor, ►hormone receptor, ►binding protein, ►stature in humans, ►pituitary gland, ►growth hormone pituitary; Machinis K et al 2001 Am J Hum Genet 69:961.

Pituitary Hormone Deficiency, Combined Familial: The pituitary hormone deficiency fails to produce normally one or more of these hormones—growth hormone (HGH), prolactin, and thyroid-stimulating hormone (TSH)—because of mutation in the POU1F1 gene (3p11). Mutation in the PROP1 gene (5q), however, cannot produce luteinizing hormone (LH) and follicular stimulating hormone (FSH). Corticotropin deficiency is caused by mutation in the LHX4 gene. LHX3 is a homeobox gene with LIM repeats. ►animal hormones

Pituitary Tumor (GNAS1, 20q13.2): Pituitary tumor is caused by autosomal dominant mutations in the α chain of a G-protein (G_s). This protein is also called gsp (growth hormone secreting protein) oncoprotein. The human securin, mediating sister chromatid cohesion, has substantial sequence homology with the pituitary tumor-transforming gene. Securin may block sister chromatid separation and thereby can be responsible for chromosome loss or gain, common characteristics of tumors. ►G-protein, ►McCune-Albright syndrome, ►sister chromatid cohesion

Piwi: ►piRNA

Pixel: A picture element in the computer that represents a bit on the monitor screen or in the video memory. ►bit, ►byte

pK_a: The negative logarithm of the dissociation constant K_a; stronger acids have higher pK_a whereas weaker acids have lower. The dissociation of weaker acids is higher and that of stronger acids is lower. (See <http://www.jenner.ac.uk/PPD/>).

PKA: Protein kinase A (activated by cAMP). There are two types, PKA-I and PKA-II; they share a common catalytic subunit (C) but distinct regulatory subunits, RI and RII. RI/PKA-I controls positively cell proliferation and neoplastic growth. RII/PKA-II controls growth inhibition, differentiation, and cell maturation. RI is detectable in many types of cancers. Antisense methylphosphonate RNA of the RI_α subunit has been known to arrest proliferation of cancer cells without toxicity to normal cells. ►protein

kinases, ►antisense technologies, ►cocaine, ►export adaptors

PKB (protein kinase B): A serine/threonine kinase, the same as Rac or Akt. It is activated by phosphatidylinositol-3,4,5-trisphosphate by binding to its pleckstrin homology domain. ►CaM-KK, ►protein kinases, ►phosphoinositides, ►pleckstrin domain

PKC: Protein kinase C. ►protein kinases

PKD: ►polycystic kidney disease

PKI (protein kinase I): A small protein, which attaches to the catalytic subunits of the heterotetrameric PKA and, with the aid of its nuclear localization sequence (NES), sends the complex to the nucleus. ►export adaptors, ►PKA, ►nuclear localization sequence

PKR: A double-stranded RNA-dependent serine-threonine protein kinase, involved in NF- κ B signaling. One of the most important targets of PKR is the eIF-2A translation factor and thus, protein synthesis. It may control cell division, apoptosis, and may serve as tumor suppressor. Translation is required for viral infection of mammalian cells. Viral infection may trigger the activation PKR as a defense against infection through shutting off protein synthesis. PKR inhibits protein synthesis by autophosphorylation and phosphorylation of the Ser51 residue of eIF2 α . Mutation at the Thr446 site prevents autophosphorylation at the catalytic domain activation segment and impairs phosphorylation of eIF2 α and viral binding (Dey M et al 2005 Cell 122:901). The PKR active cell may succumb to apoptosis but the animal may survive. Several viruses (adenovirus, vaccinia virus, HIV-1, hepatitis C, poliovirus, SV40, etc.) use various mechanisms to inhibit activation of PKR by interfering either with its dimerization or RNA binding, or regulation of eIF-2A, etc. PKR preferentially binds mutant huntingtin protein in Huntington disease. ►NF κ B, ►oncolytic virus, ►reovirus, ►eIF-2A, ►PERK, ►interferon, ►apoptosis, ►Huntington's chorea; Kaufman RJ 1999 Proc Natl Acad Sci USA 96:11693.

PKS Oncogenes: PKS oncogenes are located in human chromosomes Xp11.4 and 7p11-q11.2. These genes display very high homology to oncogene RAF1 and apparently encode protein serine/threonine kinases. ►raf, ►oncogenes

PKU: ►phenylketonuria

PLAC: Plant artificial chromosome. ►artificial chromosome, ►YAC

Place Cells: Place cells in the brain are the locations for the firing of specific nerve cells.

Placebo: A presumably inactive but similar substance used in parallel to different individuals in order to serve as a concurrent (unnamed) control for testing the effect of a drug. In some instances the placebo has positive effects not by physical or chemical properties but by expectation-caused dopamine release, e.g., in Parkinson disease. ▶concurrent control, ▶double-blind test; de la Fuente-Fernández R et al 2001 Science 293:1164; Ramsay DS, Woods SC 2001 Science 294:785.

Placenta: The maternal tissue that is in most intimate contact with the fetus through the umbilical chord, found within the uterus of animals. Most commonly, the placenta is located on the side of the uterus; the placenta praevia is situated at the lower part of the uterus. The latter situation may be correlated with the age of the mother. Also, placenta refers to the wall of the plant ovary to which the ovules are attached. During pregnancy, the placenta of eutherian mammals includes both maternal and zygotic tissues in close association (feto-maternal interface). The interaction between these two types of tissues is essential for normal embryo development and viability of the conceptus. In normal pregnancy, the uterus is invaded by the cytotrophoblasts (the nutritive cells of the conceptus) but defects in the cell adhesion system may adversely affect the pregnancy and may lead to eclampsia. In embryonic tissues of mouse, after 10.5 day hematopoietic stem cells develop to an extent comparable to the aorta-gonad-mesonephros (AGM) region (Gekkas C et al 2005 Dev Cell 8:365). The mesonephros is part of the embryonic kidney tissue. ▶eclampsia, ▶imprinting, ▶incompatibility; Zhou Y et al 1993 J Clin Invest 91:950; Georgiades P et al 2001 Proc Natl Acad Sci USA 98:4522; placenta of animal species: <http://medicine.ucsd.edu/cpa/>.

Placode: A heavy embryonal plate of the ectoderm from which organs may develop. ▶ecto-derm, ▶AER, ▶ZPA, ▶organizer, ▶neural crest, ▶germ-layer

PLADs (pro-ligand-binding assembly domains): aggregate the (death) receptors before binding the ligands. ▶death receptors

Plagiarist: ▶publication ethics, ▶ethics

Plague: The term plague has been used to loosely define widespread, devastating diseases. Strictly, the term applies today to infection by the *Pasteurella pestis* (*Yersinia pestis*) bacterium. The disease may occur in three main forms: *bubonic* plague (most important diagnostic features of is swelling lymph nodes, particularly in the groin area), *pneumonic* plague (attacking the respiratory system) and *septicemic* plague (causing general blood poisoning). Many of its symptoms overlap with those of other infectious

diseases. A 1°C increase in spring temperature and wetter summers may increase the carrier gerbil (rodent) population and can result in >50% increase of the prevalence of plague in Central Asia (Stenseth NC 13110). It used to be known also as the “black death” on account of the dark spots, appearing in largely symmetrical necrotic tissue with coagulated blood. The bacilli spreads to human populations from rodents by fleas, but infections occur also through cough drops of persons afflicted by pneumonic plague. Various animal diseases are also called plague (*pestis*) but, except those in rodents, are caused by other bacteria or viruses. Pasteurellosis can be effectively treated with antibiotics although some strains become resistant to a particular type of antibiotics (streptomycin, chloramphenicol). Eradication of rodent pests is the best measure of prevention. During the great epidemics in the 14th century, the disease claimed an estimated 25 million victims. Sporadic occurrence is known even today in the underdeveloped areas of the world. ▶zoonosis, ▶*Yersinia*, ▶plant vaccines, ▶biological weapons; Parkhill J et al. 2001 Nature [Lond] 413:523.

Plakin: >200 kDa dimeric, coiled coil, actin-binding proteins forming molecular bridges between the cytoskeleton and other subcellular structures. They also bind microtubules. ▶cytoskeleton, ▶filaments, ▶microtubule; Jefferson JJ et al 2007 J Mol Biol 366:244.

Plakoglobin: 83 kDa protein localized to the cytoplasmic side of the desmosomes. ▶desmosome, ▶adhesion, ▶desmoplakin

Planar Cell Polarity (PCP): PCP is determined by several genes involved in embryonal development, neural tubes, cochlear sensory hair cells of the ear, etc.

Planarians (flatworms): Relatively simple carnivorous organisms inhabiting fresh waters. There are about 15,000 species, all with bilateral symmetry and elaborate digestive tract and nervous system. They are well suited for studies of regeneration. The tapeworms and flukes are serious human parasites. ▶flatworm, ▶regeneration; <http://planaria.neuro.utah.edu/>.

Planck Constant (h): A constant of energy of a quantum of radiation and the frequency of the oscillator that emitted the radiation. $E = h\nu$ where E = energy, ν = its frequency; numerically 6.624×10^{-27} erg^{-s}.

Plankton: The collective name of many minute free-floating water plants, animals, and prokaryotes. ▶phytoplankton, ▶bacterioplankton; microbial oceanography: DeLong EF, Karl DM 2005 Nature [Lond] 437:336; Giovannoni SJ, Stingl U 2005 Nature [Lond] 437:343; Arrigo KR 2005 Nature

[Lond] 437:349; viruses in the sea: Suttle CA 2005 Nature [Lond] 437:356; genetic and metabolic survey of microbial plankton from 10 m to 4000 m oceanic depth: DeLong EF et al 2006 Science 311:496.

Plant Breeding: An applied science involved in the development of high-yielding food, feed, and fiber plants. It is concerned also with the production of lumber, renewable resources of fuel, and many types of industrial raw products (such as latex, drugs, cosmetics, etc.). A major goal of plant breeding is to improve the nutritional value, safety, disease resistance, and palatability of the crops. Plant breeding and technological improvements in agriculture have resulted in a near 10-fold increase in maize production and doubled wheat yields in the twentieth and twenty-first century. Plant breeding is based on population and quantitative genetics, and biotechnology. (Mazur B et al 1999 Science 285:372).

Plant Defense: Plant defense against herbivores is mediated by the signaling peptide *systemin* activating a lipid cascade. Membrane linolenic acid is released by the damage and converted into phytodienoic and jasmonic acids, structural analogs to the prostaglandins of animals. As a consequence, tomato plants produce several systemic *wound response proteins*, similar to those elicited by oligosaccharides upon pathogenic infections. Mutation in the octadecanoic (fatty acid) pathway blocks these defense responses. ▶host-pathogen relations, ▶insect resistance in plants, ▶jasmonic acid, ▶prosta-glandins, ▶fatty acids, ▶systemin, ▶oleuropein

Plant Disease Resistance: ▶host-pathogen relation, ▶plant defense

Plant Genomes: Plant genomes generally differ in size and organization from those in animals and pose new problems and answer unique questions of analysis. (See Peterson AH 2006 Nature Rev Genet 7:174).

Plant Genomics Database: <http://sputnik.btk.fi>; plant molecular markers: <http://markers.btk.fi>; see also crop plants and individual plant species in the alphabetical order.

Plant Hormones: Auxins, gibberellins, cytokinins, abscisic acid, brassinosteroids, jasmonate, and ethylene. Polypeptide hormones play roles in the defense systems of plants (Ryan CA et al 2002 Plant Cell 14:251). The natural *auxin* in plants is indole-3-acetic acid (IAA) but a series of synthetic auxins are also known such as dichlorophenoxy acetic acid (2,4-D), naphthalene acetic acid (NAA), indole-butyric acid (IBA), etc. Auxins are involved in cell elongation, root development, apical dominance, gravi- and phototropism, respiration, maintenance of membrane

potential, cell wall synthesis, regulation of transcription, etc. The bulk (≈95%) of IAA in plants is conjugated through its carboxyl end to amino acids, peptides, and carbohydrates. The conjugate regulates how much IAA is available for metabolic needs, although some conjugates may be directly active as hormones. Enzymes have been identified that hydrolyze the conjugates. Over the developing tissues, auxins show concentration gradients, indicating its role in positional signaling similarly to animal morphogens. The conjugates may transport IAA within the plant. *Gibberellic acid* and gibberellins control stem elongation, germination, and a variety of metabolic processes. *Cytokinins* also occur in a wide variety of forms such as kinetin, benzylamino-purine (BAP), isopentenyl adenine (IPA), zeatin, etc. Their role is primarily in cell division but they regulate the activity of a series of enzymes. Regeneration of plants from dedifferentiated cells requires a balance of auxins and cytokinins. *Abscisic acid* and terpenoids control abscission of leaves and fruits, dormancy and germination of seeds and a series of metabolic pathways. *Ethylene* was recognized as a *bona fide* plant hormone more recently. It is involved in the control of fruit ripening, senescence, elongation, sex determination, etc. The hormone type action of *brassinosteroids* in controlling elongation and light responses has been recognized by genetic evidence only in 1996. *Jasmonic acid* is also a hormone like substance with role in parasite defense. Generally, the various plant hormones signal to each other and their dynamic cooperative effects are essential for plant responses (Schmelz EA et al 2003 Proc Natl Acad Sci USA 100:10552). A survey indicated that hormones affected 4666 genes of *Arabidopsis* but most commonly different hormones regulated distinct members of protein families (Nemhauser JL et al 2006 Cell 126:467). ▶hormones, ▶signal transduction, ▶abscisic acid, ▶ethylene, ▶indole acetic acid, ▶jasmonic acid, ▶gibberellic acid, ▶kinetin, ▶zeatin, ▶brassinosteroids, ▶seed germination; Kende H 2001 Plant Physiol 125:81; Mok DWS, Mok MC 2001 Annu Rev Plant Physiol Mol Biol 52:89; <http://www.ualr.edu/botany/hormimages.html>.

Plant Pathogenesis: Plant pathogens pose risks for agricultural, horticultural, and forest plants and may damage natural habitats of different organisms, plants as well as animals. Several plant pathogens and saprophytes may pose human health hazards, especially for immunologically compromised individuals. (See Vidaver AK, Tolin S 2000 In: Fleming DO, Hunt DL (Eds.) Biological Safety, ASM, Washington DC, pp 27–33; ▶host-pathogen relation; <http://www.pathoplant.de>.

Plant Vaccines: Transgenic plants may express immunogenic proteins, which by consuming the plant tissues by humans or animals, may protect against bacterial or viral diarrhea. Also, plant synthesized immunoglobulins may protect against *Streptomyces mutans*, responsible for dental caries and gum disease. Hepatitis B surface antigen (HBsAg), Norwalk virus capsid protein (NVCP), *E. coli* heat-labile enterotoxin B subunit (LT-B), cholera toxin B subunit (CT-B), and mouse glutamate decarboxylase (GAD67) have been propagated in tobacco and potato tissues, respectively. Hepatitis B vaccine delivered by raw potatoes—when a sufficient quantity was consumed—increased the serum antiHB surface antigen titer in up to 62.5% of the volunteers (Thanavala Y et al 2005 Proc Natl Acad Sci USA 102:3378). So far, these edible vaccines have not shown clinical use. The S1 protein of the SARS corona virus propagated in tomato and tobacco plants displayed good immunogenicity in mice after both parenteral (injection) and oral administration. This result is similar to the early tests of gastroenteritis vaccine in swine and the infectious bronchitis virus vaccination of chickens by plant vaccines (Progrebnyak N et al 2005 Proc Natl Acad Sci USA 102:9062). Apparently, very effective vaccines can be produced by introducing into plants (tobacco) the F1 and V and the F1–V fusion antigens of *Yersinia*, the agent of plague (Santi L et al 2006 Proc Natl Acad Sci USA 103:861). Vaccinia virus antigenic domain B5 propagated in tobacco and collard plants when introduced orally in mice or the minipig (miniature pig) did not generate an anti-B5 immune response, but intranasal administration of soluble pB5 led to a rise of B5-specific immunoglobulins, and parenteral immunization led to a strong anti-B5 immune response in both mice and the minipig. Mice immunized i.m. (intramuscularly) with pB5 generated an antibody response that reduced smallpox virus spread in vitro and conferred protection from challenge with a lethal dose of vaccinia virus (Golovkin M et al 2007 Proc Natl Acad Sci USA 104:6864). ▶vaccines, ▶immunoglobulin, ▶transformation genetic, ▶plantibody, ▶TMV, ▶SARS, ▶plague, ▶*Yersinia*, ▶bronchitis, ▶gastroenteritis; Daniell H et al 2001 J Mol Biol 311:1001; Ruf S et al 2001 Nature Biotechnol 19:870; Sojikul P et al 2003 Proc Natl Acad Sci USA 100:2209.

Plant Viruses: Plant viruses vary a great deal in size, shape, genetic material, and host-specificity. The majority of them have single-stranded positive-strand RNA as genetic material and are either enveloped or not. The Reoviridae may have several double-stranded RNAs, and the Cryptovirus carries two

double-stranded RNAs. The Cauliflower (Caulimo) virus has double-stranded DNA, whereas the Geminiviruses have single-stranded DNA genetic material. The size of their genome usually varies between 4 to 20 kb and their coding capacity is at least four proteins. The 5'-end may form methylguanine cap or it may have a small protein attached to it. The 3'-end may have a polyA tail or may resemble the OH end of the tRNA. Approximately, 600–700 plant viruses have been described. ▶viruses, ▶cap, ▶polyA tail, ▶tRNA, ▶viroid, ▶TMV, ▶CaMV, ▶geminivirus, ▶viroid; Knipe DM et al (Eds.) 2001 Fundamental Virology, Lippincott Williams & Wilkins, Philadelphia, Pennsylvania; Harper G et al 2002 Annu Rev Phytopathol 40:119; Tepfer M 2002 Annu Rev Phytopathol 40:467; general virus database, including plant viruses: <http://www.ncbi.nlm.nih.gov/ICTVdb/ictvdb.htm>.

Plantibody (antibody synthesized by plants): A modified immunoglobulin produced in transgenic plants carrying the genetic sequences required for the recognition of the site of the viral coat or other proteins. The yield of the plantibody molecules is very high, up to 1% of the soluble plant proteins. The modification of the immunoglobulin involves usually the elimination of the constant region of the heavy chain while retaining the variable region. The plant antibodies are usually formed as single chains (ScFv). Other modifications for solubility and tissue-specific expression may be introduced. The plantibodies are modified also by intrinsic plant mechanisms (N-glycosylation) within the endoplasmic reticulum. Unfortunately, plant tissue lack β 1,4-galactosyltransferase, which is required for the synthesis of mammalian-like glycans. By transformation, the gene of this enzyme has been transferred into tobacco plants and it functions normally. Retention and excretion of ScFv immunoglobulin molecules is increased if the KDEL amino acid sequence is present in the polypeptide chain. For some medical applications, the plantibodies may not be suitable because they may carry plant-specific β -1,2-xylose and α -1,3-fucose residues at the galactose-carrying N-glycans and cause allergic reactions in monoclonal antibodies. When, however, a hybrid enzyme called XylGalT that consists of the N-terminal domain of the *Arabidopsis* xylosyltransferase and the catalytic domain of human β -1,4-galactosyltransferases is used in tobacco plants, the core-bound xylose and fucose residues are sharply reduced. This type of monoclonal plantibody thus appears promising (Bakker H et al 2006 Proc Natl Acad Sci USA 103:7577). Single-chain variable fragment (scFv)-Fc (fragment crystalline) antibodies, with N-terminal

signal sequence and C-terminal KDEL tag, can accumulate to very high levels as bivalent IgG-like antibodies in *Arabidopsis thaliana* seeds and illustrate that a plant-produced anti-hepatitis A virus scFv-Fc has similar antigen-binding and in vitro neutralizing activities as the corresponding full-length IgG. As expected, most scFv-Fc produced in seeds contained only oligomannose-type *N*-glycans, but, unexpectedly, 35–40% was never glycosylated. A portion of the scFv-Fc was found in endoplasmic reticulum (ER)-derived compartments delimited by ribosome-associated membranes. Additionally, consistent with the glycosylation data, large amounts of the recombinant protein were deposited in the periplasmic space, implying a direct transport from the ER to the periplasmic space between the plasma membrane and the cell wall. Aberrant localization of the ER chaperones calreticulin and binding protein (BiP) and the endogenous seed storage protein cruciferin in the periplasmic space suggests that overproduction of recombinant scFv-Fc disturbs normal ER retention and protein-sorting mechanisms in the secretory pathway (Van Droogenbroeck B et al 2007 Proc Natl Acad Sci USA 104:1430).

Monoclonal antibody against the non-protein Lewis Y oligosaccharide antigen is over-expressed in breast, lung, ovary, and colon cancers. Monoclonal antibody (mAb BR55-2) specific for LeY was expressed (30 mg/kg fresh weight of leaves) in low-alkaloid content in transgenic tobacco plants and bound specifically to SK-BR3 breast cancer and SW948 colorectal cancer cells. Its binding to the FcγRI receptor was the same as that derived from mammalian cells. The plantibody was effective in cytotoxicity assays as well as in grafting onto nude mice; thus, indicating its potential suitability for immunotherapy (Brodzik R et al 2006 Proc Natl Acad Sci USA 103:8804).

Plant-produced antibodies may find biomedical application in humans and animals. Transgenic plants may produce large quantities of IgA and IgG-IgA at low cost. In *Nicotiana benthamina* leaves, high-level expression of functional full-size monoclonal antibody (mAb) of the IgG class in plants has been ascertained. The process relies on synchronous coinfection and coreplication of two viral vectors, each expressing a separate antibody chain. The two vectors are derived from two different plant viruses that were found to be noncompeting. Unlike vectors derived from the same virus, noncompeting vectors effectively coexpress the heavy and light chains in the same cell throughout the plant body, resulting in yields of up to 0.5 g of assembled mAbs per kg of fresh-leaf biomass (Giritch A et al 2006 Proc Natl Acad Sci USA 103: 4701).

Also, other components of the immunization system may thus be synthesized with single plants after combining the genes through classical crossing procedures. By eating IgA secreting plant tissues, protection is expected through mucosal immunity or may protect against dental caries. If the antibody is expressed in seed tissues, it can be stored at room temperature (perhaps for years) without a loss of the variable region of the antibody and its antigen-binding ability. ▶antibody, ▶host-pathogen relations, ▶ScFv, ▶KDEL, ▶immunization, ▶mucosal immunity, ▶monoclonal antibody, ▶monoclonal antibody therapies, ▶plant vaccine, ▶molecular pharming, ▶Lewis blood group, ▶breast cancer, ▶colorectal cancer, ▶cancer therapy, ▶cancer gene therapy, ▶nude mouse, ▶tobacco, ▶BiP, ▶calreticulin, ▶periplasma; Bakker H et al 2001 Proc Natl Acad Sci USA 98:2899; Mayfield SP et al 2003 Proc Natl Acad Sci USA 100:438; Ma JK-C et al 2003 Nature Rev Genet 4:794.

PLAP Vector: ▶axon guidance

Plaque: The clear area formed on a bacterial culture plate (heavily seeded with cells) as a consequence of lysis of the cells by virus; turbid plaques indicate incomplete lysis (see Fig. P78). ▶lysis

Figure P78. T3 bacteriophage plaques on petri plate heavily seeded by bacteria. (Courtesy of Dr. CS Gowans)

Plaque-Forming Unit: The number of plaques per mL bacterial culture.

Plaque Hybridization: ▶Benton-Davis plaque hybridization

Plaque Lift: Plaque lifts on bacteriophage plates plaques are marked and overlaid by cellulose nitrate films. After denaturation and immobilization of the plaques on the filter, they are hybridized with probes to identify recombinants and return to the saved master

plate for obtaining plugs of interest from the original plate. The procedure generally requires repetition in order to isolate unique single recombinants. ►colony hybridization; Frolich MW 2000 Biotechniques 29:30.

Plasma: The fluid component of the blood in which the particulate material is suspended. The blood plasma is free of blood cells but clotting is not allowed during its isolation, and it contains the platelets, which harbor animal cell growth factors. ►PDGF, ►platelets, ►serum, ►cytoplasm, ►cytosol

Plasma Cell (plasmacyte): B lymphocytes can differentiate into either memory cells or plasma cells and the latter secrete immunoglobulins. ►lymphocytes, ►immunoglobulins, ►immune system

Plasma Membrane: The plasma membrane envelops all cells. ►cell membranes

Plasma Nucleic Acid: During pregnancy, a small number of fetal cells can escape into the plasma and some can also shed their chromosomal DNA (see Fig. P79). Such plasma nucleic acids can be exploited for prenatal diagnosis without many intrusive procedures (Lo YMD et al 2007 Nat Rev Genet 8:71). ►prenatal diagnosis, ►DNA circulating

Figure P79. Contact is between fetus and mother through the umbilical cord and both normal (red) and different cells (green) are transferred to the maternal plasma

Plasma Proteins: Proteins in the blood plasma. The major components are serum albumin, globulins, fibrinogen, immunoglobulins, antihemophilic proteins, lipoproteins, α_1 antitrypsin, macroglobulin, haptoglobin, and transfer proteins, such as transferrin (iron), ceruloplasmin (copper), transcortin (steroid hormones), retinol-binding proteins (vitamin A), and cobalamin-binding proteins (vitamin B₁₂). The lipoproteins carry phospholipids, neutral lipids and cholesterol esters. In addition, there are a great variety of additional proteins present in the serum. In a small population of 96 healthy individuals, 76 structural variants were observed in 25 proteins by affinity-based

mass spectrometric assays. This large variation predicts that analysis of plasma proteins may yield important biomarkers for medical purposes (Nedelkov D et al 2005 Proc Natl Acad Sci USA 102:10852)

Plasmablast: A precursor of plasmacyte or precursor cell of the lymphocytes.

Plasmacytoid Cell: Functionally, it is one type of dendritic cells with antigen-presenting properties (see Fig. P80). Plasmacytoid cells may not display dendritic morphology. They produce a large quantity of interferon α/β in response to bacterial or viral infection. They have roles in both innate and acquired immunity. ►dendritic cell, ►interferon, ►acquired immunity; McKenna K et al 2005 J Virology 79:17.

Figure P80. Plasmacytoid cell

Plasmacytoma: The cancer (myeloma) of antibody producing cells. Resistance against it is controlled mainly by different alleles of the complex FRAP. ►Fk506; Bliskovsky V et al 2003 Proc Natl Acad Sci USA 100:14982.

Plasmagene: Non-nuclear genes (mitochondrial, plasmidic or plasmid). ►mitochondrial genetics, ►chloroplast genetics

Plasmalemma: The membrane around the cytoplasm or the envelope of the fertilized egg.

Plasmatocyte: Macrophage-like elements in the insect hemolymph. ►macrophage, ►hemolymph

Plasmid: The dispensable genetic element, which can propagate independently and can be maintained within the (bacterial) cell, and may be present in yeast and mitochondria of a number of organisms. The plasmids may be circular or linear double-stranded DNA. The conjugative plasmids possess mechanisms for transfer by conjugation from one cell to another. The non-conjugative plasmids lack this mechanism and are therefore preferred for genetic engineering because they can be easier confined to the laboratory. During evolution, some of the advantageous plasmid genes are assumed to have been incorporated into the chromosomes and the plasmids, lost. The persistence of the plasmids may be warranted by their ability to disperse genetic information

horizontally. Plasmids occur also in the organelles of higher eukaryotes and lower eukaryotes. ►vectors, ►curing of plasmids, ►pBR322, ►pUC, ►transposon conjugative, ►cryptic plasmids, ►Ty; Summers DK 1996 The biology of plasmids, Blackwell; Thomas CM (Ed.) 2000 The Horizontal Gene Pool: Bacterial Plasmids and Gene Spread, Harwood Press, Durham, UK; <http://plasmid.hms.harvard.edu>.

Plasmid Addiction: The loss of certain plasmids from the bacterial cells may lead to an apoptosis-like cell death, called post-segregational killing or plasmid addiction. ►apoptosis

Plasmid, Chimeric: An engineered plasmid carrying foreign DNA.

Plasmid Incompatibility: Plasmids are compatible if they can coexist and replicate within the same bacterial cell. If the plasmids contain repressors effective for inhibiting the replication of other plasmids, they are incompatible. Generally, closely related plasmids are incompatible, and they thus belong to a different incompatibility group. The plasmids of enterobacteria belong to about two-dozen incompatibility groups. Plasmids may be classified also according to the immunological relatedness of the pili they induce to form (such as F, F-like, I, etc.). The replication system of the plasmids defines both the pili and the incompatibility groups. Cells with F plasmids may form F sex pili; the R1 plasmids belong to FII pili group, etc. ►pilus, ►F⁺, ►F plasmid, ►R plasmids, ►enterobacteria, ►incompatibility plasmids

Plasmid Instability: Plasmid instability indicates difficulties in maintenance caused by defect(s) in transmission, internal rearrangements, and loss (deletion) of the DNA. ►cointegration

Plasmid, 2 μ m: A 6.3 kbp circular DNA plasmid of yeasts, present in 50–100 copies per haploid nucleus. It carries two 599 bp inverted repeats separating 2774 and 2346 bp tracts. Re-combination between the repeats results in A and B type plasmids. Its recombination is controlled by gene *FLP* and its maintenance requires the presence of the *REP* genes. ►yeast; Scott-Drew S, Murray JA 1998 J Cell Sci 111:1779.

Plasmid Maintenance: Plasmid maintenance in prokaryotes is secured either by the high number of copies, or in low copy number plasmids, by a mechanism reminiscent to some extent to that of the centromere in mitosis of eukaryotes. The proteic plasmid maintenance system operates by the coordination of a toxin and an unstable antidote. When the labile antidote decays, the toxin kills the cells that do

not have the plasmid. The antidote may be a labile antisense RNA that keeps in check the toxin gene. A plasmid-encoded restriction-modification may also be involved. When the modification system recedes beyond an effective level in the plasmid-free cells, the genetic material falls victim to the endonuclease. One of such systems in *E. coli* is the *hok* (host killing)-*sok* (suppressor of killing)-*mok* (modulation of killing) system of linked genes. ►partition, ►antisense RNA, ►restriction-modification, ►killer plasmids; Gerdes K et al 1997 Annu Rev Genet 31:1; Møller-Jensen J et al 2001 J Biol Chem 276:35707; Hayes F 2003 Science 301:1496.

Plasmid Mobilization: Plasmid mobilization may take place by bacterial conjugation. Plasmid vectors use the gene *mob* (mobilization) if they do not have their own genes for conjugal transfer. Some plasmids may rely on *ColK* (colicin K, affecting cell membranes) that nicks plasmid pBR322 at the *nic* site, close to *bom* (basis of mobility). Mobilization proceeds from the nicked site (base 2254 in pBR322). Plasmids lacking the *nic/bom* system, e.g., pUC, cannot be mobilized. (See Chan PT et al 1985 J Biol Chem 260:8925).

Plasmid Rescue: The plasmid rescue procedure was designed originally for transformation with linearized plasmids of *Bacillus subtilis* that normally does not transform these bacteria. The linearized plasmid could be rescued for transformation in the presence of the *RecE* gene if recombination could take place.

The linearized monomeric plasmid then could carry also any in vitro ligated passenger DNA into cells. If the host cells carry a larger number of plasmids (multimeric), special selection is necessary to find the needed one. Plasmid rescue has also been used for re-isolation of inserts (plasmids) from the genome of transformed cells of plants.

The re-isolation requires appropriate probes for (the termini) of the inserts to permit recognition, after which, the DNA is re-circularized and cloned in *E. coli* and they have at least one selectable marker and an origin of replication compatible with the bacterium. The cloned DNA insert or its fragments are inserted into the M13 phage for nucleotide sequencing. This permits the identification of any changes that may have taken place in the original transforming DNA and permits an analysis of the flanking sequences of the target sites as well. A number of different variations of the procedure have been adopted in prokaryotes, microbes, animals, and plants. ►T-DNA, ►DNA sequencing, ►Rec; Perucho M et al 1980 Nature [Lond] 285:207, see Fig. P81.

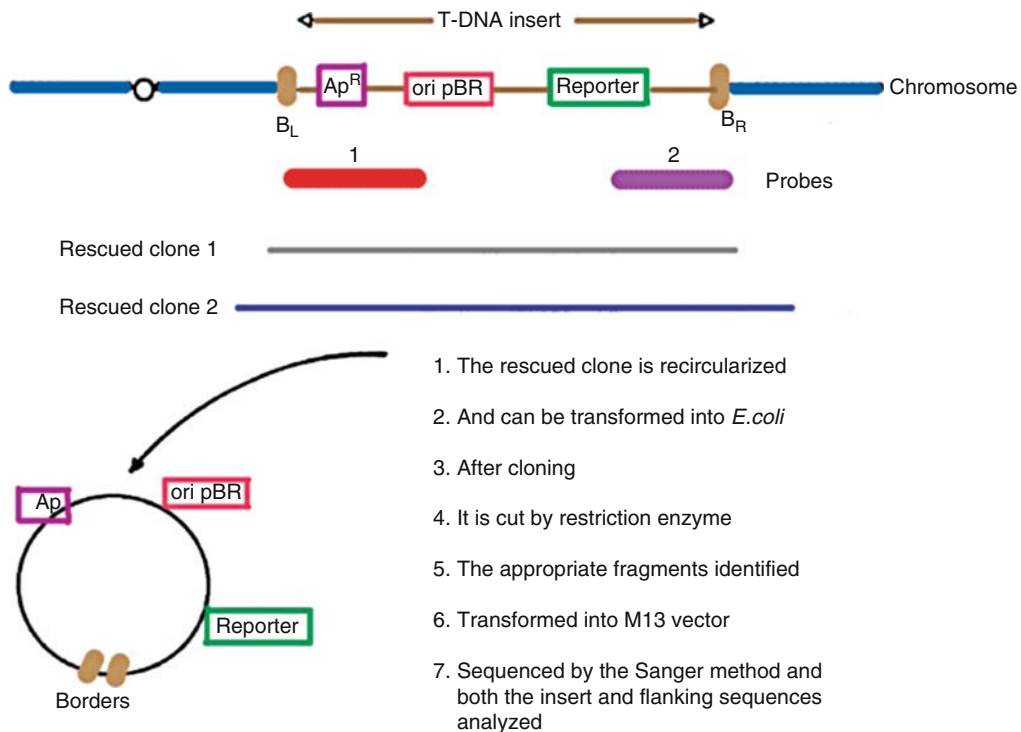

Figure P81. Outline of a plasmid rescue procedure exemplified by isolating T-DNA insert from *Arabidopsis*. Ap = ampicillin-resistance gene (Ap^R) of the pBR322, ori pBR = origin of replication of the PBR322 plasmid present in the plant-transforming vector, reporter is hygromycin resistance, left (B_L) and | right (B_R) border sequence of the T-DNA. (After Koncz C, et al. 1989. Proc. Natl. Acad. Sci. USA 86:8467.)

Plasmid Segregation: In plasmid segregation, before cell division, plasmids are partitioned to ensure transmission to mother and daughter cells. The segregation is mediated by *par* (partitioning) loci of the plasmids. Type I *pars* encode Walker box ATPases and Type II *pars* encode actin-like ATPases. The actin-like filaments act in similarity to the microtubules in higher organisms. The *par* loci involve two proteins and a centromere-like cis-acting site. The presence of Type I *par* locus positions the plasmids in the center of the cell. Integration host factor (IHF) of the bacteria plays a role in plasmid segregation. The mechanisms of plasmid segregation vary among different plasmids. ▶ [actin](#), ▶ [ATPase](#), ▶ [Walker box](#), ▶ [IHF](#); Ebersbach G, Gerdes K 2005 Annu Rev Genet 39:453.

Plasmid Shuffling: The general procedure of plasmid shuffling in yeast first disrupts the particular gene in a diploid strain. After meiosis, the cells can be maintained only if the wild type allele is carried on a replicating plasmid (episome). Mutant copies of that particular gene are then introduced into the cell on a second episome and exchanged (shuffled) for the wild type allele. The phenotype of any of the mutant alleles can be studied in these cells that carry the

disrupted (null) allele. (See Sikorski RS et al 1995 Gene 155:51; Zhao H, Arnold FH 1997 Nucleic Acids Res 25:1307).

Plasmid Telomere: Linear plasmids require exonuclease protection at the open ends. The problem may be resolved by capping with proteins or forming a lollipop type structure by fusing the ends of the single strands as shown in Figure P82. ▶ [telomere](#)

Figure P82. Plasmid telomeres

Plasmid Vehicle: A recombinant plasmid that can mediate the transfer of genes from one cell (organism) to another. ▶ [vectors](#)

Plasmids, Amplifiable: Amplifiable plasmids continue replication in the absence of protein synthesis (in the presence of protein synthesis inhibitor). ▶ [amplification](#)

Plasmids, Conjugative: Conjugative plasmids carry the *tra* gene, promoting bacterial conjugation and can be transferred to other cells by conjugation and can also mobilize the main genetic material of the bacterial cell. ►conjugation, ►F plasmid

Plasmids, Cryptic: Cryptic plasmids have no known phenotype.

Plasmids, Monomeric: Monomeric plasmids are present in a single copy per cell.

Plasmids, Multimeric: Multiple plasmids have multiple copies in a cell.

Plasmids, Non-Conjugative: Non-conjugative plasmids lack the *tra* gene required for conjugative transfer, but have the origin of replication and therefore when complemented by another plasmid for this function, they can be transferred. ►conjugation

Plasmids, Promiscuous: Promiscuous plasmids have conjugative transfer to more than one type of bacteria.

Plasmids, Recombinant: Recombinant plasmids are chimeric; they carry DNA sequences of more than one origin. (See Fig. P83).

Figure P83. Recombinant plasmid

Plasmids, Relaxed Replication: Relaxed replication plasmids may replicate to 1000 or more copies per cell.

Plasmids, Runaway Replication: In runaway replication plasmids, the replication is conditional, e.g., under permissive temperature regimes they may replicate almost out-of-control whereas under other conditions their number per cell may be quite limited.

Plasmids, Single Copy: Single copy plasmids may have single or very few copies per cell.

Plasmids, Stringent Multicopy: Stringent multicopy plasmids may grow to 10 to 20 copies in a cell.

Plasmin (fibrinolysin): Proteolytic protein (serine endopeptidase) with specificity of dissolving blood clots, fibrin, and other plasma proteins. For its activation, urokinases (tissue plasminogen activator) are required. Plasmin may be used for therapeutic

purposes to remove obstructions in the blood vessels. ►urokinase, ►plasminogen, ►plasminogen activator, ►streptokinase, ►CAM; Lijnen HR 2001 Ann NY Acad Sci 936:226.

Plasmin Inhibitor Deficiency (PLI, AAP): Plasmin inhibitor deficiency is encoded in human chromosome 18p11-q11 as recessive gene, and is involved in the regulation of fibrinolysin. ►plasmin

Plasminogen: A precursor of plasmin. Human plasminogen markedly increases mortality of mice infected with streptococci due to bacterial expression of streptokinase. Streptokinase is highly specific for human plasminogen but not for other mammalian plasminogens (Hun H et al 2004 Science 305:1283). ►plasmin, ►plasminogen activator, ►angiostatin

Plasminogen Activator (PLAT): PLAT cleaves plasminogen into plasmin; it is encoded in human chromosome 8q11-p11. The plasmin activator inhibitor (PLANH1/PAI-1) is encoded in human chromosome 7q21-q22 and PLANH2 at 18q21.1-q22. The plasminogen activator receptor was localized to 19q13.1-q13.2. Tissue-specific plasminogen activator coupled to the surface of red blood cells can dissolve blood clots and prevent thrombosis (Murciano, J-C et al 2003 Nature Biotechnol 21:891). ►plasminogen, ►plasmin, ►urokinase, ►PN-1, ►streptokinase, ►thrombosis, ►MET oncogene

Plasmodesma (plural plasmodesmata): About 2µm or larger channels connecting neighboring plant cells, lined by extension of the endoplasmic reticulum. Functionally, they correspond to the gap junctions of animal cells. Various molecules, signals, including even viruses, may move through these intercellular communication channels. The plasmodesmata are subject to temporal and spatial regulation. ►gap junctions; Zambryski P, Crawford K 2000 Annu Rev Cell Dev Biol 16:393; Hake S 2001 Trends Genet 17:2; Haywood V et al 2002 Plant Cell 14:S303; Kim I et al 2005 Proc Natl Acad Sci USA 102:11945.

Plasmodium: A syncytium of the amoeboid stage of slime molds (such as in *Dictyostelium*).

Plasmodium: One of the several parasitic coccid protozoa causing malaria-like diseases in vertebrates, birds, and reptiles. A single *Plasmodium falciparum* (n = 14, ~23 Mb, ~5268 proteins) parasite transcribes simultaneously multiple *var* genes (at several chromosomal locations), encoding the erythrocyte-membrane protein (PfEMP-1) that binds to the vascular endothelium and red blood cells. Functionally related genes tend to be clustered in the subtelomeric regions of the chromosomes. A protein interaction network of *P. falciparum* expressed at the intra-erythrocyte-stage parasites involving >2000 fragments of 1295 genes

has been constructed on the basis of the two-hybrid system. These networks can reveal potential drug targets (LaCount DJ et al 2005 Nature [Lond] 438:103). These interaction networks are quite different from those known in other organisms (Suthram S et al 2005 Nature [Lond] 438:108). Alignment of these *var* genes in heterologous chromosomes at the nuclear periphery may facilitate gene conversion and promotes diversity of antigenic determinants and adhesive phenotypes. Such a mechanism aids the evasion of the host immune system. The parasite invades the erythrocytes and destroys the host cells through the formation of merozoites (mitotic products) and spreading thus to other cells (see Fig. P84). The merozoites may develop into gametocytes (gamete forming cells) that infect blood-sucking mosquitos where they are transformed into sporozoites (the sexual generation) that are transmitted through insect bites to the higher animal host. The invaders first move to the liver where merozoites are formed and then return to the erythrocytes; thus the cycle continues. *Plasmodium falciparum* causes falciparum malaria. *P. malariae* is responsible for the *quartan*, or fourth day recurring malaria. The protozoan contains two double-stranded extranuclear DNA molecules; that of circular DNA resembles mitochondria whereas the second bears similarities to ctDNA, and contains 68 genes. Mutation in a single gene (*pfmdr1/PfEMP1*) encoding the P-glycoprotein homolog, Pgh1, may result in resistance to several antimalarial drugs of which some may or may not be chemically related. Transformation of the gene encoding the SM1 peptides into the *Anopheles* vector may render the insect resistant to *Plasmodium* infection. The rodent parasite *Plasmodium yoellii yoellii* genome (~23.1 Mb) is similar to that of *P. falciparum*. ▶malaria, ▶sex determination,

Plasmogamy: fusion of the cytoplasm of two cells without fusion the two nuclei and thus resulting in dikaryosis. Plasmogamy is common in fungi but may occur in fused cultured cells of plants and animals.

▶fungal life cycle, ▶cell genetics

Plasmolemma (plasmalemma): Plant cell membrane; the ectoplasm of the fertilized egg of animals.

Plasmolysis: The shrinkage of the plant cytoplasm caused by high concentration of solutes (salt) outside the cell resulting in loss of water. The cytoplasm separates from the cell wall.

Plasmon: The sum of non-nuclear hereditary units such as exists in mitochondrial and plastid DNA.

▶mtDNA, ▶chloroplasts, ▶plastome

Plasmon-Sensitive Gene: ▶nucleo-cytoplasmic interaction

Plasmaphoresis: A procedure to filter blood to allow the plasma proteins of the patient to be removed. At the same time, new donor plasma is replaced into the patient's blood, which is located in the plasmaphoresis machine. Subsequently, the blood is sent back to the patient. ▶hemolysis

Plasmotomy: The fragmentation of multinucleate cells into smaller cells without nuclear division.

Plasmovirus: The plasmovirus bears some similarity to phagemids but in this case a retrovirus is combined with an independent vector cassette containing various elements. The envelope gene of the Moloney provirus is replaced by a transgene to prevent infective retroviral ability and it would not regain it by chance recombination with another retrovirus. Such a construct can express transgene(s), can multiply within the target cells, and provide a tool for cancer therapy.

▶vectors, ▶retrovirus, ▶transgene, ▶cancer therapy, ▶viral vectors, ▶phagemid; Morozov VA et al 1997 Cancer Gene Ther 4(5):286.

Figure P84. Life cycle of *Plasmodium* in humans and mosquitos

Plasticity: In general, the ability of a cell or organism to display different expressions (phenotype) dependent on the environment. The ability of cells to change from what they normally are enables them to perform tasks not normally found in differentiated cells. ▶stem cells, ▶MAPCs, ▶adaptation, ▶noise, ▶reaction norm

Plastid: The cellular organelle of plants, containing DNA. It may differentiate into chloroplasts, etioplasts, amyloplasts, leucoplasts, or chromoplasts. In *Arabidopsis*, mechanosensitive ion channel proteins (localized in the plastid envelope) seem to control plastid size and shape (Haswell ES, Meyerowitz E M 2006 Curr Biol 16:1). ▶under separate names, ▶plastid number per cell, ▶plastid male transmission, ▶ctDNA, ▶chloroplast, ▶chloroplast genetics, ▶apicoplast

Plastid Male Transmission: Generally, the genetic material in the plastids is transmitted only through the egg cytoplasm but in a few species of higher plants (*Pelargonium*, *Oenothera*, *Solanum*, *Antirrhinum*, *Phaseolus*, *Secale*, etc.) a variable degree of male transmission takes place. Biparental transmission of plastid genes (about 1%) may occur also in the alga *Chlamydomonas reinhardtii*. The male transmission of these nucleoids is controlled by one or two nuclear genes. The nucleoids of the plastid and mitochondria of the male are usually degraded or if they are included in the generative cells of the male, most commonly fail to enter the sperm or are not transmitted to the egg cytoplasm. In contrast to the angiosperms, in conifers (pines, spruces, firs) the plastid DNA is usually transmitted through the males. In some interspecific hybrids, exclusively paternal, exclusively maternal, and biparental transmission were also observed. In other conifer crosses, the mtDNA is transmitted maternally. In redwoods, the transfer is paternal. One scientific claim posits that the destruction of the paternal ctDNA in the females is carried out by a restriction enzyme while the maternal ctDNA is protected by methylation. Others implicate a special nuclease C. ▶chloroplast, ▶genetics, ▶ctDNA, ▶mtDNA, ▶paternal leakage; Diers L 1967 Mol Gen Genet 100:56; Avni A, Edelman N 1991 Mol Gen Genet 225:273; Sears B 1980 Plasmid 4:233.

Plastid Number Per Cell: In the giant cells of *Acetabularia* algae, there may be one million chloroplasts but in the alga *Chlamydomonas* there is only one per cell. In higher plants, the number of plastids vary according to the size of the cells, about 30–40 in the spongy parenchyma to about twice as many in the palisade parenchyma. ▶plastid, ▶ctDNA

Plastochrome: The pattern of organ differentiation in time and space is genetically controlled. (See Miyoshi K et al 2004 Proc Natl Acad Sci USA 101:875).

Plastocyanin: an electron carrier in photosynthesis between cytochromes and photosystem I. ▶Z scheme; Ruffle SV et al 2002 J Biol Chem 277:25692.

Plastome: The sum of hereditary information in the plastids. ▶ctDNA, ▶chloroplast genetics

Plastome Mutation: Mutation in the plastid (chloroplast) DNA. ▶chloroplast genetics, ▶mutation in cellular organelles

Plastoquinone: An isoprenoid electron carrier during photosynthesis. ▶isoprene

Plate: A Petri dish containing a nutrient medium for culturing microbial or plant cells. Cell plate divides the two daughter cells after mitosis.

Plate Incorporation Test: The most commonly used procedure for the Ames test when the *Salmonella* suspension (or other bacterial cultures), the S9 activating enzymes, and the mutagen/carcinogen to be tested are poured over the bacterial nutrient plate in a 2 mL soft agar. After incubation for two days at 37°C, the number of revertant colonies is counted. ▶Ames test, ▶spot test

Platelet Abnormalities: ▶Glanzmann's disease, ▶thrombopathic purpura, ▶thrombopathia, ▶giant platelet syndrome, ▶Hermansky-Pudlak syndrome, ▶May-Hegglin anomaly, ▶platelets

Platelet Activating Factor (PAF): An inflammatory phospholipid. PAF acetylhydrolase may be a factor in atopy. ▶platelets, ▶atopy

Platelet-Derived Growth Factor (PDGF): A mitogen, secreted by the platelets, the 2–3 μm size elements in the mammalian blood, originated from the megakaryocytes of the bone marrow, and concerned with blood coagulation. PDGF controls the growth of fibroblasts, smooth muscle cells, blood vessel formation, nerve cells, cell migration in the oocytes, etc. This protein bears substantial homologies to the oncogenic product of the simian sarcoma virus, the product of the KIT oncogene, and the CSF1R (it activates also other oncogenes, such as c-fos). The PDGF is required for the healing of vascular injuries and in these cases the expression induced Egr-1 (early growth response gene product) may bind to the PDGF β chain promoter after displacing Sp1. PFGF- and insulin-dependent S6 kinase (pp70^{S6k}) is activated by phosphatidylinositol-3-OH kinase. Its receptor (PDGFR) is a tyrosine kinase. The detection of PDGF is facilitated by the construction of aptamers labeled with pyrene monomers at both ends. When an excimer is produced, the fluorescence emission is increased from 400 nm to 485 of PDGF bound excimer. The principle may be applicable to other molecules for facilitating biomedical analyses (Yang CJ et al 2005 Proc Natl Acad Sci USA

102:17278). ▶**oncogenes**, ▶**growth factors**, ▶**signal transduction**, ▶**platelets**, ▶**Sp1**, ▶**S6 kinase**, ▶**phosphatidyl inositol**, ▶**aptamer**, ▶**excimer**, ▶**heart diseases**; Betsholtz C et al 2001 Bioessays 23(6):494; Duchek P et al 2001 Cell 107:17.

Platelets: Platelets originate as cell fragments or “minicells” (without DNA) from the megakaryocytes of the bone marrow. Their function is in blood clotting and in the repair of blood vessels; they also secrete mitogen(s). Platelet abnormalities may cause stroke, myocardial infarction (damage of the heart muscles), and unstable angina (sporadic, spasmic chest pain). A balance between Bcl-x and Bak determines the life span of platelets. Inactive Bcl-x may cause thrombocytopenia (Mason KD et al 2007 Cell 128:1173). ▶**blood**, ▶**megakaryocyte**, ▶**platelet derived growth factor**, ▶**blood serum**, ▶**BAK**, ▶**BCL**, ▶**thrombocytopenia**; Prescott SM et al 2000 Annu Rev Biochem 69:419.

Plating Efficiency: The percentage of cells or protoplasts placed on a Petri plate that grows. The relative plating efficiency compares the fraction of growing cells in a treated series to that of an appropriate control.

Platyfish (*Xiphophorus/Platypoecilus*): Tropical fishes with complex sex determination. WX, WY, and XX are females and the males are XY and YY. The pseudoautosomal region seems to be long. Their melanocytes frequently turn into melanoma. ▶**pseudoautosomal**, ▶**sex determination**, ▶**melanocyte**, ▶**melanoma**

Platykurtic: ▶**kurtosis**

Platypus: ▶**monotreme**

Platysome: The nucleosome core (when it was thought of as a flat structure). ▶**nucleosome**

Playback: The number of non-repetitive sequences in a DNA can be determined by the saturation of single-strand DNA with RNA of unique sequences. The kinetics of saturation, R_{0t} (by analogy to C_{0t}), is then determined. The annealed fraction is generally a small percent of the eukaryotic DNA, which is highly redundant. To be sure that the RNA is hybridized to only the unique DNA sequences, in the DNA-RNA hybrid molecules the RNA is degraded enzymatically and the remaining DNA is subjected to a reassociation test to determine its C_{0t} curve. This “play-back” then reveals whether all the DNA so isolated, includes only genic DNA and is not redundant. Such studies may assist in estimating the number of housekeeping genes plus the genes that were transcribed when the RNA was collected. ▶ **C_{0t}** , ▶**housekeeping genes**, ▶**gene number**

PLC: Phospholipase C. ▶**phospholipase**

Pleated Sheets: Relaxed β -configuration polypeptide chains hydrogen-bonded in a flat layer. ▶**protein structure**

Pleckstrin Domain: The pleckstrein domain is approximately 100-amino acids in length and occurs in many different proteins such as serine/threonine kinases, tyrosine kinases, and the substrates of these kinases, phospholipase C, small GTPase regulators, and cytoskeletal proteins. Pleckstrin domains may participate in various signaling functions; they bind phosphatidylinositol 4,5-bisphosphate. Pleckstrin is a substrate of protein kinase C in activated platelets. separate entries, ▶**PH**, ▶**SHC**, ▶**SH2**, ▶**SH3**, ▶**WW**, ▶**PTB**, ▶**adaptor proteins**, ▶**phosphatidylinositol**, ▶**platelets**, ▶**desensitisation**, ▶**phosphoinositides**; Lemmon MA, Ferguson KM 1998 Curr Top Microbiol Immunol 228:39; Rebecchi MJ Scarlata S 1998 Annu Rev Biophys Biomol Struct 27:503.

Plectin: A 500 kDa keratin of the cytoskeleton encoded in human chromosome 8q24. ▶**epidermolysis** ▶**[bullosa simplex]**, ▶**keratin**

Plectonemic Coils: The DNA double helix represents plectonemic coils (see Fig. P85). Here, the two coils are wound together, therefore they can be separated only by unwinding rather than simple pulling apart, like in paranemic coils. ▶**paranemic coils**

Figure P85. Plectonemic coil

Pleiomorphic: A pleiomorphic organism displays variable expression (without a genetic basis for the special changes).

Pleiomorphic Adenoma: A salivary gland tumor caused by human chromosome breakage points, primarily at 8q12, 3p21, and 12q13-15. The translocation t(3;8) (p21;q12) results in swapping the promoters of PLAG1, a Zn-finger protein encoded in chromosome 8 and β -catenin (CTNNB1), and activation of the oncogene. ▶**Zinc finger**, ▶ **β -catenin**

Pleiotrophin (PTN): A 18 kDa heparin-binding cytokine, inducible by the platelet derived growth factor (PDGF). It is 50% identical with retinoic acid-inducible midkine growth factor, which like PTN is also a growth and differentiation factor. PTN reduces cell colony formation, interacts with receptor protein tyrosine phosphatase, and leads to tumor growth, angiogenesis, and metastasis. PTN regulates phosphorylation of serine 713 and 726 of β -adducin by activating protein kinase C and mediates its translocation to the nucleus. This phosphorylation contributes to uncoupling of the adducin-actin-spectrin

complexes and stabilizes the cytoskeleton (Pariser H et al 2005 Proc Natl Acad Sci USA 102:12407). ►adducin, ►actin, ►protein kinase, ►spectrin, ►cytoskeleton; Meng K et al 2000 Proc Natl Acad Sci USA 97:2603; PTN in breast cancer: Chang Y et al 2007 Proc Natl Acad Sci USA 104:10888.

Pleiotropy: One gene affects more than one trait; mutation in various elements of the signal transduction pathways, in general transcription factors, or in ion channels may have pleiotropic effects. The existence of pleiotropy has been questioned with the emergence of the one gene–one enzyme theory. Earlier, it was inconceivable on the basis that one tract of DNA could code for more than a single function (“Pleiotropism non est... that is the dogma”, p 161. In Genetics, 1959 Sutton EH (ed), Josiah Macey Found, New York). However, it has been since shown that mutation at different sites within single mitochondrial tRNA genes may lead to several different human diseases. Cytokines involved in signaling through different receptors in different pathways are pleiotropic molecules. The complete sequence of the *Drosophila* genome shows that ~13,601 genes encode ~14,113 transcripts indicating that a minimum of nearly 4% of the genes display pleiotropy. An analysis of 150,000 high-abundance human proteins derived from two-dimensional gels indicated an average of 10 isoforms per protein following the (MALDI-TOF) matrix-assisted laser desorption ionization/time of flight mass spectrometry (Humphery-Smith I 2004, p 2 In: Albala JS, Humphery-Smith I (Eds.) Protein Arrays, Biochips, and Proteomics, Marcel Dekker, New York). In yeast, pleiotropy is attributable to multiple consequences of single functions (He X, Zhang J 2006 Genetics 173:1885). *Antagonistic pleiotropy* claims that evolution does not work against variations, which adversely affect the individuals after the completion of the reproductive stage of life, and the alternative genotypes display opposite phenotypes. Actually, the genes displaying antagonistic pleiotropy can be silent in early life but are harmful later and contribute to aging; yet, they may have some selective advantage early and this assures their maintenance in populations.

The F1F0-ATP synthase is a ubiquitous mitochondrial enzyme that works as a rotary motor, harnessing the electrochemical proton gradients to carry out ATP synthesis from ADP and inorganic phosphate. It is composed of a membrane-embedded proton-translocating sector (F0), coupled to a soluble sector (F1) that contains catalytic sites for ATP synthesis/hydrolysis. Several of the most deleterious human mitochondrial diseases, such as the maternally inherited Leigh syndrome, neurogenic ataxia, retinitis pigmentosa, and some cases of Leber hereditary optic neuropathy are caused by point mutations in the mitochondrial

ATP6 gene that encodes subunit 6 of the ATP synthase F0 sector. The same single point mutation can produce either Leigh syndrome or retinitis pigmentosa, depending on the mtDNA mutation load. The mtDNA mutations most frequently associated with retinitis pigmentosa or Leigh syndrome are T8993G, T8993C, T9176G, and T9176C, which replace the conserved leucine residues at positions 156 or 217 of subunit 6 by arginine or proline, respectively. The primary molecular pathogenic mechanism of these deleterious human mitochondrial mutations is functional inhibition in a correctly assembled ATP synthase (Cortés-Hernández P et al 2007 J Biol Chem 282:1051). ►signal transduction, ►transcription factors, ►epistasis, ►two-hybrid method, ►mitochondrial diseases in humans, ►MALDI-TOF, see Fig. P86.

Figure P86. Pleiotropic mutations in the mtDNA Leu tRNA^{UUR} gene. The diagram displays the mutations in the human mitochondrial Leu tRNA^{UUR}. The first letter indicates the base that is changed, in parenthesis is the nucleotide number at the physical map, after the → the substituted base is given and after → the diseases described under mitochondrial diseases in humans are identified with abbreviations. Redrawn after Moraes CT 1998, p 167 In: Singh KK (Ed.) Mitochondrial DNA Mutations in Aging, Disease and Cancer, Springer, New York

P

Pleomorphism: Carl Wilhelm Nägeli’s nineteenth century suggestion claiming lack of hard heredity in bacteria and that they simply exist in a variety of pliable forms. This idea held back the development of bacterial genetics, although physicians like Robert Koch and the taxonomist W. Migula sharply criticized it and stated that it ignored facts known by the 1880s. ►*Hieracium*

Plesiomorphic: A trait in its more primitive state among several evolutionarily related species. ►apomorphic, ►symplesiomorphic, ►synapomorphic

Pleura: Serous (moist) membrane lining the lung or insects' thoracic cavity.

Plexins: Receptors for semaphorins. Plexin-B1 is activates GTPase for RAS (Oinuma I et al 2004 Science 305:862). ►semaphorins, ►RAS, ►GTPase

PLGA: See Fig. P87, ►angiogenesis

Figure P87. PLGA

Plk (polo-like kinase): Plk regulates the maturation of the centrosome, spindle assembly, the PICH checkpoint helicase, and the removal of cohesins, inactivates the anaphase promoting complex inhibitors, and controls mitotic exit and cytokinesis. ►polo, terms in alphabetical order; Baumann C et al 2007 Cell 118:101.

Ploidy: Ploidy represents the number of basic chromosome sets in a nucleus. The haploids have one set (x), the diploids two (xx), autotetraploids (xxxx), and so on. ►polyploidy

P-Loop: The ATP- and GTP-binding proteins have a phosphate-binding loop, the primary structure of which typically consists of a glycine-rich sequence followed by a conserved lysine and a serine or threonine. (See Saraste M et al 1990 Trends Biochem Sci 15:430).

P

PLTP (phospholipid transfer protein): The PLTP mediates the exchange of HDL cholesteryl esters with very low-density triglycerides and vice versa. ►HDL, ►cholesterol, ►CETP

Plug-In: A small circuit in a developmental function that can be present in several developmental networks.

Plum (*Prunus*): Basic chromosome number $x = 7$ but a variety of polyploid forms exist. (Bliss FA et al 2002 Genome 45:520).

Plumule: The embryonic plant shoot-initial.

Pluralism in Evolutionary Biology: Pluralism indicates sympatric speciation. ►sympatric

Pluripotency: A cell with pluripotency has the ability to develop into various, but not necessarily all types of tissues. Embryonic stem cells (from the inner mass of blastocysts), embryonic germ cells (primordial cells of the gonadal ridge), and the mesenchymal stem cells of the bone marrow possess pluripotency. Transcription factor Zfx controls the self-renewal of embryonic and hematopoietic stem cells (Galan-Caridad JM et al 2007 Cell 129:345). The

good cultures may grow for more than 70 doublings ($2^{70} \geq 10^{20}$) and may be free of chromosomal defects. The ability of the embryonic stem cells to differentiate into many types of cells is regulated by MYC and Nanog proteins that regulate transcription factors, signal molecules, and suppress lineage specific cells. These two factors target a core set of 345 genes. The mouse and human MYC and Nanog target sites overlap in ~9 to 13% (Loh Y-H et al 2006 Nat Genet 38:431). Nanog proteins enable the reprogramming of somatic cells into pluripotent stem cells after fusion with embryonic stem cells of mouse (Silva J et al 2006 Nature [Lond] 441:997). Histone3 arginine26 methylation appears to be a crucial event in the formation of the pluripotent inner cell mass of the four-cell stage mouse embryos. CARM1 methyltransferase activity also upregulates Nanog and Sox2 proteins (Torres-Padilla A-E et al 2007 Nature [Lond] 445:214). ►totipotency, ►CARM1, ►MYC, ►Nanog, ►Sox, ►stem cells, ►ZFX; Donovan PJ, Gearhart J 2001 Nature [Lond] 414:92.

Plus and Minus Method (Sanger F et al 1975 J Mol Biol 94:441): The plus and minus method was an early version of DNA sequencing using dideoxy analogs of nucleosides (+ batch) during replication. After the analog was incorporated to a site, T4 exonuclease failed to continue degradation. In the minus (–) batch the synthesis stopped depending upon which single nucleotide was omitted (the precursor mixture containing only 3 deoxyribonucleotides). Thus nucleotide sequences of specific ends and length were generated and the fragments of different lengths were analyzed by electrophoresis. The Sanger et al (1977 Proc Natl Acad Sci USA 74:5463) method and its improvements replaced it. ►DNA sequencing

Figure P88. Plus and minus strands

Plus End: The preferential growing end of microtubules and actin filaments. ►minus end

Plus Strand: The plus strand of the single stranded DNA or RNA of a virus is represented in the mature virion whereas the minus strand serves as a template for the transcription (replication) of the plus strand and the mRNA (see Fig. P88). In most cases, the plus strands are synthesized far in excess to the minus strands. (►replicative form, ►RNA replication). The plus strand viral genomic RNA serves directly as mRNA.

Plutonium (Pu): A metallic fissile element (atomic number 94, atomic weight 242) produced by neutron bombardment of uranium (U^{238}) during the production of nuclear fuel and used for making nuclear weapons. Radioactive Pu powers some heart pacemakers. Thus, the wearers, as well as his/her family members and surgeons, will be exposed to some radiation, generally below 1.28 Sv per person per year, a little more than the average natural background (the doses are additive, however). If the highly toxic particles of Pu are inhaled (the most common type of ingestion), the element may affect the lung and may eventually be preferentially deposited in the skeletal system, causing bone cancer by the emission of X and γ rays. Pu^{238} has a half-life of 86.4 years. It propels some space vehicles. Pu^{239} has a half-life of 24.3×10^3 years and targets primarily the bone marrow. Other Pu isotopes have an even longer half-life. The level of Pu may be detected by radioactivity in the urine and by instruments placed on the body. Appropriate instruments can detect as low as 4 nCi (nanoCurie) values. ▶atomic radiation, ▶isotopes, ▶radiation hazard assessment, ▶Curie

Plx1: A kinase that phosphorylates the amino-terminal domain of Cdc25. ▶Cdc25

Plymouth Rock: A recessive white-feathered breed of chickens with the genetic constitution of *iicc*. The dominant *I* gene is a color inhibitor and *C* symbolizes color. ▶White Wyandotte, ▶Leghorn White

PLZF: The zinc-finger protein encoded in human chromosome 11q23. It normally represses the promoter of cyclin A but a transposition of RAR α (retinoic acid receptor) results in transactivation of the cyclin A gene, and may be involved in the initiation of cancer. ▶cyclin A, ▶RAR, ▶transcriptional activator, ▶transactivator, ▶leukemia [acute promyelotic leukemia].

PMA: See ▶phorbol 12-myristate-13-acetate (Fig. P89)

Figure P89. Phorbol

PMAGE (polony multiplex analysis of gene expression): PMAGE can detect single mRNA molecules in three cells (Kim JB et al 2007 Science 316:1481). ▶polony

pMB1: ▶ColE1

PMCA (protein misfolding cyclic amplification): ▶prion

PMDS (persistence of Müllerian duct syndrome): ▶Müllerian ducts

PME: Point mutation element where in the 3'-UTR regulatory proteins may bind and cause developmental switching.

PMF (peptide-mass fingerprinting): A method of rapid identification of proteins without sequencing but using mass spectrometry information. ▶MALDI; Jonsson AP 2001 Cell Mol Life Sci 58:868.

PML (promyelotic leukemia): A putative Zinc finger protein, encoded in human chromosome 15q21. Formerly, this gene was called MYL. There are about 10–20 PML bodies of ~ 0.3 – $1 \mu\text{m}$ per mammalian nuclear matrix. In acute promyelotic leukemia, these bodies become disorganized as the PML-RAR α oncogenic complex is formed. PML bodies are associated with caspase- and FAD-induced apoptosis. Casein kinase 2 (CK2) promotes PML ubiquitin-mediated degradation by phosphorylation at serine 517. In case of resistance to CK2, tumor-suppressor activity of PML is enhanced (Scaglioni PP et al 2006 Cell 126:269). Overexpressed PML also promotes apoptosis but without an enhanced caspase-3 activity. In the absence of PML (PML $^{-/-}$), the cells become resistant to ionizing radiation. ▶leukemia, ▶PLZF, ▶nuclear matrix, ▶RAR, ▶apoptosis, ▶POD, ▶AKT; Lallemand-Breitenbach V et al 2001 J Exp Med 193:1361.

PML39: A yeast upstream effector regulating Mlp1/Mlp2 nucleopore-associated proteins suppressing nuclear export of un-spliced mRNA (Palancade B et al 2005 Mol Biol Cell 16:5258). ▶nuclear pores

PMS1 (2q31-q33), **PMS2** (7q22) yeast homologs and colorectal cancer: Increased post-meiotic segregation in yeast and increased colorectal cancer (or Turcot syndrome) in humans due to mismatch repair deficiency. ▶mismatch repair, ▶colorectal cancer, ▶Turcot syndrome

PN-1 (protease nexin): A 43 kDa inhibitor of serine proteases (thrombin, plasminogen activator). It is involved in the development of embryonic organs (cartilage, lung, skin, urogenital system, and nervous system). PN-1 is abundant in the seminal vesicle and its dysfunction leads to male infertility. ▶thrombin, ▶plasminogen activator, ▶urokinase, ▶nexin, ▶infertility, ▶claudin-11; Murer V et al 2001 Proc Natl Acad Sci USA 98:3029.

pN: ▶Newton

PNA: ▶peptide nucleic acid

Pneumococcus: ▶*Diplococcus pneumoniae*

Pneumocystis carinii: A group of pathogenic ascomycetes with special susceptibility to immune-compromised individuals (e.g., AIDS patients) and rodents. It carries about 3740 genes in the about 8 Mb genome. It reproduces both asexually and sexually. ▶acquired immunodeficiency, ▶ascomycete; Kolls JK et al 1999 J Immunol 162:2890.

PNPase: ▶polynucleotide phosphorylase

Pocket: The motif of the retinoblastoma (RB) tumor-suppressor protein family that binds to viral-DNA coded oncoproteins. Binding of RB to the E2F family of transcription factors blocks transcription, needed for the progression of the cell cycle. The pocket proteins share this retinoblastoma (RB) motif. ▶E2F1, ▶tumor suppressor, ▶cell cycle, ▶transcription factors, ▶retinoblastoma, ▶p107, ▶p130; Botazzi ME et al 2001 Mol Cell Biol 21:7607.

POD (PML-oncogenic domain): ▶PML

Podophyllotoxin (epipodophyllotoxin): Antimitotic plant product.

Podosomes (invadopodia): Actin-containing electron-dense adhesion structures on human primary macrophages, Src-transformed fibroblasts, and in some cancer cells, controlling cell motion migration and immune reactions. N-WASP WH2 nucleation promoting protein domains capture the barbed end (the protrusive attachment structure of actin) to the podosome (Co C et al 2007 Cell 128:901). ▶Src, ▶macrophage, ▶actin, ▶WASP, ▶immune reaction; Linder S, Aeppelbacher M 2003 Trends Cell Biol 13:376.

Podospora anserina: $n = 7$, is a genetically well-studied ascomycete fungus.

Pof (Painting of fourth): *Drosophila* protein that binds only to the small 4th chromosome.

pogo: ▶hybrid dysgenesis

Poikilocytosis: A hemolytic anemia with variable-shape red blood cells. The defect is due to the reduction of ankyrin binding sites or mutation in spectrin. ▶ankyrin, ▶spectrin, ▶anemia

Poikiloderma Atrophicans (poikiloderma telangiectasia): ▶Rothmund-Thompson syndrome

Poikiloploidy: In poikiloploidy, different cells of the body have different numbers of chromosomes.

Poikilothermy: In poikilothermy, the body temperature or the organism depends on the surrounding environmental conditions.

Point Mutation: Point mutations do not involve detectable structural alteration (loss or rearrangement of the chromosome), and are expected to involve base

substitutions. The point mutation rate per locus in eukaryotes is about 10^{-5} and may vary from locus to locus and among various organisms. The rate per nucleotides of a locus is in the range of 10^{-8} . ▶substitution mutation; Krawczak M et al 2000 Hum Mut 15:45.

Point-of-Care Technologies: Point-of-care technologies use small bench top analyzers (for example, saliva, blood gas, and electrolyte systems) and hand held, single use devices (such as urine albumin, blood glucose, and coagulation tests). Hand held devices have been developed using microfabrication techniques. They are outwardly simple but internally complex devices that perform several tasks for example, separate cells from plasma, add reagents, and read color or other end points (Price CP 2001 BMJ 322:1285). These are also called bedside technologies, because the samples do not have to be transferred for analysis to laboratories and therefore are much faster, especially when the newest microfluidic devices are used. ▶microfluidics; Herr AE et al 2007 Proc Natl Acad Sci USA 104:5268.

Poise: ▶viscosity, ▶stoke

Poison Sequence: A poison sequence may be present in the genomes of some RNA viruses and thus even their cDNA cannot be cloned in full length in bacterial hosts. The problem may be overcome by propagating it in segments. (Brookes S et al 1986 Nucleic Acids Res 14:8231).

Poisson Distribution: Basically, an extreme form of the normal distribution, found when in large populations rare events occur at random, such as e.g., mutation. The general formula is $e^{-m} (m^i/i!)$, and expanded $e^{-m}(m^0/0!, m^1/1!, m^2/2! \dots m^i/i!)$, where e = base of natural logarithm ($\cong 2.718$), m = mean number of events, i = the number by which a particular m is represented at a given frequency, $!$ = factorial (e.g., $3! = 3 \times 2 \times 1$, but $0! = 1$). (See Fig. P90, ▶negative binomial).

Pokemon: A repressor of the tumor suppressor ARF; thus, it represents a protooncogene. ▶ARF, ▶oncogenes; Maeda T et al 2005 Nature [Lond] 433:278.

poky (synonym: *mi-1*): A slow-growing and cyanide-sensitive respiration defective mitochondrial mutation in *Neurospora*. The basic defect appears to be a four-base deficiency of the 15 bp consensus at the 5'-end of the 19S rRNA of the mitochondria. Because of this defect, a further upstream promoter is used, making the transcript longer but during processing, shorter RNAs are made. It is analogous to the petite colony mutations of budding yeast. ▶petite colony mutation, ▶stoppers, ▶mtDNA; Akins RA, Lambowitz AM 1984 Proc Natl Acad Sci USA 81:3791.

Figure P90. The Poisson distribution. Each curve corresponds to a numbered m value. The i classes represent the distribution of each mean value (m) with the ordinate indicating the frequencies

pol (bacterial RNA polymerase): pol synthesizes all the bacterial and viral RNAs in the bacterial cells. Its subunits are $\alpha\alpha\beta\beta'$ and σ . The σ subunit identifies the promoter sequences and is required for the initiation of transcription within the cell. After about a half dozen nucleotides are hooked up, it dissociates from the other subunits and further polymerization continues with the assistance of elongation protein factors. ▶transcription, ▶pol I, ▶pol II, ▶pol III eukaryotic RNA polymerases

pol I: Prokaryotic DNA polymerase, where the polymerase (Klenow fragment) and exonuclease functions are located about 30 Å distance apart in a subunit, and editing (removal of wrong bases) follows the melt and slide model. It plays a major role in prokaryotic repair and in the extension of the Okazaki fragments for joining them into a contiguous strand by ligase. It adds 10–20 nucleotides/second to the chain and so it is much slower than pol III. ▶melt and slide model, ▶DNA replication, ▶replication fork, ▶Klenow fragment, ▶pol III, ▶DNA ligase

pol I: RNA polymerase involved in the synthesis of ribosomal RNA (except 5S rRNA) in eukaryotes. By endonucleolytic cleavage, it generates the 3' end of rRNA from longer transcripts. The upstream control regions for transcription initiation (binding proteins) vary from species to species. The human RNA pol I requires an activator UBF (upstream binding factor)

and promoter selectivity factor SL1, including the TBF (TATA box binding protein) and associated subunits, TAF_I 110, TAF_I 63, and TAF_I 48. The former two keep contact with the promoter, whereas TAF_I 48 interacts with UBF and prevents RNA pol II from using this promoter site. ▶ribosome; Reeder RH 1999 Progr Nucleic Acid Res Mol Biol 62:293; Grummt I 1999 Progr Nucleic Acid Res Mol Biol 62:109.

pol II: Prokaryotic DNA polymerase, the functions of which are not completely defined so far; it has known role in repair. ▶DNA repair

pol II: The RNA polymerase transcribes messenger RNA and most of the snRNAs of eukaryotes with the assistance of different transcription factors. Nine or ten of its subunits are very similar to other polymerases; pol II has four to five smaller unique subunits. The two largest subunits are very similar in the three eukaryotic RNA polymerases and are similar also to prokaryotic subunits. It is most sensitive to α -amanitin inhibition (0.01 µg/mL). The site of sensitivity is in the largest 220 kDa polypeptide. This large subunit is activated by phosphorylation. At the carboxy terminal, there are 26 (yeast), 40 (*Drosophila*), or 52 (mouse) heptapeptide (Tyr-Ser-Pro-Thr-Ser-Pro-Ser) repeats. These repeats are essential for function. The Ser and Thr residues may be phosphorylated. Phosphorylation of the carboxy-terminal domain may affect the promoter-specificity of

the enzyme. The C-terminus of (CTD) of the large subunit is instrumental also in the processing of the 3'-end of the transcript and the termination of transcription downstream of the polyA signal. CTD does not seem to affect initiation of transcription but it also mediates the response to enhancers. This enzyme is different from RNA pol I and RNA pol III inasmuch that it requires a hydrolyzable source of ATP for the initiation of transcription. RNA pol II is different from the other polymerases in its requirement for a large array of special transcription factors that modulate the transcription of the thousands of proteins. ►transcription factors, ►regulation of gene activity, ► α -amanitin, ►transcription factories, ►RNA polymerase; Cramer P et al 2001 Science 292:1863.

pol III: Prokaryotic DNA polymerase, where the α subunit carries out the replication function and the ϵ -subunit is involved in editing (exonuclease) activity. It plays a major role in the replication of the leading and lagging strands. The replication has a speed of ≈ 1 kb/sec. There are only about 10–20 copies of the 10-subunit holoenzyme/cell. ►DNA replication, ►replication fork, ►core polymerase, ►replisome

pol III: RNA polymerase involved in the synthesis of transfer RNA, 5S rRNA, 7S rRNA and U6 snRNA in eukaryotes. Transcription of pol III is higher during S and G2 phases of the cell cycle than during G1. Many neoplastic cells display high pol III activity indicating that protein synthesis is demanded for tumorous growth. The RET protein appears to be a suppressor of increased pol III activity. ►tRNA, ►ribosomal RNA, ►ribosomes, ►La; Geiduschek EP, Tocchini-Valentini GP 1988 Annu Rev Biochem 57:873; Huang Y, Maraia RJ 2001 Nucleic Acids Res 29:2675.

pol IV: A low-fidelity lesion bypass DNA polymerase belonging to the Y family. ►Y-family DNAs polymerases, ►RNA polymerase

pol α : DNA polymerase (encoded in fission yeast by gene *pol1/swi7*), replicating the nuclear DNA (lagging strand) in cooperation with the primase of eukaryotes. Its mutation may result in mutator activity (Gutiérrez PJA, Wang TS-F 2003 Genetics 165:65). ►lagging strand, ►replication fork, ►DNA polymerases, ►primase

pol β : A eukaryotic DNA repair polymerase. ►DNA polymerases

pol δ : A eukaryotic DNA polymerase (replicating the leading strand) of the nuclear chromosomes. ►replication fork, ►DNA polymerases

pol δ_2 : Synonymous with pol ϵ . ►DNA polymerases

pol ϵ : A eukaryotic DNA polymerase (*cdc20*) with repair role. ►DNA polymerases

pol γ : A DNA polymerase replicating eukaryotic organelle DNA. ► θ type replication, ►DNA polymerases

pol ζ : A eukaryotic DNA polymerase without exonuclease activity. It is a repair enzyme inasmuch that it can bypass pyrimidine dimers more efficiently than pol α . It is insensitive to 200 μ M aphidicolin (and in this respect it is similar to pol β and pol γ) and also insensitive to dideoxynucleotide triphosphates (which inhibit pol β and pol γ). It is moderately sensitive to 10 μ M butylphenyl-guanosine triphosphates. It is relatively inactive with salmon sperm DNA or primed homo-polymers. ►DNA polymerases

Poland Syndrome: An autosomal dominant defect with low penetrance. the teratogenic effects of diverse exogenous factors complicate the inheritance pattern. It is characterized by fusion of fingers (syndactily), short fingers, and anomalies of chest and, sometimes, other muscles. ►limb defects, ►syndactily, ►penetrance, ►teratogenesis

Polar: Hydrophilic, i.e., soluble in water; molecules with polarized bonds.

Polar Body: ►gametogenesis in animals

Polar Body Diagnosis: In polar body diagnosis, the genetic constitution of the polar body is tested by molecular techniques prenatally. ►prenatal diagnosis

Polar Bond: A polar bond is covalent, yet the electrons are more firmly tied to one of the two molecules and therefore the electric charge is polarized.

Polar Coordinate Model: The polar coordinate model of regeneration states that when cells are in non-adjacent positions, the process of growth restores all intermediate positions by the shortest numerical routes. The shortest intercalation mandates that small fragments may undergo duplication and large fragments may require regeneration. The position of each cell on a collapsed cone (the idealized primordium) is specified by the radial distance from a central point at the tip of the cone and the circumferential position on the circle defined by the radius of the base. ►distalization; Held LI 1995 Bioessays 17:721.

Polar Cytoplasm: Polar cytoplasm is situated in the posterior (hind) portion of the fertilized egg cell. ►pole cells

Polar Ejection Force (PEF): Microtubule

Polar Granules: The polar granules are present in the posterior pole region of insect eggs and have maternal effect and germ cell specification roles during

embryogenesis. These granules are the mitochondrially coded 16S ribosomal RNA large subunits (mtRNA), exported from that organelle. ►[animal pole](#), ►[morphogenesis in *Drosophila*](#), ►[RNA localization](#); Strom S, Lehmann R 2007 Science 316:392.

Polar Molecule: A polar molecule is generally soluble in water; the distribution of the positive and negative charges are not even, thus resulting in a polarized effect.

Polar Mutation: A polar mutation may be a base substitution (nonsense mutation), insertion, frame shift, or any chromosomal alteration that affects the expression of genes down-stream in the transcription–translation system. ►[frame shift mutation](#); Jacob F, Monod J 1961 Cold Spring Harbor Symp Quant Biol 26:193.

Polar Nuclei: The polar nuclei occur in the embryosac of plants, and are formed at the third division of the megaspore. After they have fused ($n + n$) and have been fertilized by one sperm (n) they give rise to the triploid ($3n$) endosperm nucleus. ►[megagametophyte](#), ►[embryosac](#)

Polar Overdominance: An unusual type of inheritance, i.e., mutants heterozygous for the dominant *calypige* gene of sheep (chromosome 18) display the (*CLPG*) allele only when inherited from the males but not from the females. The phenotype is a muscular hypertrophy resulting from the cis-regulation of four imprinted genes. ►[imprinting](#), ►[overdominance](#); Charlier C et al 2001 Nature Genet 27:367; Smit M et al 2003 Genetics 163:453.

Polar Transport: Certain metabolites move only in one direction in the plant body, e.g., the auxins under natural conditions are synthesized in the tissues over the ground and then move toward the roots.

Polarimeter: The polarimeter measures the rotation of the plane of polarized light.

Polarisome: A polarisome defines polarity within a cell with the aid of several proteins. (See Weiner OD 2002 Curr Opin Cell Biol 14:196).

Polarity, Embryonic: Embryonic polarity is required for differentiation and requires asymmetric cell divisions. In *Caenorhabditis*, the PAR proteins (serine/threonine kinase) control embryonic polarity and a non-muscle type myosin II heavy chain protein (NMY-2) is a cofactor of this polarity. Upon fertilization the Rho guanosine triphosphatase-activating protein CYK-4—enriched in the sperm—and the RhoA guanine exchange factor ECT-2—modulate myosin light chain activity and create an actomyosin gradient, which determines the anterior domain in the one-cell embryo in *Caenorhabditis*

(Jenkins N et al 2006 Science 313:1298). In *Drosophila*, the major body axes, primarily the anterior-posterior polarity are controlled by the gurken-torpedo gene products, but other genes are also involved. Polarity may be achieved either by the asymmetric distribution of proteins or mRNA. ►[morphogenesis in *Drosophila*](#), ►[differentiation](#), ►[polar cytoplasm](#), ►[RNA localization](#), ►[BUD](#), ►[RHO](#), ►[myosin](#), ►[actomyosin](#); Drees BL et al 2001 J Cell Biol 154:549; Wodarz A 2002 Nature Cell Biol 4:E39; Frizzled pathway: Seifert JRK, Mlodzik M 2007 Nature Rev Genet 8:126.

Polarity of Hyphal Growth: See Fig. P91, Nelson WJ 2003 Nature [Lond] 422:766.

Figure P91. Polarity of hyphal growth

Polarity Mapping: ►[mapping mitochondrial genes](#)

Polarization: The distortion of the electron distribution in one molecule caused by another. ►[bouquet of chromosomes](#)

Polarized Differentiation: the basis of morphogenesis, chemotactic response, response to pheromones, etc. Polarized differentiation and growth is typical for neural and microtubule growth, for the pollen tubes, and for the roots of plants. Neuronal polarization requires the activity of SAD kinases in mammals (Kishi M et al 2005 Science 307:929). ►[asymmetric cell division](#); Hepler PK et al 2001 Annu Rev Cell Dev Biol 17:159; Science [2002] 298:1941–1964.

Polarized Light: Polarized light exhibits different properties in different directions at right angles to the line of propagation. Specific rotation is the power of liquids to rotate the plane of polarization.

Polarized Recombination: ►[polarized segregation](#)

Polarized Segregation: Polarized segregation may be brought about by meiotic anomalies, e.g., in maize plants heterozygous for some knobbed chromosomes (and syntenic markers) are preferentially included into the basal megaspore. Polarized segregation has been observed as a result of gene conversion, e.g., in *Ascobolus immersus* alleles of the *pale* locus in the cross $\frac{188w^+}{188^+w}$ segregated in both cases, it is 6:2, but in the first case the results were $(4[188] + 2[w^+]) : 2(w)$ whereas in the cross $\frac{w^{137+}}{w^{+137}}$ the conversion asci were $(4[w] + 2[137]) : 2(w^+)$. The genetic order of these alleles were *188 w 137*. Thus in the first cross *white*

was in the minority class whereas in the second cross it was part of the majority class. ►[gene conversion](#), ►[meiotic drive](#), ►[map expansion](#); Whitehouse HLK, Hastings PJ 1965 Genet Res 6:27.

Polarizing Microscope: The polarizing microscope uses a *polarizer* (a polaroid screen) in front of the light beam and an *analyzer* (permitting rotation) over the eyepiece. The anisotropic specimens (having difference in transmission or reflection depending on the angle of light) will display optical contrast. ►[microscopy](#)

Polarography: Electrochemical measurement of reducible elements.

Polaroid Camera: The Polaroid camera was developed during the 1940s and has found many uses in biological laboratories because it can provide almost immediate negative or positive images for recording observations such as those of electrophoretic gels. The combined developing and fixing solution is contained in between the exposed negative film and the receiving film or paper and when the storage “pod” bursts under pressure of pulling, the processing is carried out within the camera. For the majority of tasks, the digital cameras are even better suited for fast imaging.

Polaron: The part of a locus within which gene conversion (or recombination) is polarized. ►[gene conversion](#), ►[polarized segregation](#); Whitehouse HLK, Hastings PJ 1965 Genet Res 6:27.

Pole Cells: Pole cells localized in the posterior-most part of the cellularized embryo and give rise eventually to the germline. ►[germline](#)

Polintons: Typically, 15–20 kb long transposable elements in a wide range of lower and higher eukaryotes. They require a unique set of proteins for transposition such as protein-primed DNA polymerase B, retroviral integrase, cysteine protease, and ATPase. They show a 6 bp target site duplication and long inverted terminal repeats with 5'-AG and 3'-TC termini (Kapitonov VV, Jurka J 2006 Proc Natl Acad Sci USA 103:4540). ►[transposable elements](#)

Polioviruses: Icosahedral single-stranded RNA viruses with about 6.1 kb RNA in a total particle mass of about 6.8×10^6 Da; Type 1 was responsible for about 85% of the poliomyelitis (infantile paralysis) cases before successful vaccination (live oral, Sabin or inactivated, Salk) began to be widely used in the developed countries (see Fig. P92). These small RNA viruses are highly mutable because their genetic material lacks repair systems. The three serotypes produce a cell-surface receptor (PVR) by alternative

Figure P92. Apparent polio-stricken leg on a more than 3000 year old Egyptian hieroglyph

splicing of its transcript. Infectious poliovirus has been synthesized *de novo* without a natural template (Cello J et al 2002 Science 297:1016). Susceptibility to poliovirus was located to human chromosome 19q12-q13. Mice are very resistant to this virus because they lack the membrane receptor for the infection. ►[picornaviruses](#), ►[IRES](#), ►[synthetic genes](#)

Polled: A dominant/recessive gene (PIS) in goats and cattle, responsible for lack of horns/inter-sexuality. The forkhead transcription factor (FOXL2)—responsible also for blepharophimosis—may be involved. In goats, an 11.7 kb deletion at 1q43 (homologous to human band 3q23) normally encodes two mRNAs. The FOXL2 transcript is homologous with the human blepharophimosis syndrome gene. ►[blepharophimosis](#); Crisponi L et al 2001 Nature Genet 27:159; Pailhoux E et al 2001 Nature Genet 29:453.

Pollen: The male gametophyte of plants developing from the microspores by two postmeiotic divisions (see Fig. P93). The first division results in the formation of a vegetative and a generative cell. The round vegetative cell directs the elongation of the pollen tube growing through the pistil toward the ovule. Pollen tube growth is guided by sporophytic secretions (GABA, arabinogalactans and

Figure P93. The sculptured surface of the mature pollen of *Arabidopsis*. (From Craig S, Chaudhury A 1994 In: Bowman JL (Ed.) *Arabidopsis: An Atlas of Morphology and Development*. Courtesy of Bowman JL By permission of Springer-Verlag, New York)

Figure P94. Fluorescent-phalloidin staining of the F-actin cytoskeleton in maize pollen. The bright spot on top is the pollen tube initial. (Courtesy of Dr. Chris Staiger. See Gibbon BC et al 1999 *Plant Cell* 11:2349)

proteins) (see Fig. P94). Synergids provide attraction by the 94-amino acid ZmEA1 protein in maize (Márton M et al 2005 *Science* 307:573).

The crescent-shaped generative cells may divide before or after the shedding of the pollen grains. One of them fertilizes the egg and thus, gives rise to the diploid embryo, the other fuses with the diploid polar cell in the embryosac and thus contributes to the formation of the endosperm. The pollen tube

elongates quite rapidly; it may grow 15 cm in just 5 to 15 h. A protein that is glycosylated in that tissue regulates the pollen tube elongation. In allogamous species, a single individual may shed over 50,000,000 pollen grains whereas in autogamous species the number of pollen grains per anther may not exceed a couple of hundreds. Since the pollen grain is haploid and may be autonomous (gametophytic control), it may express its genetic constitution independently from the genotype of the anther tissues (e.g., waxy pollen, various color or sterility alleles), in some instances, however, the morphology of the pollen grain is under sporophytic control. Since the pollen is a more independent product than the megaspore, it is more likely to suffer from genetic defects for which the surrounding tissues cannot compensate, therefore pollen sterility is more common in plants than female sterility. However, pollen sterility may not necessarily affect the fertility of the individuals because of the abundance of functional pollen grains in case of heterozygosity for the defects. Under normal atmospheric conditions (high humidity) and high temperature, the viability of the pollen is maintained (depending on the species) for a few minutes or for several hours. In a refrigerator, at low humidity the viability of the pollen can be extended substantially. Freeze-dried and properly stored pollen of several species retains its ability to fertilize for years. Insects may carry viable pollen for long distances. According to a study, in rye populations cross-pollination (mediated by wind) may occur to 50% at 100 m distance and to 20% at about 400 m distance, but only to 3% at 600 to 700 m. Other studies reported in rye only 7% cross-pollination within a distance of 20 m. Creeping bentgrass (*Agrostis stolonifera*) pollen, transgenic for a resistance marker (5-enolpyruvylshikimate-3-phosphate synthase), was spread by the wind primarily within a distance of 2 km but some dispersal occurred up to 21 km (Watrud LS et al 2004 *Proc Natl Acad Sci USA* 101:14533). The prevailing environmental conditions (humidity, temperature, wind, etc.) and the quantity of the pollen influences the spread and viability. These problems gained new interest with the use of genetically engineered crops that are opposed by some environmentalists. The extracellular matrix of the pollen contains proteins, which recognize species-specificity and efficient pollination (Myfield JA et al 2001 *Science* 292:2482). These proteins are lipid-binding oleosins and lipases. ▶microsporogenesis, ▶gametogenesis, ▶pollen tetrad, ▶gametophyte, ▶self-incompatibility, ▶cross-pollination, ▶GMO, ▶autogamy, ▶allogamy

Pollen Competition: ▶certation

Pollen-Killer: Pollen-killer or spore-killer genes in wheat, tomato, and tobacco render the pollen incapable of functioning effectively in fertilization and may cause segregation distortion. ▶segregation distorter, ▶pollen tube competition, ▶killer strains, ▶killer plasmids, ▶killer genes

Pollen Mother Cell: Microspore mother cell, microsporeocyte. ▶gametogenesis

Pollen Sterility: The inability of the pollen to function during fertilization. It can frequently be detected by the poor staining of the pollen grains with simple nuclear stains (acetocarmine, acetoorcein, etc.). Deletions, translocations, and inversion heterozygosity generally result in pollen sterility. Mitochondrial plasmids may also be responsible for some types of male sterility. ▶pollen, ▶certation, ▶gametophyte, ▶cytoplasmic male sterility, ▶fertility restorer genes

Pollen Tetrad: The four products of a single male meiosis (see Fig. P95). The components of the pollen tetrad may not stick together and may shed in a scrambled state. In some instances (*Salpiglossis*, *Elodea*, some orchids), the tetrads remain together, however, in a way similar to the unordered tetrads of fungi. In *Arabidopsis*, induced mutations (*qrt1*, *qrt2*, *quartet*) cause the four pollen grains to stay together because of the alteration of the outer membrane of the pollen mother cell. Each tetrad may then fertilize four ovules. ▶tetrad analysis

Figure P95. Pollen tetrad

Pollen Tube: In the majority of plants, the time between pollination and fertilization takes 24 to 48 h or less. In the alder tree (*Alnus*) the pollen tube travels slowly in the pistil (for about one month) because the ovary matures late and it arrives at fertilization in five successive steps. Also in some species, the ovaries may have multiple megaspore tetrads although, generally only one is fertilized (Sogo A, Tobe H 2005 Proc Natl Acad Sci USA 102:8770). ▶pollen, elongating pollen tube in Figure P96, ▶synergid,

▶GABA, ▶gametophyte, ▶double fertilization; Palavinelu R, Preuss D 2000 Trends Cell Biol 10:517.

Figure P96. Pollen tube germination

Pollen-Tube Competition: ▶certation

Pollination: The transfer of the male gametophyte to the stigmatic surface of the style (ovary). Obligate allogamous plant populations may suffer if the pollinator insect populations are reduced by adverse environmental conditions (Vamosi J C et al 2006 Proc Natl Acad Sci USA 103:956). ▶gametophyte, ▶autogamy, ▶alogamy, ▶fertilization, ▶self-sterility

Pollinium: A mass of pollen sticking together and may be transported as such by the pollinator insects or birds.

Pollitt Syndrome: ▶trichothiodystrophy

Pollution: Spoiling the environment by the release of unnatural, impure, toxic, mutagenic, carcinogenic, or any other undesirable and unaesthetic material, or to disturb nature by sound, odor, heat, and light. Pollution may cause mutation, cancer, and various other diseases. ▶DNA-zyme; <http://www.scorecard.org>.

Polo: A 577-amino acid serine/threonine protein kinase of *Drosophila*, required for mitosis. It regulates centromeric cohesion protein MEI-S332 (Clarke AS et al 2005 Dev Cell 8:53). During interphase, it is predominantly cytoplasmic but at the end of prophase it associates with the chromosomes until telophase. Loss of polo kinase 4 allele(s) increases the probability of mitotic errors and cancer. In about 60% of the cells of mice, loss of heterozygosity takes place (Ko MA et al 2005 Nat Genet 37:883). ▶CDC5, ▶FEAR, ▶cohesin; Llamazares S et al 1991 Genes Dev 5:2153; Alexandru G et al 2001 Cell 105:459.

Polony (polymerase colony): A small batch of DNA synthesized by PCR with the assistance of a primer to

be used for sequencing. The PCR colonies on the glass microscope slide are the “colonies.” On a single slide in the polyacrylamide film, as many as 5 million clones can be amplified. The amplified products stay at the vicinity of the linear DNA. If acrydite modification is used, the DNA is covalently attached to the polyacrylamide matrix and thus further enzymatic modifications are possible on all clones. The technology is well suited for genotyping and localizing of SNPs. ▶PCR, ▶SNPs; Mitra RD, Church GM 1999 Nucleic Acids Res 27(24):e34; Mitra RD et al 2003 Proc Natl Acad Sci USA 100:5926.

Poly I-G: A DNA strand containing more cytosine is called heavy chain of a DNA double helix because it binds more of the polyI-G (inosine-guanosine) sequences. Ultracentrifugation in CsCl separates these DNA heavy strands. ▶ultracentrifuge, ▶density gradient centrifugation, ▶DNA heavy chain, ▶inosine

PolyA⁺ Element: Transposons without long terminal repeats but poly-A sequences at the 3'-OH end. The RNA elements are usually mobilized via a DNA transcript with the aid of their encoded reverse transcriptase. Such elements are L1 (LINE) in mammals, the TART of *Drosophila*, the TRAS1 of silkworm, or the yeast Ty5 telomere-specific elements. Other polyA⁺ elements (L1, I, and fungal and plant elements) can target a variety of other sites. ▶TART, ▶hybrid dysgenesis, ▶transposable elements

polyA mRNA: Eukaryotic mRNAs post-transcriptionally polyadenylated at the 3' tail before leaving the nucleus. Subsequently, in the cytoplasm, the tail may be reduced to 50–70 residues or further extended to hundreds. Polyadenylation improves the stability and efficiency of translation in cooperation with mRNA cap. The polyA tail and the mRNA cap seem to cooperate in the initiation of translation. PolyA tail is frequently added also to bacterial RNA. The addition of polyA tail accelerates the decay of RNA I of *E. coli*. All the data are consistent with polyadenylation being part of a quality control process targeting folded bacterial RNA fragments and non-functional RNA molecules to degradation. In *Escherichia coli*, polyadenylation may directly control the level of expression of a gene by modulating the stability of a functional transcript. Inactivation of poly(A) polymerase I causes overexpression of glucosamine-6-phosphate synthase (GlmS) and both the accumulation and stabilization of the *glmS* transcript (Joanny G et al 2007 Nucleic Acids Res 35:2494).

The majority of eukaryotic viruses (except arenaviruses and reoviruses) also produce a poly A tail. In *Drosophila*, the length of the poly(A) tail may be

correlated with the function in the differentiation of the mRNA. The regulatory mechanism of polyadenylation is interchangeable between mouse and *Xenopus*. Some genes use alternative polyadenylation sites (Edwards-Gilbert G et al 1997 Nucleic Acids Res 25:2547). ▶polyadenylation signal, ▶mRNA tail, ▶RNA I, ▶PABP, ▶mRNA degradation, ▶capping enzymes, ▶eIF; de Moor CH, Richter JD 2001 Int Rev Cytol 203:567; <http://polya.umdj.edu/>.

polyA Polymerase (PAP): adds the polyA tail post-transcriptionally to the eukaryotic mRNA and antisense RNA transcripts (see Fig. P97). In yeast, at least two other genes *RNA14* and *RNA15* are involved in the processing of the 3'-end of the pre-mRNA.

Figure P97. Poly(A) polymerase is regulated by inhibition (or stimulation) by the polyadenylation inhibition RNA element (PIE). PIE forms a trimolecular complex including the two U1A protein molecules. The U1A consists of a four-stranded β -sheet and two α -helices. The two C helices of the protein interface. The PIE RNA, which contains two asymmetric internal loops is separated by four Watson-Crick-paired nucleotides. (From Puglisi JD 2000 Nature Struct Biol 7:263)

E. coli also encodes at least two PAP enzymes. PolyA polymerase also facilitates the degradation of mRNA because it provides single-strand tails for polynucleotide phosphorylase. Bacterial PAP and tRNA nucleotidyl transferase are highly similar in structure but different in function inasmuch the latter catalyzes the addition of CCA to the 3'-end of tRNA. The C-terminal domain of nucleotidyl transferase restricts polymerization to these three nucleotides whereas a 27-aminoacid sequence determines whether the protein becomes a transferase or PAP. Both proteins have identical nucleotide recognition and incorporation domains (Betat H et al 2004 Mol Cell 15:389). ▶mRNA tail, ▶polyadenylation signal, ▶polynucleotide phosphorylase; Dickson KS et al

polyA Tail: ►polyadenylation signal, ►polyA mRNA

Polyacrylamide: See Fig. P98, ►electrophoresis, ►gel electrophoresis

Figure P98. Polyacrylamide gel

Polyadenylation Signal: The endonucleolytic processing of the primary transcript of the majority of eukaryotic genes is followed by post-transcriptional addition of adenylic residues downstream of the structural gene. The consensus signal for the process is 5'-AAUAAA-3' in animals and fungi, about half of the plants use the same signal, the rest rely on diverse signals. In humans, ~54%, and in mouse, ~32% of the genes have alternative polyadenylation sites and different cleavage sites resulting in heterogeneity of the transcripts, which may represent a type of regulation of gene expression (Tian B et al 2005 Nucleic Acids Res 33:201). In eukaryotes, the number of added A residues might vary from 50 to 250. The crystal structure of the 73 kDa subunit of the human polyadenylation-specificity endonuclease has been determined (Mandel CR et al 2006 Nature [Lond] 444:953).

Polyadenylation is under the control of several genes (see Fig. P99). The RNA transcript of eukaryotes besides the poly(A) signal contains a CA element (PyA in yeast) and a GU-rich downstream element.

Figure P99. Some of the mechanisms in polyadenylation

To the AAUA AA *positioning element*, binds the *polyadenylation specificity factor* (CPSF) that is a tetrameric protein consisting of 160, 73, 100, and 33 kDa subunits. The *cleavage stimulating factor* (CstF), a trimeric protein of 64, 77, and 50 kDa subunits, binds to GU-rich element of the RNA. The *polyadenylation polymerase* protein (PAP) binds

downstream of the CPSF binding sites. The *cleavage factors* (CFI) and (CFII) are positioned upstream of the GU-rich element and they terminate the mRNA. The polyadenylation complex of yeast is somewhat different. The PABP (poly-A-binding protein, 70 kDa) regulates mRNA stability, translation, and degradation. CPEB (cytoplasmic element binding protein), maskin, and cyclin B1 are regulators of polyadenylation and the transcription of some mRNAs. Poly(A)-specific ribonuclease (PARN) is a cap-interacting 3' exonuclease. In cooperation with the cap, it mediates de-adenylation from cis position, or at low concentration it may be inhibitory to de-adenylation. From trans position, it inhibits de-adenylation if its concentration is high. The poly(A) tail, in synergy with the mRNA cap, stimulates the initiation of translation. The poly(A) binding protein (PABP) interacts with eIF4G of the eIF4F complex and eIF4E interacts with the cap and stabilizes mRNA. PABPs are located both in the nucleus and in the cytoplasm. In the human testes, a specific poly(A) binding protein occurs that is absent from other tissues (Féral C et al 2001 Nucleic Acids Res 29:1872). De-adenylation of the tail initiates mRNA decay and when less than ten A residue is left, an exonuclease attacks the RNA in 5'→3' direction (Martínez J et al 2001 J Biol Chem 276:27923). In prokaryotes, rarely a few (14–60) adenine residues are also found at the mRNA 3'-terminus in 1 to 40% of the cases. In bacteria, *host factor q* (Hfq) plays a role similar to PABP. It stimulates the elongation of the polyA tail by poly(A) polymerase I (PAP) and protects against exoribonuclease attack. Some adenine sites are found in about 30% of both the early transcripts (transcribed by host polymerase) and late transcripts (transcribed by viral polymerase). Sometimes the poly-A sequence has interspersed other bases and may be located also within coding sequences. An interspersed long poly(A) sequence was detected also in chloroplast RNA transcripts. In mitochondria, the poly-A tract (35–55 A residues) directly attaches to the termination codon without an untranslated sequence, after the endonucleolytic cleavage of the polycistronic transcript. In liver cancer, mitochondria tails of hundreds of As have been observed. In prokaryotes, two similar (36 and 35 kDa) poly-A polymerases with overlapping functions have been identified. With the exception of histone transcripts, all eukaryotic mRNAs appear polyadenylated, although some can be processed to become non-polyadenylated and the two types may coexist (bimorphic transcript). Polyadenylation of RNA in bacteria regulates plasmid replication and the degradation of RNAI. In yeast, the Trf4 complex recruits exosomes and the incorrectly folded polyadenylated RNA is degraded (Vaňáčová S et al 2005 PLoS Biol 3(6):e189). (In *Archaea* short poly-A tracts

exist). Cordycepin (3'-deoxyadenosine) is an inhibitor of polyadenylation.

In the *Drosophila melanogaster* genome, 17 polyadenylated sequences were detected without protein coding transcripts, yet many of these sequences were conserved in related species indicating some roles because of their conservation (Tupy JL et al 2005 Proc Natl Acad Sci USA 102:5495). Let-7 miRNPs, containing, Argonaute and GW182, dampen the synergistic enhancement of translation by the 5'-cap and 3'-poly(A) tail, resulting in translational repression (Wakayama M et al 2007 Genes Dev 21:1857). ▶mRNA tail, ▶U1 RNA, ▶polyA polymerase, ▶RNA I, ▶cleavage stimulation factor, ▶PABp, ▶mRNA circularization, ▶eIF4, ▶TRAP, ▶symplekin, ▶microRNA, ▶Argonaute, ▶GW body; Hirose Y, Manley JL 1998 Nature [Lond] 395:93; Sarkar N 1997 Annu Rev Biochem 66:173; Beaulieu E et al 2000 Genome Res 10:1001; Mendez R Richter JD 2001 Nature Rev Mol Cell Biol 2:521; Wang L et al 2002 Nature [Lond] 419:312; <http://polya.umdj.edu/>; http://polya.umdj.edu/PolyA_DB2.

Poly(ADP-Ribose) Polymerase: A DNA-binding enzyme but it appears to have no indispensable function.

Polyamides: Polyamides containing *N*-methylimidazole and *N*-methylpyrrole amino acids have high affinity for specific DNA sequences and may regulate the transcription similarly to DNA binding proteins. ▶binding proteins, ▶inhibition of transcription, ▶netropsin, ▶lexitropsin; Maeshima K et al 2001 EMBO J 20:3218.

Polyamidoamine Dendrimers (PAMAM): Highly branched, soluble, non-toxic molecules with amino groups on their surface. They are suitable for attaching to this surface antibodies, various pharmaceuticals, and DNA. They are effective vehicles for transfection. (See Gebhart CL, Kabanov AV 2001 J Control Release 73:401).

Polyamines: Polyamines are various protein molecules derived in part from arginine and present in cells in millimolar concentrations, yet have important roles in RNA and DNA transactions, replication, supercoiling, bridging between strands, binding phosphate groups, biosynthesis, degradation, etc. Typical polyamines are spermine, spermidine, putrescine, etc. ▶antizyme, ▶lexitropsins; Coffino P 2001 Nat Rev Mol Cell Biol 2:188; van Dam L et al 2002 Nucleic Acids Res 30:419.

Polyandry: A form of polygamy involving multiple males for one female. It may have the advantage of reducing the relatedness within colonies of social insects and thereby increasing fitness. In the

live-bearing pseudoscorpions (*Cordylochernes scorpioides*), outbred embryos have beneficial effects on inbred half-siblings in mixed-paternity broods developing in the external, translucent brood sac and fed by nutrients of the maternal reproductive tract by an unclear mechanism (Zeh JA, Zeh DW 2006 Nature [Lond] 439:201). Honeybee queen matings with several drones enhances productivity and fitness of the colony (Mattila HR, Seeley TD 2007 Science 317:362). ▶fitness; Tregenza T, Wedell N 2002 Nature [Lond] 415:71.

Polyaromatic Compounds: Polyaromatic compounds include various procarcinogens and promutagens, such as benzo(a)pyrene, dibenzanthracene, methylcholanthrene, etc. ▶polycyclic hydrocarbons.

Polybrene (hexadimethrine bromide): A polycation used for introduction of plasmid DNA into animal cells; it is also an anti-heparin agent and an immobilizing agent in Edman degradation. Polybrene may have different toxicity to various cells. ▶transformation genetic animal cells, ▶heparin, ▶Edman degradation

Polycentric Chromosome: ▶neocentromeres

Polychlorinated Biphenyl (PCB): A highly carcinogenic compound and an inducer of the P-450 cytochrome group of monooxygenases. It had been used in electrical capacitors, transformers, fire retardants, hydraulic fluids, plasticizers, adhesives, pesticides, inks, copying papers, etc. *Pseudomonas* sp. KKS102 is capable of degrading PCB into tricarboxylic acid cycle intermediates and benzoic acid. ▶microsomes, ▶S-9, ▶P-450, ▶carcinogen; Ohtsubo Y et al 2001 J Biol Chem 276:36146.

Polychromatic: A polychromatic substance is stainable by different dyes or displays different shades when stained.

Polycistronic mRNA: A contiguous transcript of adjacent genes, such as exist in an operon but may also be formed in the short genes of eukaryotes, e.g., oxytocin. The *Trypanosomas* produce multicistronic transcripts. A gene (*mlpt*) of *Tribolium* involved in body segmentation also produces polycistronic mRNA. ▶operon, ▶oxytocin, ▶*Trypanosoma*, ▶*Caenorhabditis*, ▶*Tribolium*

Polyclonal Antibodies: Polyclonal antibodies are produced by a population of lymphocytes in response to antigens. These are not homogeneous as are the monoclonal antibodies. ▶monoclonal

Polycomb (*Pc*, chromosome 3-47.1): The *Drosophila* gene is a negative regulator of the *Bithorax* (*BXC*) and *Antennapedia* (*ANTC*) complexes (see Fig. P100). The homozygous mutants are lethal and the locus

Figure P100. Sex combs on the second legs of male *Drosophila* in the *Sex comb extra* (*Scx*, 3.47, at left) and *Scx-Pc* (at right) homeotic mutants. Similar extra sex combs appear also on the third leg whereas sex combs in the wild type are limited to the first pair of legs. (After Hannah-Alava A 1958 *Genetics* 43:878)

(and its homologs in vertebrates [*M33* in mice]) is involved in the repression of homeotic genes, which control body segmentation. *Pc* is a member of a group (*Pc-G*) of repressors of homeotic genes (Cao R et al 2002 *Science* 298:1039). Although *Pc* is located in the euchromatin, it is involved in the silencing of genes by heterochromatin (Francis N et al 2004 *Science* 306:1574). Genes have been identified that are targeted for transcriptional repression in human embryonic stem (ES) cells by the *Pc-G* proteins suppressor of zeste 12 (*SUZ12*) and embryonic ectoderm development (*EED*), which form the Polycomb repressive complex 2 (*PRC2*) and which are associated with nucleosomes that are trimethylated at Lys27 of histone H3 (H3K27). Stem cell occupancy by *SUZ12* and *EED* and the trimethylation status of H3K27 for 77/177 genes showed evidence of cancer-associated DNA methylation when compared with matched normal colorectal mucosa. The observations suggest that the first predisposing steps towards malignancy may occur very early and are consistent with reports of field changes in histologically normal tissues adjacent to malignant tumors. These results provide a mechanistic basis for the predisposition of certain promoter CpG islands to cancer-associated DNA hypermethylation as an early epigenetic cancer marker (Widschwendter M et al 2007 *Nat Genet* 39:157).

Pc is involved in Histone2A ubiquitylation and the inactivation of mammalian X chromosome

(de Napoles M et al 2004 *Dev Cell* 7:663). Insertion into the 5th exon of *M33* caused male→female sex-reversal. *Pc* is required for the activation of other silencing elements and its mutation may lead to derepression of these elements. The suppressive effect of *Pc* may be associated with chromatin remodeling and histone deacetylation. The Polycomb group of proteins forms a large complex and the TATA-box-binding proteins, Zeste and others, are associated with the general transcription machinery (Czermin B et al 2002 *Cell* 111:185). The *SUZ12* subunit of the Polycomb Repressive Complex 2 (*PRC2*) extends over 200 genes encoding developmental regulators of human embryonic stem cells (such as Nanog, Oct4, Sox2, RNAP2 and *SUZ12*) (see Fig. P101). These genes are transcriptionally repressed because in the nucleosomes histone H3K27 is trimethylated. The *PRC2* target genes are repressed in order to maintain pluripotency of these cells but they are activated during differentiation (Lee TI et al 2006 *Cell* 125:301). The *PRC1* and *PRC2* polycomb complexes co-occupy 512 genes and bind hundreds of others (►Venn diagram) coding for transcription factors during mouse embryonic development until differentiation (Boyer LA et al 2006 *Nature [Lond]* 441:349).

►morphogenesis in *Drosophila*, ►transdetermination, ►*SWI*, ►homeobox, ►homeotic genes, ►chromodomain, ►sex-reversal, ►*w* locus, ►*zeste*, ►*Antennapedia*, ►*Bithorax*, ►*trithorax*, ►chromatin remodeling, ►nucleosomes, ►histone deacetylase, ►histones, ►TBP, ►transcription factors, ►Lyonization, ►ubiquitin, ►epigenesis, ►stem cells, ►genetic networks, ►pairing-sensitive repression; Breilling A et al 2001 *Nature [Lond]* 412:651; Simon JA, Tamkun JW 2002 *Curr Opin Genet Dev* 12:210; Polycomb repressor complex in epigenesis: Kuzmichev A et al 2005 *Proc Natl Acad Sci USA* 102:1859; review: Schwartz YB, Pirrotta V 2007 *Nat Rev Genet* 8:9; review: Schüttengruber B et al 2007 *Cell* 128:735.

Figure P101. Polycomb group proteins overlap and repress many developmental regulators of mouse

Polycross: An intercross among several selected lines to produce a “synthetic variety” of a crop (See Tysdal HM et al 1942 Alfalfa Breeding, Nebr Agric Exp Sta Res Bull 124, Lincoln, Nebraska).

Polycyclic Aromatic Hydrocarbons (PAH): Generally, carcinogenic and mutagenic compounds. They become more active during the process of attempted detoxification by the microsomal enzyme complex. PAHs are the products of burning organic material (coal, charbroiling, smoking, etc.). Mice oocytes exposed to PAHs suffer apoptosis by activation of BAX. ▶carcinogens, ▶procarcinogens, ▶mutagens, ▶promutagens, ▶benzo(a)pyrene, ▶environmental mutagens, ▶PAH, ▶BAX, ▶apoptosis; Matikainen T et al 2001 Nature Genet 28:355.

Polycystic Lipomembraneous Osteodysplasia with Sclerosing Leukoencephaly (PLOS), Nasu-Hakola disease, 19q13.1): A recessive psychosis turning into presenile dementia and bone cysts limited to the wrists and ankles. Prevalence in Finland is 2×10^{-6} . The basic problem is a loss of function of the TYROBP/DAP12 tyrosine kinase binding transmembrane protein, an activator of killer lymphocytes. ▶killer cells

Polycystic Kidney Disease (PKD): PKD occurs in two main forms, and within each several form variations exist (see Fig. P102). The short arm of human chromosome 16p13.31-p13.12 apparently controls the adult type dominant (ADPKD), which involves fragility of the blood vessel walls. In the autosomal recessive ARPKD, the basic defect is in the

Ca^{2+} -permeable non-selective cation channel. About 15% of the APKD cases are due to mutation in the gene (PKD2) encoding polycystin. Another gene (PKD1) is involved in the proliferation of the epithelial cells lining the cyst cavity, the thickening of the basement membrane, fluid secretion, and protein sorting (Bukanov NO et al 2002 Hum Mol Genet 11:923). ARPKD generally has an early onset. Both forms occur at frequencies of 0.0025 to 0.001. Even the late onset type may be detectable early by tomography. The symptoms vary and involve kidney disease, cerebral vein aneurism (sac like dilatation), underdeveloped lungs, liver fibrosis, and growth retardation, etc. The dominant type can be identified with high accuracy using chromosome 16p13 DNA probes but less than 10% of the cases are due to genes not in chromosome 16. The autosomal recessive form is at an unknown location and it can be identified after the third trimester by ultrasonic methods because the kidneys are enlarged. The genetic transmission of the dominant and recessive diseases is very efficient. One polycystic kidney (PKD1, 4300-amino acid integral membrane glycoprotein) locus was assigned to 6q21-p12, and sequences were also found in 2p25-p23 and 7q22-q31; these are homologous to polycystic kidney disease of the mouse. There is a PKD2 locus in 4q21-q23 and this is similar in function to PKD1. PKD2 interacts with PKD1 and PKD2 interacts also with the Hax-1 protein binding F-actin, suggesting that the system affects the cytoskeleton. Thus defect in PKD2 may be one of the causes of cyst formation in the kidney, liver, and pancreas. The

Figure P102. Polycystic kidney disease in RRRCHa:SPRD rat. a: wild type, b: heterozygote, and c: homozygous *Pkdr1* mutant. The homozygous mutant rats die at age 3–4 weeks. Heterozygous males develop renal failures by about 6 months whereas the heterozygous females rarely progress to renal failure and death. Heterozygous males can be identified by blood urea nitrogen (BUN) level of the serum or plasma at age 9–10 weeks. PCR analysis and sequencing detected A for G substitution in exon 12 of the mutant gene. (The histological images are the courtesy of Professors Beth A. Bauer and Craig L. Franklin, Rat Resource and Research Center University of Missouri, Columbia, Missouri 6211; <http://www.nrrrc.missouri.edu/Straininfo.asp?apn=46>)

infantile type recessive PKD is also called Caroli disease. The ARPKD locus encodes a 968-amino acid protein, which forms six transmembrane spans with intracellular amino and carboxyl ends. It appears to be a voltage-activated Ca^{2+} (Na^+) channel protein. In a mouse model and in humans, TOR antagonist rapamycin protein may alleviate the dominant ADPKD disease (Schillingford JM et al 2006 Proc Natl Acad Sci USA 103:5466). The CDK inhibitor roscovitine ($\text{C}_{19}\text{H}_{26}\text{N}_6\text{O}$) appears to be an effective inhibitor of PKD in mouse (Bukanov NO et al 2006 Nature [Lond] 444:949). PKD1 may involve haplo-insufficiency. The PKD1 homolog in *Caenorhabditis* (*LOV-1*) controls sensory neurons required for male mating behavioral steps. The traditional Chinese drug, a diterpene triptolide (Lei Gong Teng), induces PC2-dependent calcium release and attenuates cyst formation (see Fig. P103) (Leuenroth SJ et al 2007 Proc Natl Acad Sci USA 104:4389). ▶cardiovascular disease, ▶Caroli disease, ▶hypertension, ▶genetic screening, ▶ion channels, ▶haplo-insufficient, ▶rapamycin, ▶CDK; Pei Y et al 2001 Am J Hum Genet 68:355; Lin F et al 2003 Proc Natl Acad Sci USA 100:5286; autosomal dominant polycystic kidney disease: <http://pkdb.mayo.edu/>.

Figure P103. Triptolide

Polycystic Liver Disease; (PCLD, 19p13.2-p13.1): A dominant, often accompanying polycystic kidney disease. It involves fluid-filled cysts on the liver. The protein involved is hepatocystin. (See Drenth JPH et al 2003 Nat Genet 33:345).

Polycystic Ovarian Disease (Stein-Leventhal syndrome): Polycystic ovarian disease generally involves enlarged ovaries, hirsuteness, obesity, lack of or irregular menstruation, increased levels of testosterone high ratios of luteinizing hormone: follicle-stimulating hormone, and infertility. It appears to be due an autosomal factor, yet 96% and 82% of the daughters of affected mothers and carrier fathers, respectively, developed the symptoms indicating a meiotic drive-like phenomenon. Deficiency of 1- α -ketosteroid reductase/dehydrogenase (9q22) may cause polycystic ovarian disease as well as pseudohermaphroditism with gynecomastia in males. ▶infertility, ▶luteinization, ▶Graafian follicle, ▶meiotic drive, ▶pseudohermaphroditism, ▶gynecomastia

Polycystin: Polycystin proteins are supposed to regulate different functions, such as mating behavior, fertilization by the sperm, asymmetric gene expression, and mechanosensory transduction (Delmas P 2004 Cell 118:145).

Polycythemia (PFCP): An autosomal dominant proliferative disorder of the erythroid progenitor cells, resulting in an increase in the number of red blood cells and in vitro hypersensitivity to erythropoietin. Mutations in the von Hippel-Lindau protein are responsible for about half of the cases. Mutations of valine→phenylalanine at amino acid site 617 in Janus kinase 2 occurs in more than 80% of acquired polycythemic mice and leads to constitutive tyrosine phosphorylation and increased sensitivity to cytokinins (James C et al 2005 Nature [Lond] 434:1144) ▶erythropoietin, ▶Janus kinases, ▶von Hippel-Lindau syndrome; Pastore Y et al 2003 Am J Hum Genet 73:412.

Polydactyly: The presence of extra fingers or toes. In *postaxial* polydactyly (the most common type), the extra finger is in the area of the “little finger” (see Fig. P104) and in *preaxial* cases, this malformation is on the opposite side of the axis (thumb) of the palm or foot. The various types of polydactyly may be determined by autosomal recessive or dominant gene(s) and their expression is usually part of other syndromes. Crossed polydactyly indicates coexistence of postaxial and preaxial types with discrepancy between hands and feet. Synpolydactyly is caused by an expansion of the normal 15 GCG trinucleotides to 22–29.

►Ellis-van Creveld syndrome, ►Opitz syndrome, ►Meckel syndrome, ►Majewski syndrome, ►orofacial-digital syndromes, ►Patau's syndrome, ►diastrophic dysplasia, ►syndactyly, ►polysyndactyly, ►Greig's cephalopolysyndactyly syndrome, ►Rubinstein-Taybi syndrome, ►Pallister-Hall syndrome, ►focal dermal hypoplasia, ►ectrodactyly, ►adactyly, ►*hedgehog*

Polyelectrolytes: Polymers with attached anions and cations, respectively. Proteins and nucleic acids can be polyelectrolytes by carrying negatively and positively charged groups.

Polyembryony: In polyembryony, more than one cell of the embryo sac develops into an embryo in plants or in insects a single egg by clonal reproduction of hundreds of embryos. ►adventive embryos, ►embryo sac; Zhurov V et al 2004 Nature [Lond] 432:764.

Polydna Virus: ►parasitoid

Polyethylene Glycol (PEG): A viscous liquid or solid compound of low-toxicity, promoting fusion of all types of cells. PEG is widely used in textile, cosmetics, paint, and ceramics industry. ►PEG

Polyethyleneimine (PEI): A water-soluble polymer, which binds and precipitates DNA. It assists in the uptake of molecules including transforming DNA, especially in RGD-coated particles. Polyethyleneimine (25 kDa) contains N-acyl groups, which handicap its use for genetic transfection (see Fig. P105). Removal of these groups enhances its utility as an artificial vector. New linear PEIs synthesized by acid-catalyzed hydrolysis of poly(2-ethyl-2-oxazoline) yielded products, which increased transfection efficiency up to 115-fold compared to deacetylated commercial PEI. In addition, its efficiency for targeting lung cells increased 200-fold. Using this vector for RNAi delivery against the nucleocapsid protein gene of influenza virus dropped the virus titer in the lung of mice. A further advantage was the lower toxicity. Note: ethyleneimines are poisonous and mutagenic. ►RGD, ►vectors, ►gene therapy

Figure P105. Left: PEI25 commercially available before hydrolysis. Right: Newly synthesized PEI after hydrolysis. After Thomas M et al. 2005 Proc. Natl. Acad. Sci. USA 102:5679

Polygalacturons: Complex carbohydrates in the plant cell wall.

Polygamy: Polygamy implies having more than one mating partner. In western human societies, it is illegal but in others, it is still acceptable for men to have more than one wife at the same time. Polyandry or polygyny is a common practice in animal breeding but it may be objectionable to humans on moral grounds. In the USA, polygamy laws are applied to all citizens, irrespective of religious affiliation or cultural tradition.

Polygenes: A number of genes involved in the control of quantitative traits. ►gene number in quantitative traits, ►QTL

Polygenic Inheritance: Polygenic inheritance is determined by a number of non-allelic genes, all involved in the expression of a single particular trait (such as height, weight, intelligence, etc.). Polygenic inheritance is characterized by counting and measurements and the segregating classes are not discrete but display continuous variation. ►quantitative genetics, ►QTL, ►complex inheritance, ►chaos, ►digenic diseases, ►selection long term, ►gain; Tanksley SD 1993 Annu Rev Genet 27:205; Klose J et al 2002 Nature Genet 30:385.

Polygenic Plasmids: are obtained when two plasmids carrying identical genes cointegrate. Such plasmids may have merit in genetic engineering if the genes show positive dosage effect for anthropocentrically useful traits. ►cointegration

Polygyny: In polygyny, one male has more than a single female mate. In *sororal polygyny*, the females are sisters. ►polygamy, ►effective population size

Polyglutamylase: The polyglutamylase enzyme adds several glutamic acids to the γ -carboxyl of a glutamate residue of proteins, such as tubulin and nucleosome assembly proteins (Janke C et al 2005 Science 308:1758).

Polyglutamine Diseases: ►trinucleotide repeats, ►res-veratrol

Polygyne: Polygyne describes social insect colonies with more than a single queen. ►monogyne

Polyhaploid: A polyhaploid has half the number of chromosomes of a polyploid. The gametes of polyploids are polyhaploid. ►polyploidy

Polyhedrosis Virus, Nuclear (BmNPV): An about 130 kbp DNA baculovirus of the silkworm (and other insects). It has been used (after size reduction) as a 30 kb cloning vector and it may propagate in a single silkworm larva about 50 μ g DNA. ►baculoviruses,

►viral vectors, ►silkworm; Xia Q et al 2003 J Biol Chem 278:1094.

Polyhybrid: A polyhybrid is heterozygous for many gene loci.

Polyhydroxybutyrate (PHB): A bacterial polymer that can be manufactured by transgenic plants and is biodegradable.

Polyisoprenyl Phosphates: Intermediates in cholesterol biosynthesis; they play a role in signaling to the immune system. ►immune system, ►cholesterols

Polyketenes: Polymers of $\text{CH}_2 = \text{C} = \text{O}$ (ketene). Their biosynthesis is related to fatty acids. Several antibiotics (tetracycline, griseofulvin, etc.) contain ketenes. ►antibiotics

Polyketides: Various naturally occurring compounds, built from residues, which each usually contribute two carbon atoms to the assembly of a linear chain of which the β -carbon carries a keto group. These keto groups are frequently reduced to hydroxyls. The remaining keto groups at many of the alternate carbon atoms form the chains, which are called polyketides. Polyketide synthesis pathway resembles the fatty acid path. Flavonoids, mycotoxins, antibiotics, etc., occurring in plants from angiosperms to bacteria qualify for the polyketide collective name. Polyketide synthetases generate the precursors of erythromycin, rapamycin, and rifamycin antibiotics. ►lovastatin, ►epothilone; Khosla C et al 1999 Annu Rev Biochem 68:219; Walsh CT 2004 Science 303:1805.

P

Polykinetic Chromosome: A polykinetic chromosome has centromeric activity at multiple sites. ►neocentromeres

Polylinker: A DNA sequence with several restriction enzyme recognition sites (multiple cloning sites, MCS) used in construction of different cloning or transformation vehicles (plasmids). e.g., TTCTA-GAATTCT sequence has an overlapping XbaI (TCTAGA) and an EcoRI recognition sites (GAATTC) and thus linking it to the DNA may

generate both types of cloning sites. ►vectors, ►restriction enzymes, ►cloning sites, ►pUC

Poly(L-Lysine): A polycation that can form complex(es) with negatively charged DNA and mediate gene transfer using retroviral vector. In case the polycation has bound specific ligand(s), it can be targeted to special cell types. Without such a complex, the viral vector would have no target specificity. Some of the polycationic delivery systems are cytotoxic and/or may be subject to lysosomal degradation. ►transformation genetic; Putnam D et al 2001 Proc Natl Acad Sci USA 98:1200.

Poly-Marker Test: ►DNA fingerprinting

Polymer: A large molecule composed of a series of covalently linked subunits such as amino acids, nucleotides, fatty acids, carbohydrates, etc. ►DNA, ►protein; biopolymer motifs: <http://bayesweb.wadsworth.org/gibbs/gibbs.html>.

Polymerase: An enzyme that builds up large molecules from small units, such as the DNA and RNA polymerases generated from nucleotides DNA and RNA, respectively. ►pol

Polymerase Accessory Protein (RF-C): An essential part of the DNA replication unit in SV40. ►SV40

Polymerase Chain Reaction (PCR): A method of the rapid amplification of DNA fragments, employed when short flanking sequences of the fragments to be copied are known (see Fig. P106). The reaction begins by the denaturation of the target DNA, then primers are annealed to the complementary single strands. After adding a heat-stable DNA polymerase, such as Taq or Vent/Tli (originally the less thermostable Klenow fragment of polymerase I was used), chain elongation proceeds starting at the primers. The cycles are repeated 20–30 times, resulting in over a million fold ($2^{20} = 1,048,576$) replication of the target. The actual rate of replication may be less (80%) than that theoretically expected.

The DNA amplified can be subjected to molecular analysis such as preimplantation analysis, genetic

Figure P106. Polymerase chain reaction

screening, prenatal analysis, sperm typing, gene identification, etc. The error frequency for the Klenow fragment is about 8×10^{-5} , for Taq 10^{-5} to 10^{-4} , for Tli 2 to 3×10^{-5} . PCR amplification can be performed with a variety of mechanical devices, including chemical amplification on a microchip where the 20 cycles may be completed as fast as in 90 seconds. All types of technical information and references are available at <http://apollo.co.uk/a/pcr>. ▶RAPDS, ▶DNA fingerprinting, ▶vectorette, ▶sperm typing, ▶genetic screening, ▶prenatal analysis, ▶preimplantation genetics, ▶tissue typing, ▶primer extension, ▶ancient DNA, ▶molecular evolution, ▶RT-PCR, ▶in situ PCR, ▶recursive PCR, ▶inverse PCR, ▶capture PCR, ▶PCR overlapping, ▶tail-PCR, ▶electronic PCR, ▶PCR broad-base, ▶PTPCR, ▶methylation-specific PCR, ▶AP-PCR, ▶PCR asymmetric, ▶PCR allele-specific, ▶immuno-PCR, ▶RNA-PCR, ▶PCR-based mutagenesis, ▶small-pool PCR, ▶INTER-SS PCR, ▶PRINS, ▶reverse ligase-mediated polymerase chain reaction, ▶thermal cycler, ▶hot-start PCR, ▶touch-down PCR, ▶double PCR and digestion, ▶PCR-LSA; Mullis KB, Faloona FA 1989, p 189 In: Wu R et al (Eds.) Polymerase Switching: In polymerase switching, DNA replication is initiated by the polymerase α /primase complex, but subsequently the chain elongation is continued by the eukaryotic polymerase δ . Polymerase ϵ may also have some role in the initiation and elongation. ▶replication fork, ▶DNA polymerases, ▶primase, ▶processivity

Polymery: In polymery, several genes cooperate in the expression of a trait. ▶polygenes

Polymorphic: A trait that occurs in several forms within a population. The polymorphism may be balanced and genetically determined. ▶polymorphism, ▶balanced polymorphism, ▶RFLP, ▶SNP

Polymorphic Information Content (PIC): PIC is used to identify and locate a hard-to define marker locus. If the alleles of the marker locus are codominant, then PIC is the fraction of the progeny (the informative offspring) that cosegregates by phenotype with an index locus. The index locus (which is used for the detection of linkage with marker alleles) has two alternative alleles, a wild type and a dominant (mutant)

allele. The marker locus is polymorphic for dominant (genetic or physical [nucleotide sequences]) alleles. Only those progenies are informative, where the index locus is homozygous in one of the parents and the other parent is heterozygous for the marker. The converse constitutions are not informative. In case both parents are heterozygous at the marker locus, only half of the offspring is informative.

$$\text{PIC} = 1 - \sum_{i=1}^n p_i^2 - \left(\sum_{i=1}^n p_i^2 \right)^2 + \sum_{i=1}^n p_i^4$$

where p_i = frequency of the index allele and i and n are the number of different alleles. The PIC values may vary theoretically from 0 to 1. A hypothetical example: four A alleles occur in a population with frequencies A^1 : 0.2, A^2 : 0.1, A^3 : 0.15, and A^4 : 0.55. After substitution, $\text{PIC} = 1 - (0.2^2 + 0.1^2 + 0.15^2 + 0.55^2) - (0.2^2 + 0.1^2 + 0.15^2 + 0.55^2)^2 + (0.2^4 + 0.1^4 + 0.15^4 + 0.55^4)$, thus $\text{PIC} = 1 - 0.375 - 0.140625 + 0.0937125 \approx 0.578$, and in this case almost 58% of the progeny is informative. Usually, PIC values of 0.7 or larger are required for showing good linkage. The larger the number of the marker alleles, the more informative is the PIC. ▶microsatellite typing; Da Y et al 1999 Anim Biotechnol 10:25.

Polymorphism: In polymorphism, morphologically different chromosomes, or different alleles at a gene occur, or variable length restriction fragments are found within a population. Polymorphism can now be also detected through automated molecular techniques. During PCR amplification of a gene, one or more fluorescent reporter probes are attached to the 5' end, and a quencher substance(s) added slightly downstream or at the 3'-end. During amplification, the quencher may be cleaved by the Taq polymerase if it hybridizes to an amplified segment. The cleavage of the quencher enhances the fluorescence of the reporter fluorochrome. The samples placed in a 96-well plate can be scanned at three wavelengths in about 5 min. The procedure may be sensitive enough to detect a single base difference. In the human DNA sequences, there is ca. one variation/500 bp. About 15% of the polymorphism involves insertions or deletions. At least 100 chromosomes are usually examined for base substitution before the alteration is considered as a polymorphism. The average estimated nucleotide polymorphism in human populations is $\sim 8 \times 10^{-4}$. The diversity is variable at different loci and affected by several factors. Among normal human individuals, on the average, 11 deletions and duplications of the average length of 465 kb have been observed (Sebat J et al 2004 Science 305:525). ▶balanced polymorphism, ▶mutation, ▶diversity, ▶mutation detection, ▶fluorochromes, ▶PCR, ▶clone validation, ▶RLP, ▶SNP,

►microsatellite, ►blood groups, ►linkage disequilibrium, ►haplomap; Reich DE et al 2002 *Nature Genet* 32:135; polymorphism detection tool for large datasets: <http://pda.uab.es/pda/>; <http://pda.uab.es/pda2/>; mammalian: <http://mampol.uab.es/>.

Polymorphonuclear Leukocyte (PMN): ►granulocytes, ►leukocyte

Polyomyositis: The inflammation of muscle tissues, which may lead to rheumatoid arthritis, lupus erythematosus, scleroderma, Sjögren syndrome, and neoplasia. Polyomyositis is caused by two autoantigens PMSCL1 and PMSCL2. Dermatomyositis is a form affecting the connective tissues. Polyomyositis as such are not under direct genetic control. conditions under separate entries, ►IVIG; Wang HB, Zhang Y 2001 *Nucleic Acids Res* 29:2517.

Polyneme: The linear structure includes more than one strands, e.g., polytenic chromosomes (salivary gland chromosomes) may have $1024 (2^{10})$ parallel strands.

Polynucleotide: A nucleotide polymer hooked up through phosphodiester bonds.

Polynucleotide Kinase (PK): PK phosphorylates 5' positions of nucleotides in the presence of ATP, such as $\text{ATP} + \text{XpYp} \xrightarrow{\text{PK}} \text{p} - 5'\text{XpYp} + \text{ADP}$ (where X and Y are nucleotides), and can heal nucleic acid termini with ligase assistance. It functions in base excision repair and in non-homologous end-joining. ►ligase, ►DNA repair, ►non-homologous end-joining; crystal structure: Bernstein NK et al 2005 *Mol Cell* 17:657; Wang LK, Shuman S 2001 *J Biol Chem* 276:26868.

Polynucleotide Phosphorylase (PNPase): PNPase generates random RNA polymers $[(\text{NMP})_n]$ —without a template—from ribonucleoside diphosphates (NDP) and releases inorganic phosphate (P_i): $(\text{NMP})_n + \text{NDP} \rightarrow (\text{NMP})_{n+1} + \text{P}_i$. It degrades mRNA from the 3'-end.

Polynucleotide Phosphotransferase: Polynucleotide phosphotransferase transfers nucleotides to the ends of DNA or RNA sequences, such as in the polyadenylation of mRNA or nucleotidyl transferase of DNA. ►polyA polymerase, ►terminal deoxynucleotidyl transferase

Polynucleotide Vaccination: Inoculation by subcutaneous, intravenous, or particle bombardment-mediated transfer of specific viral or other nucleotides/nucleoproteins to develop an immune response. The immune reaction is generally low. ►immunization genetic

Polyoma: Neoplasia induced by one of the polyomaviruses. The globoid (icosahedral) mouse polyoma

viruses (a papova virus of 23.6×10^6 Da) contain double-stranded, circular DNA (4.5 kb). The BK and the JC viruses infect humans. ►Papova viruses; Cole CN, Conzen SD 2001, p 985 In: Knipe DM, Howley PM (Eds.) *Fundamental Virology*, Lippincott Williams & Wilkins, Philadelphia, Pennsylvania.

Polyp: An outgrowth on mucous membranes such as may occur in the intestines, stomach, or nose. They may be benign, precancerous, or cancerous. Nasal polyps may occur in aspirin sensitivity and can be treated surgically or with nasal steroid drugs. ►PAP, ►polyposis adenomatous, ►Gardner syndrome

Polypeptide: A chain of amino acids hooked together by peptide bonds. ►protein synthesis, ►amino acids, ►peptide bond

Polyphenols: Polyphenols are catechol-related plant products causing the formation of melanin-like brown color. The polyphenols in tea (theaflavin, catechins) have apparently antimutagenic and anticarcinogenic effects. ►thea

Polypheny: In polyphony, the same gene(s) can determine alternative phenotypes in response to internal or external cues, e.g., the queens and workers in social insects. Polyphenism in insect coloration may be the result of mutation of juvenile hormone-regulatory pathway and temperature effects may reveal hidden genetic variations. The mechanism that regulates developmental hormones can mask genetic variations and can act as an evolutionary capacitor for facilitating novel adaptive changes by genetic accommodation (Suzuki Y, Nijhout HF 2006 *Science* 311:650). Some older dictionaries and glossaries equate it with pleiotropy but this does not conform to current usage. ►genetic accommodation

Polyphosphates: Linear polymers of orthophosphates (n up to 100 or more) present in all types of cells with roles similar to ATP in metal chelation, bacterial competence for transformation, mRNA processing, growth regulation, etc. (see Fig. P107). Polyphosphates can buffer cellular phosphate levels in case of limited external supply and affect phosphate uptake (Thomas MR, O'Shea EK 2005 *Proc Natl Acad Sci USA* 102:9565). ►competence of bacteria, ►chelation; Kulaev I, Kulakovskaya T 2000 *Annu Rev Microbiol* 54:709.

Figure P107. Polyphosphate

PolyPhred: A computer program that automatically detects heterozygotes for single nucleotide substitutions by fluorescence-based sequencing of PCR products at high efficiency. It is integrated by the Phred, Phrap, and Consed programs. ▶SNIP, ▶PCR, ▶Phred, ▶Phrap, ▶Consed; Nickerson DA et al 1997 Nucleic Acid Res 25:2745.

Polyphyletic: An organism (cell) that originated during evolution from more than one line of descent. A polyphyletic group may contain species that are classified into this group because of convergent evolution. ▶convergence, ▶divergence

Polypeplexes: Polypeplexes are employed for delivery of DNA to cells. They include DNA-binding and condensing molecules, cell-specific ligands, and other molecules necessary for protection and uptake.

Polyploid Crop Plants: The most important polyploid crop plants include alfalfa (4x), apple (3x), banana (3x), birdsfoot trefoil (4x), white clover (4x), coffee (4x, 6x, 8x), upland cotton (4x), red fescue (6x, 8x, 10x), johnsongrass (8x), cultivated oats (6x), peanut (4x), Euro-pean plum (6x), cultivated potatoes (4x), sugarcane (*x), common tobacco (4x), bread wheat (6x), and macaroni wheat (4x). Most of these are apparently allopolyploids. ▶allopolyploid

Polyploidy: Having more than two genomes per cell. Definitive identification of polyploidy requires cytological analysis (chromosome counts), although many of the polyploid plants display broader leaves, larger stomata, larger flowers, etc. Polyploidy regulates the expression of individual genes in + or – manner. A yeast study (using microarray hybridization) found that the level of expression of some genes remained the same in haploid and tetraploid cells, whereas the expression of some cyclin genes decreased with tetraploidy. Additionally, a gene associated with cell adhesion was greatly over-expressed with tetraploidy (see Fig. P108).

Figure P108. Autotetraploid (top) and diploid (bottom) flowers of *Cardaminopsis petraea* (G.P. Rédei, unpublished)

Polyploidy may permit separate evolutionary paths for the additional gene copies. ▶autopolyploid, ▶endopolyploidy, ▶inbreeding autopolyploids, ▶chromosome segregation, ▶duplication, ▶maximal equational segregation, ▶alpha parameter, ▶allopolyploid, ▶tetrasomic, ▶trisomy, ▶microarray hybridization; Otto SP, Whitton J 2000 Annu Rev Genet 34:401.

Polyploidy in Animals: Polyploidy in animals is rare and limited mainly to parthenogenetically reproducing species (e.g., lizards). It occurs also in bees, silkworm, and other species. Some cells in special tissues of the diploid body may have increased chromosome number as a normal characteristic. Among mammals, tetraploidy was found in the red visacha rat, *Tympanoctomys barrarae* (2n = 112). The rarity of polyploidy in animals is attributed to its incompatibility with sex determination and dosage compensation of the X chromosome. ▶parthenogenesis, ▶honey bee, ▶silkworm; Zimmet J, Ravid K 2000 Exp Hematol 28:3; Wolfe KH 2001 Nature Rev Genet 2:333.

Polyploidy in Evolution: Polyploidy in evolution is common in the plant kingdom but the majority of polyploid species are allopolyploid. Some of the single copy genes of invertebrates are, however, detectable up to four copies in vertebrates. A survey of plants indicated only 38% of polyploid species in the Sahara region, 51% in Europe, 82% in the Peary Islands, and thus show an increasing trend towards the North. In yeast, after polyploidization, different genes were lost leading to speciation (Scannell DR et al 2006 Nature [Lond] 440:341). In parasites, haploidy is advantageous because selection favors organisms that express a narrow array of antigens and elicitors. In contrast, in the host mounting a defense response, selection favors a broader array of recognition molecules and thus diploids or polyploids (Nuismer SL, Otto SP 2004 Proc Natl Acad Sci USA 101: 11036). Polyploids are also less vulnerable to mutation despite the fact that the mutational target numbers are larger. ▶allopolyploid, ▶duplications; Otto SP, Whitton J 2000 Annu Rev Genet 34:401; Wu R et al 2001 Genetics 159:869; function of the duplicated genes: Kellog EA 2003 Proc Natl Acad Sci USA 100:4369; Adams KL et al 2003 Proc Natl Acad Sci USA 100:4649.

Polyposis Adenomatous, Intestinal (APC): APC is controlled by autosomal dominant genes responsible for intestinal, stomach (Gardner syndrome), or other types (kidney, thyroid, liver, nerve tissue, etc.) of benign or vicious cancerous tumors. The various forms are apparently controlled by mutations or deletions in the 5q21-q22 region of the human chromosome and represent allelic variations. Retinal lesions (CHRPE)

are associated with truncations between codons 463–1387; truncations between codons 1403–1528 involve extra-codonic effects, etc. In addition, it is conceivable that this is a *contiguous gene* region where adjacent mutations affect the expression of the polyposis. By the use of single strand conformation polymorphism technique, DNA analysis may permit the identification of aberrant alleles prenatally or during the presymptomatic phase of the condition. The situation is further complicated, however, by the possibilities of somatic mutations. The *Min* gene of mouse appears to be homologous to the human APC, thus, lending an animal model for molecular, physiological, and clinical studies. The expression of *Min* is regulated also by the phospholipase-encoding gene *Mom1*, indicating the involvement of lipids in the diet. Polyposis may affect a very large portion of the aging human populations, especially high is the risk for females. Certain forms of polyposis may affect the young (juvenile polyposis). Regular monitoring by colorectal examination is necessary for those at risk. Bloody diarrhea and general weakness are symptoms usually too late for successful medical intervention. Molecular genetic information suggests that vertebrates use the same pathway of signal transduction as identified by *Drosophila* genes: *porcupine* (*porc*, 1.59)→*wingless* (*wg*, 2-30.0)→*dishevelled* (*dsh*, 1-34.5)→*zeste white3* (*z^{w3}*, 1.1.0)→*armadillo* (*arm*, 1-1.2)→cell nucleus. The normal human APC gene appears to be either a negative regulator (tumor suppressor) or an effector, acting between *z^w* and the nucleus. When it mutates, it can either no longer carry out suppression or it may become an effector. The product of *dsh* also appears to be a negative regulator of *z^w*. When the *zeste* product, glycogen synthase kinase (GSK3β) is inactive, the *arm* product (catenin) is associated with the APC product and a signal for tumorigenesis is generated. Alternatively, when no signal is received, GSK phosphorylates and activates a second binding site on APC for catenin but that causes the degradation of catenin and thus no tumor signal is generated. The APC protein may act as a tumor gene also by docking at its COOH end with a human homolog of the *dlg1* (*disc large*, 1-34.82) of *Drosophila*). The *Dlg* product belongs to the *membrane associated guanylate kinase* protein family that is analogous to proteins in vertebrates sealing adjacent cell membranes (tight junction). *Dlg* is also considered to be a tumor gene. Although, the molecular information reveals a number of mechanisms of action, it is not clear which one is being used or if multiple pathways are involved in polyposis. APC/FAP has a prevalence of about 1×10^{-4} . The EB1 protein binds the APC protein, is situated on the microtubules of the mitotic spindle, and serves as a checkpoint for cell division. ▶Gardner syndrome, ▶Turcot syndrome, ▶cancer, ▶single-strand conformation, ▶GSK3β,

▶polymorphism, ▶hereditary non-polyposis colorectal cancer, ▶contiguous gene syndrome, ▶animal models, ▶tight junction, ▶catenin, ▶effector, ▶polyposis hamartomatous, ▶polyposis juvenile, ▶spindle, ▶cyclooxygenase, ▶microtubule, ▶PTEN

Polyposis Hamartomatous (Peutz-Jeghers syndrome, PJS): A chromosome-19p13.3 rare dominant overgrowth of mucous membranes (polyp), especially in the small intestine (jejunum), but also in the esophagus (the canal from mouth to stomach), bladder, kidney, nose, etc. Melanin spots may develop on lips, inside the mouth, and fingers. Ovarian and testicular cancers were also observed. The susceptibility to this cancer is due to deletion in a serine/threonine protein kinase gene (LKB). LKB1 mediates glucose homeostasis in the liver (Alessi DR et al 2006 Annu Rev Biochem 75:137). This gene signals to VEGF and it is a player in the anterior-posterior axis formation as well as in epithelial polarity. ▶pigmentation of the skin, ▶cancer, ▶Gardner syndrome, ▶colorectal cancer Muir-Torre syndrome, ▶polyposis adenomatous intestinal, ▶multiple hamartomas, ▶VEGF; Hemminki A et al 1998 Nature [Lond] 391:184; Sapkota GP et al 2001 J Biol Chem 276:19469; Ilikorkala A et al 2001 Science 293:1323; Bardeesy N et al 2002 Nature [Lond] 419:162.

Polyposis, Juvenile: An early onset polyposis frequently turning malignant, caused by a defect at the carboxyl terminal of the SMAD4/DPC4 (552 amino acids) protein, encoded in human chromosome 18q21.1. SMAD4 in a trimeric association is involved in TGF-β signaling pathway. Although some of the symptoms are similar to other hamartomas, the Cowden disease gene (PTEN, phosphatase and tensin homolog) is encoded in chromosome 10 and the Peutz-Jeghers syndrome is coded for in chromosome 19. ▶multiple hamartomas, ▶TGF, ▶polyposis hamartomatous, ▶SMAD, ▶DCC, ▶PTEN; Howe JR et al 2002 Am J Hum Genet 70:1357.

Polypeptide: A contiguously translated long chain polypeptide that is processed subsequently into more than one protein.

Polypurine: A stretch of purine residues in nucleic acids.

Polypyrimidine: A sequence of multiple pyrimidines (mainly Us) in nucleic acids adjacent to the 3' splicing site. Py-tract-binding proteins (PTB) recognize these such as the essential splicing factor U2AF⁶⁵, the splicing regulator sex-lethal (*Sxl*), etc. ▶splicing, ▶introns, ▶sex determination; Le Guinier C et al 2001 J Biol Chem 276:43677.

Polyribosome: Same as polysome (see Fig. P109).
 ▶protein synthesis

Figure P109. Polyribosome

Polysaccharide: Monosaccharides joined by glycosidic bonds (e.g., starch, glycogen, glycoprotein).

Polysome: In a polysome, the mRNA holds multiple ribosomes together. The ovalbumin polysomes comprise an average of 12 ribosomes and one peptide initiation takes place in every 6–7 s if all the required factors are functioning normally. The average polysome size for globin is ~5 ribosomes (1 ribosome/~90 nucleotides). Pactamycin may be an inhibitor of translation initiation and cycloheximide may interfere with peptide chain elongation. ▶ribosome, ▶mRNA, ▶transcription, ▶translation, ▶pactamycin, ▶cycloheximide

Polysome Display: In a polysome display, polysomes are isolated and screened by the affinity of the nascent peptides on an immobilized specific monoclonal antibody. The mRNA of the enriched pool of polysomes is reverse-transcribed into cDNA and amplified by PCR. The amplified template may be cloned and translated in vitro. The procedure is highly efficient for the screening of large, specific peptide pools. ▶reverse transcription, ▶cDNA, ▶PCR, ▶translation in vitro; Mattheakis LC et al 1994 Proc Natl Acad Sci USA 91:9022.

Polysomic Cell: In a polysomic cell, some chromosomes are present in more than the regular number of copies. The polyploids are polysomic for entire genomes. ▶aneuploidy, ▶polyploidy

Polysomy: In polysomy, some of the chromosomes in a cell are present in more than the normal numbers, examples of these cases in humans are 48,XXXX, 48,XXXY, 49,XXXXX or 49,XXXXY ▶nondisjunction, ▶polyploid, ▶trisomy

Polyspeirism: In polyspeirism, one cell makes several types of related molecules, e.g., different chemokines. (See Montovani A 2000 Immunol Today 2(4):199).

Polyspermic Fertilization: In polyspermic fertilization, more than a single sperm enters the egg and, because each may provide a centriole, multipolar mitoses may take place resulting in aneuploidy and abnormal embryogenesis. ▶fertilization

Polysyndactyly: Polysyndactyly is encoded by the HOXD13 gene at human chromosome 2q31-q32 (see Fig. P110). The amplification of the alanine codons (CCG, GCA, GCT, GGC) leads to an expanded (25 to 35) alanine residues in the protein. Some polysyndactyly is due to mutation in GLI3 gene at 7p13. ▶trinucleotide repeats, ▶syndactyly, ▶Pallister-Hall syndrome

Figure P110. Polysyndactylic toes

Polytenic Chromosomes: Polytenic chromosomes are composed of many chromatids (e.g., in salivary-gland cell nuclei) because in such cases DNA replication is not followed by chromatid separation (see Fig. P111). The polytenic chromosomes in the salivary glands nuclei of diptera may have undergone ten cycles of replication ($2^{10} = 1024$) without division and may have over 1000 strands. Also, the polytenic chromosomes in the salivary glands are extremely long. A regular feature is the very close somatic pairing. Additionally, they all are attached at one point, at the chromocenter.

Polytenic chromosomes have been extensively exploited for analysis of deletions, duplications,

Figure P111. Polytenic chromosomes of *Allium ursinum*. Courtesy of G. Hasischka-Jenschke

inversions, and translocations. The characteristic banding pattern was used also as a cytological landmark for identification of the physical location of genes. Rarely, polyteny occurs in some specialized plant tissues (antipodals) too. ►salivary gland chromosomes, ►giant chromosomes, ►somatic pairing

Polytocous Species: Polytocous species produce multiple offspring by each gestation. ►monotocous

Polytomy: Multifurcating rather than bifurcating analysis of phylogenetic relations. ►evolutionary tree; Walsh HE et al 1999 Evolution 53:932.

Polytopic Protein (multispanning): A polytopic protein traverses the plasma membrane several times.

Polytopic Retrovirus: ►amphotropic retrovirus

Polytypic: A species that includes more than one variety or subtype.

POMC (pre-pro-opiomelanocortin): ►melanocortin, ►opiocortin, ►ACTH

Pomegranate (*Punica granatum*): A Mediterranean fruit tree, $2n = 2x = 16$ or 18 .

Pompe's Disease: ►glycogen storage diseases

Pongidae (anthropoid primates [hominoidea]): *Gorilla gorilla gorilla* $2n = 48$ (see Fig. P112); *Hylobates concolor s* [gibbon] $2n = 52$; *Hylobates lar* [gibbon] $2n = 44$; *Pan paniscus* [pygmy chimpanzee] $2n = 48$; *Pan troglodytes* [chimpanzee] $2n = 48$; *Pongo pygmaeus* [orangoutan] $2n = 48$; *Symphalangus brachytanites* $2n = 50$. ►primates, ►chimpanzee

Figure P112. Gorilla

Pontin: ►chromatin remodeling

PO-PS Copolymers: Phosphorothioate-phosphodiester copolymers are used for antisense technologies. ►antisense RNA

POP': POP' symbolizes the ends of the temperate transducing phage genome integrating into the bacterial host chromosome. The corresponding bacterial integration sites are BOB' and after integration (recombination) the sequence becomes: BOP' and POB', respectively ►attachment sites

Pop1p: A protein component of ribonuclease P and MRP. ►ribonuclease P, ►MRP

Poplar (*Populus* spp): $2n = 2x$, $2n = 38$ (see Fig. P113). Poplar includes cottonwood trees also. The genome of the black cottonwood (*Populus trichocarpa*, 485 ± 10 Mb) has been sequenced and 45,000 putative protein-coding genes detected. Substantial portions of the nuclear and organellar (chloroplasts and mitochondria) genes the genome have been annotated in different tissues. About 8000 duplications were found (Tuskan GA et al 2006 Science 313:1596). (See Cervera M-T et al 2001 Genetics 158:787).

Figure P113. Poplars

Popliteal Pterygium Syndrome (PPS, 1q32-q41): PPS is allelic to the Van der Woude syndrome and it involves a defect in the interferon regulatory factor 6 (Irf6). Clinical symptoms include cleft palate, harelip, and webbing of the skin. Pterygium is membrane or skin folding; popliteal indicates THE ligament behind the knee. ►Van der Woude syndrome, ►epithelial cell, ►Pterygium

Pop-Out, Chromosomal: Chromosomal pop-out originates due to the intrachromatid reciprocal exchange between direct repeats. It excises one of the repeats (the popout) but may retain the other member of the duplication. ►intrachromosomal recombination, ►sister chromatid exchange

Poppy (*Papaver somniferum*): The latex of poppy is a source of opium, codein, morphine, heroin, and other alkaloids. Their biosynthetic pathway, including a mutant blocked in the biosynthesis of the illicit drug (morphine and codeine) pathways (See Millgate AG et al 2004 Nature [Lond] 431:413). The plant is grown for its oil-rich seed as a food and also for pharmaceutical purposes (see Fig. P114). Basic chromosome number $x = 11$, diploid and tetraploid forms are known.

Figure P114. Poppy seed capsule

Population: A collection of individuals that may either interbreed and freely trade genes (Mendelian population, deme) or may be a closed population that is sexually isolated from other groups that share the same habitat. ▶ **Hardy-Weinberg theorem**, ▶ **population equilibrium**

Population Critical Size: ▶ **critical population size**

Population Density: The number of cells or individuals per unit volume or area.

Population Effective Size (N_e): The number of individuals in a group or within a defined area that actually transmit genes to the following reproductive cycles (offspring). Each breeding individual has 0.5 chance to contribute an allele to the next generation, and $0.5 \times 0.5 = 0.25$ is the probability to contribute two particular alleles. The probability that the same male contributes two alleles is $(1/N_m) 0.25$ and for the same female it is $(1/N_f) 0.25$ where N_m and N_f are the number of breeding males and females, respectively. The probability that any two alleles are derived from the same individual is $0.25N_m + 0.25N_f = 1/N_e$ and N_e is computed as $4N_mN_f / (N_m + N_f)$. ▶ **founder principle**, ▶ **genetic drift**, ▶ **inbreeding and population size**; Wright S 1931 *Genetics* 16:97.

Population Equilibrium: ▶ **Hardy-Weinberg theorem**

Population Genetics: Population genetics studies the factors involved in the fate of alleles in potentially interbreeding groups (see Fig. P115). The individuals within these groups (demes) may actually reproduce by random mating or selfing or by the combination of the two within this range. Population genetics can be entirely theoretical and developing mathematical formulas for predicting the allelic frequencies and the effect of various factors that affect these frequencies and the historical paths of the genes and factors as they emerge, become established or disappear, form equilibria or remain unstable during microevolutionary periods. Experimental population

genetics conducts biological studies in the sense of the theoretical framework. Population genetics thus deals with the consequences of mutation, genetic drift, migration, selection and breeding systems and is also one of the most important approaches to experimental (micro) evolution. It provides also the theory for many human genetics, animal and plant breeding research efforts. The availability of molecular information greatly advanced the resolving power of population genetics. The availability of mitochondrial (maternally transmitted) and Y chromosomal (paternally transmitted) markers provide effective tools to study the dynamics and history of human populations. ▶ **terms mentioned**, and ▶ **SNIPS**, ▶ **DNA chips**, ▶ **microsatellites**, ▶ **minisatellites**, ▶ **mtDNA**, ▶ **Y chromosome**; population modeling software: <http://www.trinitysoftware.com>; population genetics tools and Internet resources: Excoffier L, Heckel G 2006 *Nature Rev Genet* 7:745; Arlequin, analysis of molecular genetic variations: Marjoram P, Tavaré S 2006 *Nature Rev Genet* 7:759.

Figure P115. Population genetics is concerned with the fate of genes in large collection of organism rather than in the descendants of single individuals

P

Population Growth, Human: $P_t = P_0(1 + r)^t$ where P_0 = the population at time 0, r = rate of growth and t = time. It can be calculated also by $P_t = P_0e^{rt}$ where e = the base of the natural logarithm. ▶ **age-specific birth and death rates**, ▶ **human population growth**, ▶ **Malthusian parameter**

Population Size, Ancestral: Ancestral population size can be estimated by different methods. The ancestral modern human population might have been about 10,000, whereas the common ancestral human and chimpanzee populations were of the order of 100,000. Newer estimate of the latter is only about 20,000 (Rannala B, Yang Z 2003 *Genetics* 164:1645).

Population Structure: Population structure is endemic by subpopulation groups. The dispersal of the subdivisions reflect adaptive genetic differences, gene

flow and natural selection pressure, inbreeding, overlapping generations, effective population size, and sometimes genetic drift. Sometimes there are too few differences in some population and therefore it is difficult to trace the origin of possible demographic changes. Parasites, e.g., viruses may evolve much faster and from their dispersal one may get good information on the demography/distribution of the host in a region (Bick R et al 2006 Science 311:538). ▶population genetics, ▶endemic, ▶natural selection, ▶genetic drift, ▶population effective size, ▶stratification; Marth G et al 2003 Proc Natl Acad Sci USA 100:376.

Population Subdivisions: Smaller relatively separated breeding groups with restricted gene flow among them. ▶gene flow, ▶migration

Population Tree: The population tree is constructed on the basis of genes frequencies among populations indicating their evolutionary relationship. ▶evolutionary tree, ▶gene tree

Population Wave: Periodic changes in the effective population size. ▶population size effective, ▶random drift, ▶founder principle, ▶gene flow

Porcupine Man (ichthyosis hystrix): Ichthyosis is a dominant form of hyperkeratosis. ▶keratosis, ▶ichthyosis

Porencephaly: Porencephaly is a generally rare dominant (13qter region) brain disease with cerebrospinal fluid-filled cavities or cysts, affecting primarily infants and young children. Few survivors are plagued by many other debilitating symptoms. In a mouse mutant, single-nucleotide alteration in collagen Col4a1 was the primary cause of the disease. ▶collagen; Gould DB et al 2005 Science 308:1167.

Porin: Porin is a voltage-dependent anion channel. It is opened by Bax and Bak pro-apoptotic proteins and closed by the anti-apoptotic Bcl-x_L. Bax and Bak permit the exit of cytochrome c from the mitochondria and thus facilitate apoptosis by the activation of caspases. In case of IL-7 deficiency and increase in pH over 7.8 the conformation of Bax is altered and the protein moves from the cytoplasm to the mitochondria and facilitates apoptosis. The anti-apoptotic, 24 amino acid-peptide prevents the translocation of Bax to the mitochondria (Guo B et al 2003 Nature [Lond] 423:456). The Bcl-2 protein, localized to the mitochondrial membrane, normally suppresses the release of cytochrome c. Bax deficiency extends the ovarian life span into advanced age of mice. Normally the ovarian follicles fade by menopause in women and at similar developmental stages also in mice. Degradation of Bax by the proteasomes may protect against the apoptosis over-protective effect of Bcl-2 and reduce

cancer cell survival. For drug therapy of epithelial cancer the state of BAX vs. Bcl-2 may be significant. ▶Bak, ▶ion channels, ▶cytochrome c, ▶apoptosis, ▶hypersensitive reaction; Suzuki M et al 2000 Cell 103:645; Gogvadze V et al 2001 J Biol Chem 276:19066; Scorrano L et al 2003 Science 300:135.

Porphyria: Porphyria is a collective name for a variety of genetic defects involved in heme biosynthesis resulting in under- and/or over-production of metabolites in the porphyrin-heme biosynthetic pathway. These diseases may be controlled by recessive or dominant mutations. The affected individuals may be suffering from abdominal pain, psychological problems and photosensitivity. The autosomal dominant acute *intermittent porphyria* (human chromosome 11q23-ter) is caused by a periodic 40–60% reduction in porphobilinogen deaminase enzyme resulting in insufficient supplies of the tetrapyrrole hydroxymethyl bilane that is normally further processed by non-enzymatic way into uroporphyrinogen I. It was speculated that the famous Dutch painter van Gogh was a victim of this rare disease. Prevalence is in the range of 10^{-4} to 10^{-5} . Exogenous effects such as barbiturate, sulfonamide, alkylating and many other drugs, alcohol consumption, poor diet, various infections and hormonal changes, generally elicit the periodic attacks. An *adult type* of (hepatocutaneous) porphyria, controlled by another human gene locus (1p34), involves light-sensitivity and liver damage by the accumulation of, porphyrins caused by uroporphyrinogen decarboxylase deficiency. The general effect may be less severe than in the intermittent porphyria. The rare congenital *erythropoietic porphyria* (CEP) is the result of a defect in the enzyme uroporphyrinogen III co-synthetase controlled by a recessive mutation in human chromosome 10q25.2-q26.3. The laboratory identification is generally based on urine analysis for intermediates in the heme pathway. Porphyrias affect also various mammals. Defects in the porphyrin pathways are involved in several types of pigment deficiency mutations of plants. The *variegate porphyria* is caused by a defect of protoporphyrinogen oxidase (PPOX) with symptoms basically similar to that of intermittent porphyria. This dominant disease has low penetrance. Its prevalence is very high (about 3×10^{-3}) in South-African populations of Dutch descent; it apparently represents founder effect. The mental problems of King George III of England (reigned during the US War of Independence) were also attributed to variegate porphyria.

ALAD porphyria also known as “Doss porphyria,” is a very rare porphyric disorder linked to a profound lack of porphobilinogen synthase PBGS, also known as δ -aminolevulinatase (ALAD), is encoded by the *ALAD* gene (9q34). Human (PBGS) exists as an

equilibrium of functionally distinct quaternary structure assemblies, known as morphoeins, in which one functional homo-oligomer can dissociate, change conformation, and reassociate into a different oligomer. In the case of human PBGS, the two assemblies are a high-activity octamer and a low-activity hexamer (Jaffe EK, Stith L 2007 Am J Hum Genet 80:329). ►porphyrin, ►heme, ►skin diseases, ►light-sensitivity diseases, ►founder effect, ►coproporphyrin, ►aminolevulinic acid conformation

Porphyrin: Four special pyrroles joined into a ring; generally with a central metal, like iron in hemoglobin or in chlorophylls with magnesium (see Fig. P116). ►porphyria, ►coproporphyrin, ►heme

Portable Dictionary of the Mouse Genome: Data on ~12,000 genes and anonymous DNA loci of the mouse, homologs in other mammals, recombinant inbred strains, phenotypes, alleles, PCR primers, references, etc. The dictionary can be used on Macintosh, PC in FileMaker, Pro, Excel, and text formats, and is accessible through the Internet (WWW, Gopher, FTP), CD-ROM, or on floppy disk. Information: R.W. Williams, Center for Neuroscience, University of Tennessee, 875 Monroe Ave., Memphis, Tennessee 36163. Phone: 901-448-7018. Fax: 901-448-7266. e-mail: rwilliam@nb.utmem.edu.

Portable Promoter: An isolated DNA fragment, including a sufficient promoter that can be carried by transformation to other cells, and may function in promoting transcription. ►promoter, ►transformation, ►gene fusion

Portable Region of Homology: Insertion and transposon elements may represent homologous DNA sequences and can recombine. The recombination may then generate deletions, cointegrates or insertion, or inversions. These events can take place even in RecA⁻ hosts.

►Tn10, ►cointegrate, ►deletion, ►inversion, ►targeting genes

Position Effect: change in gene expression by a change in the vicinity of the gene.

The new expression may be *stable* or *variable* (*variegation type position effect*) (see Fig. P117). Stable position effect is observed when promoterless structural genes are introduced by transformation and the transgene is expressed with the assistance of a “trapped” promoter that is regulated differently than the gene’s natural (original) promoter. Variegated position effect (PEV) is more difficult to interpret by molecular models. When, however, centromeric heterochromatin was inserted at the *brown* locus of *Drosophila* during larval development the transposed heterochromatin stochastically associated with the centromeric region and caused PEV (Dernburg AF et al 1996 Cell 85:745). The telomere-linked *ADE2* locus of yeast displayed alternative *ADE* and *ade* phenotypes (Gottschling DE et al 1990 Cell 63:751). It has been assumed that heterochromatin affects the intensity of somatic pairing and variations in somatic association and variations in cross-linking between the homologs by binding proteins bring about the silencing. The *trithorax-like* gene of *Drosophila* encodes a GAGA-homology transcription factor that enhances variegation type position effect (PEV) by decondensation of the chromatin. The mosaicism may also be the result of the spontaneous and random derepression of the promoter in the presence of an activator. The telomeric isochores have been also implicated in position effect (TPE). Position effect may be observed by altering the site or distance of the locus control region. In *Drosophila* over 100 genes were found that affect variegation type position effect (PEV). In *Drosophila* HP1, HP2 proteins of the heterochromatin and histone H3 lysine⁹ methyltransferase play important role in gene silencing. It seems that RNAi also affects the heterochromatin and several genes encode the RNAi system and their mutations results in loss of silencing (Pal-Bhadra M et al 2004 Science 303:669). It has been hypothesized that these genes control the packaging of the DNA. Many of the cancers develop after translocations or transpositions, indicating the significance of position effect on the regulation of growth. Proteins affecting AT-rich heterochromatin can modify PEV. Transposable elements may also cause position effect (Kashkush K et al 2003 Nature Genet 33:102). Position effects may be exerted even from long distances (2 Mb) and may make difficult to distinguish the position effect causing gene from mutation within the target gene. Such cases may complicate positional cloning. Position effect occurs also in yeasts and other organisms. Some human genetic disorders are due to

Figure P117. Duplication of the wildtype (p^+) allele into heterochromatic DNA results in the (p) eyes variegated expression of p^+ in the malaria mosquito *Anopheles gambiae*. (Courtesy of Dr. Mark Benedict, original photograph by James Gathany, CDC)

Position-Specific Scoring Matrix (PSSM): PSSM represents amino acids at specific positions in a

sequence alignment. It can be used for scanning proteins with matches to this tract. ▶PWM; Gribskov M et al 1987 Proc Natl Acad Sci USA 84:4355.

Position Weight Matrix: ▶PWM

Positional Cloning: ▶chromosome walking, ▶chromosome landing, ▶map-based cloning

Positional Information: Positional information is provided to some cells by signal transducers in a multicellular organism and has an important influence on differentiation and development. ▶morphogenesis, ▶differentiation

Positional Sensing: Positional sensing provides information for specific differentiation functions. ▶morphogenesis

Positive Control: In positive control, gene expression is enhanced by the presence of a regulatory protein (in contrast to negative control, where its action is

reduced). The arabinose operon of *E. coli* is a classic example. The regulator gene *araC* produces a repressor (P_1) in the absence of the substrate arabinose. If arabinose is available, P_1 is converted to P_2 (by a conformational change), which is an activator of transcription in the presence of cyclic adenosine monophosphate (cAMP). While the negative control (P_1) is correlated with a low demand for expression, the activator (P_2) appears in response to the demand for high level of expression. In general cases, the addition of an activator protein to the DNA makes possible normal transcription but adding a special ligand to the system removes the activator and the gene is turned off. ▶ *arabinose operon*, ▶ *negative control*, ▶ *lac operon*, ▶ *autoregulation*, ▶ *catabolite activator protein*, ▶ *regulation of gene activity*

Positive Cooperativity: Binding of a ligand to one of the subunits of a protein facilitates the binding of the same to other subunits.

Positive Interference: ▶ *interference*, ▶ *coincidence*

Positive/Negative Selection: Selection may be used to isolate cloned constructs containing the desired integrated sequence (positive selection). Negative selection is expected to eliminate integration sites containing the entire vector inserted at non-targeted sites and vector components that have no relevance to cloning. Negative selection is usually less efficient—if it takes place at all—than positive selection. For positive selection in case of hypoxanthine/guanine phosphoribosyl transferase marker, one may use hypoxanthine, aminopterin, and thymidine (HAT) chemicals, whereas in the same experiment for negative selection 6-thioguanine or 5-bromodeoxyuridine may be used.

Positive Selection: In general, it indicates the selection of a desirable type in a population rather than the elimination of the undesirable phenotype/genotypes. ▶ *selection entries*

Positive Selection of Lymphocytes: A process of maturation of lymphocytes into functional members of the immune system. In contrast, negative selection eliminates, by apoptosis, early lymphocytes with autoreactive receptors. ▶ *immune system*, ▶ *lymphocytes*

Positive Selection of Nucleic Acids: Positive selection of nucleic acids isolates and enriches desired types of nucleic acid sequences. The desired (tracer) sequences are digested by restriction endonucleases that generate cohesive ends. The rest of the nucleic acids (driver) are exposed to sonication (or the ends may be even dephosphorylated) and so much sticky ends are not expected. Thus, mainly the tracer-tracer sequences are annealed when the mixture is treated with a ligase enzyme. ▶ *subtractive cloning*, ▶ *genomic*

subtraction, ▶ *RFLP subtraction*, ▶ *ligase DNA*, ▶ *cohesive ends*, ▶ *sonicator*

Positive-Strand Virus: The genome of a positive-strand virus is also a mRNA. Upon transcription, the virus may directly produce an infectious nucleic acid. This is a very large class of RNA viruses including the Brome Mosaic Virus, the Hepatitis C Virus, West Nile Virus, Corona Viruses, etc. Their replication is affected by at least 100 genes (Kushner DB et al 2003 Proc Natl Acad Sci USA 100:15764). ▶ *replicase*, ▶ *plus strand*, ▶ *mRNA*, ▶ *negative strand virus*

Positive Supercoiling: The overwinding follows the direction of the original coiling, i.e., it takes place rightward. ▶ *supercoiling*, ▶ *negative supercoil*

Positron Emission Tomography (PET): ▶ *tomography*

Post-Adaptive Mutation: Post-adaptive mutation is supposed to arise de novo in response to the conditions of selection. Actually, post-adaptive mutation may not be found if the data are well scrutinized. ▶ *directed mutation*, ▶ *pre-adaptive mutation*

Post Coitum (p.c.): During embryonal development, the days that follow mating.

Posterior: Pertaining to the hind part of the body or behind a structure toward the tail end.

Posterior Distribution: A summary of random variables collected after new empirical data became available. It is the product of likelihood and prior distribution. ▶ *prior distribution*

Posterior Probability: ▶ *Bayes theorem*

Post-Genome Analysis: The post-genome analysis studies the experimental results and the informatics of the sequential function (metabolic pathways) and interactions of genes and their products. ▶ *annotation of the genome*, ▶ *genetic networks*; Lin J et al 2002 Nucleic Acids Res 30:4574, <http://www.genome.ad.jp>; <http://www.genome.ad.jp/kegg/comp/GFIT.html>.

Postmeiotic Segregation: Postmeiotic segregation takes place when the DNA was a heteroduplex at the end of meiosis. Among the octad spores of ascomycetes, this may result in 5:3 and 3:5 or other types of aberrant ratios instead of the normal 1:1. Postmeiotic segregation may be an indication of failures in mismatch or excision repair. ▶ *DNA repair*, ▶ *tetrad analysis*, ▶ *gene conversion*

Postnatal: Postnatal refers to that which occurs after birth; generally one to 12 months after birth.

Postprandial: After consuming a meal, a process, e.g., protein anabolism modifies protein synthesis due the change in the amino acid pool or change in insulin supply after eating (postprandially).

Postreduction: As per postreduction, the segregation of the alleles takes place at the second meiotic division.
 ▶tetrad analysis, ▶meiosis, ▶prereduction

Postreplicational Repair: ▶unscheduled DNA synthesis, ▶DNA repair

PostScript: A computer application to handle text and graphics the same time. The PostScript code determines what the graphics look like when printed, although may not be visible on the screen of the monitor.

Post-Segregational Killing: ▶plasmid addiction

Post-Transcriptional Gene Silencing (PTGS): As per PTSG, the transcript of a transgene is degraded before translation takes place and thus, its expression is prevented. Also, it may be a defense mechanism against viruses in plants. The viral gene may be integrated into the chromosome and duly transcribed, yet it is not expressed. In addition, since the replication of the virus is mediated through a double-stranded RNA that has been found to be a potent inhibitor, it is conceivable that both the plant defense and the transgene silencing rely on similar mechanism(s). In some plant species, the potyviruses, tobacco etch virus, and cucumber mosaic virus may produce a *helper component protease* (HC-Pro) and may inactivate this plant defense by degradation. The HC-Pro may have another role. When a plant is infected simultaneously by two different viruses, one of them promotes the vigorous replication of the other, and the latter by its production of HC-Pro eventually facilitates the spread of the first type of the virus and thus enhances the symptoms of the viral disease. In some of the silenced plant cells, a 25-nucleotide long antisense RNA has been detected that seems to inactivate the normal transcript or infectious viral RNA. According to other studies, the ~25-nt RNA sequence apparently conveys specificity for a nuclease by homology to the substrate mRNA. Several types of hairpin structures of RNAs involving sense and antisense sequences and introns appeared to silence very effectively viral genes in plants. A calmodulin-related plant protein (rgs-CAM) may also suppress silencing. ▶silencing, ▶plant viruses, ▶RNAi, ▶RNA interference, ▶co-suppression, ▶homology-dependent gene silencing, ▶methylation of DNA, ▶host-pathogen relations; Bass BL 2000 Cell 101:235; Jones L et al 1999 Plant Cell 11:2291; Waterhouse PM et al 2001 Nature [Lond] 411:834; Mitsuhashi I et al 2002 Genetics 160:343.

Post-Transcriptional Processing: The primary RNA transcript of a gene is cut and spliced before translation or before assembling into ribosomal subunits or functional tRNA; it includes removal of introns, modifying (methylating, etc.) bases, adding

CCA to tRNA amino arm, polyadenylation of the 3' tail, etc. ▶opiotropin; McCarthy JEG 1998 Microbiol Mol Biol Revs 62:1492; Bentley D 1999 Curr Opin Cell Biol 11:347.

Post-Transcriptional Operons: A hypothesis according to which, functionally related genes may be regulated post-transcriptionally as groups by mRNA-binding proteins that recognize common sequence elements in the untranslated 5' and 3' subsets of the transcripts. This conclusion is based on findings that mRNA-binding proteins recognize unique subpopulations of mRNAs, the composition of these subsets may vary depending on conditions of growth and the same mRNA occurs in multiple complexes. These conserved *cis* elements were named USER (untranslated sequence elements for regulation) codes. These systems may permit plasticity during developmental processes or responses to drug treatment. ▶operon, ▶genetic networks; Keene JD, Tenenbaum SA 2002 Mol Cell 9:1161.

Posttranslational Modification: Enzymatic processing of the newly synthesized polypeptide chain, the product of translation. The modification may include proteolytic cleavage, glycosylation, phosphorylation, farnesylation, conformational changes, assembly into quaternary structure, etc. These modifications may alter function. Mass spectrophotometry is generally used for the identification the alterations. ▶protein synthesis, ▶protein structure, ▶conformation, ▶proteomics; Németh-Cawley JF et al 2001 J Mass Spectrom 36:1301; Mann M, Jensen ON 2003 Nature Biotechnol 21:255; <http://dbptm.mbc.nctu.edu.tw/>; tandem mass spectra interpretation server: <http://modi.uos.ac.kr/modi/>.

Post-Transplantational Lymphoproliferative Disease (PTDL): In PTDL, after engraftment, the Epstein-Barr virus-infected B cells may continue to proliferate because the immuno-suppressive therapy required to maintain the graft inhibits cytotoxic T lymphocytes. Bone marrow transplantation may alleviate the problems. ▶Epstein-Barr virus, ▶immuno-suppression, ▶CTL

Postzygotic: ▶prezygotic

Postzygotic Isolation: Postzygotic isolation arises when in allopatric evolution the taxa diverge from the common ancestor by accumulation of different non-deleterious mutations. Although the divergent forms are well adapted, their hybrids may be inviable or sterile because the negative effects of the alleles in a shared background. ▶allopatric speciation; Orr HA, Turelli M 2001 Evolution 55:1085.

Potassium-Argon Dating: Potassium-Argon dating is based on the conversion of K^{40} into Ar^{40} , a stable gas.

It is used for dating rocks over 100,000 years old.
 ►argon dating, ►radiocarbon dating

Potassium Ion Channel: ►ion channel

Potato (*Solanum tuberosum*): The genus has 170 to 300 related species with basic chromosome number $x = 12$. In nature, species with diploid, tetraploid, and hexaploid chromosome numbers are found. The cultivated potatoes originated from the *S. brevicaulis* group in the Andes Mountains (Spooner DM et al 2005 Proc Natl Acad Sci USA 102:14694), and secondarily from *Solanum andigena* in Central America where they produce tubers under short-day conditions. The majority of the modern varieties is day-neutral and develops tubers under long-day conditions. The cultivated potatoes are usually cross-pollinating species but many set seeds also by selfing. Generally, the seed progeny is very heterogeneous genetically. Potatoes are rarely propagated by seed, as is a crop. The diploid relatives are usually self-incompatible whereas the polyploids may set seeds by themselves. Among the cultivated groups, the tuber color may vary from white to yellow to deep purple. Also the chemical composition of the tubers shows a wide range, depending on the purpose of the market. Potato, besides being a popular vegetable, is an important source of industrial starch. The related species carry genes of agronomic importance (disease, insect resistance, etc.) that have not yet been fully exploited for breeding improved varieties. The application of the molecular techniques of plant breeding seems promising. ►patatin; Isidore E et al 2003 Genetics 165:2107; <http://www.tigr.org/tdb/tgi>; <https://gabi.rzpd.de/projects/Pomamo/>; <http://www.sgn.cornell.edu>.

Potato Beetle: (*Leptinotarsa decemlineata*, $n = 18$): One of the most devastating pests of the agricultural production of potatoes (see Fig. P118). Plants transgenic for the δ endotoxin of *Bacillus thuringiensis* are commercially available ►potato, ►*Bacillus thuringiensis*

Figure P118. Potato beetle

Potato Leaf Roll Virus: The potato leaf roll virus has double-stranded DNA genetic material.

POTE: A family of genes encoding proteins with an amino-terminal cysteine-rich domain, a central domain

with ankyrin repeats, and a carboxyl-terminal domain containing spectrin-like helices. In humans, the POTE gene family is composed of 13 closely related paralogs dispersed among eight chromosomes. These genes are found only in primates, and many paralogs have been identified in various primate genomes. The expression of POTE family is generally restricted to a few normal tissues (prostate, testis, ovary, and placenta but several family members are expressed in breast cancer and many other cancers (Lee Y et al 2006 Proc Natl Acad Sci USA 103:17885).

Potocki-Shaffer Syndrome: ►exostosis

Potocytosis: Moving ions and other molecules into cells by caveola vehicles. ►caveolae

POU: A region with several transcriptional activators of 150–160 amino acids (including a homeo-domain), involved with a large number of proteins controlling development. The acronym stands for a prolactin transcription factor (PIT), an ubiquitous and lymphoid-specific octamer binding protein (OTF), and the *Caenorhabditis* neuronal development factor (Unc-86). A POU domain may directly facilitate the recruitment of TBP and transcriptional activators and may stimulate transcription even when the enhancer is at a distance from the core promoter. POU domain proteins are involved in shuttling between nucleus and cytoplasm (Baranek C et al 2005 Nucleic Acids Res 33:6277). ►homeodomain, ►transcription factor, ►TBP, ►transcriptional activator, ►enhancer, ►core promoter, ►octa, ►unc, ►*Caenorhabditis*, ►deafness; Ryan AK, Rosenfeld MG 1997 Genes Dev 11:1207; Bertolino E, Singh H 2002 Mol Cell 10:397.

pOUT: A strong promoter opposing pIN and directing transcription to the outside end of an insertion element. ►RNA-OUT, ►pIN

Power of a Test: Algebraically, the power of a test is $1 - \beta$, where β = type II error. This test reveals the probability of rejecting a false null hypothesis and accepting a correct alternative. The experimenter needs as large a value of $1 - \beta$ as possible, by reducing β to a minimum. To improve the power, the size of the experiment (population) can be increased. In case the size cannot be increased, a more powerful test (statistics) should be chosen. ►error types, ►significance level

Pox Virus: A group of oblong double-stranded DNA viruses of 130–280 kbp (see Fig. P119). Some of these are parasites on insects, others in the family are the chicken pox, cowpox (vaccinia), and smallpox viruses (see Fig. P120).

Figure P119. Pox virus

Figure P120. Pox virus lesion

Their transmission takes place through insect vectors or by dust or other particles. Engineered pox virus vectors that are not able to multiply in mammalian cells may have the ability to express passenger genes without the risk of disease. Due to the success of vaccination, smallpox as a disease has now been eradicated and vaccination against is no longer necessary except in case of terrorist attacks (Halloran ME et al 2002 Science 298:1428). The smallpox virus (VARV) linear DNA genome is about 186 kbp with inverted terminal repeats containing 196 to 207 open reading frames. Apparently, there is small variation among the various isolates. The genes of the smallpox virus overlap and its mRNA is not spliced (Esposito JJ et al 2006 Science 313:807).

Poxvirus based vectors are being used orally to protect wild life (red fox) from rabies, for the protection of chickens against the Newcastle virus. Recombinant canarypox virus is employed for the protection of dogs and cats against the distemper, feline leukemia, equine influenza, etc. Highly attenuated derivatives, expressing rabies virus glycoprotein, Japanese encephalitis virus polyprotein, or seven antigens of *Plasmodium falciparum* are used for safe and effective vaccination. Smallpox virus disease has been eradicated and at this time only the Center of Disease Control and Prevention in Atlanta, GA in the USA and the Russian State Research Center of Virology and Biotechnology in Kolsovo, Novosibirsk, Russia, maintain active samples. Limited-scale

vaccinations have been performed as protection against terrorism. Large-scale use of the current vaccine may involve side effects such as heart disease in some individuals. A new vaccine developed and used in Japan does not pose serious side effects even at very high doses. It may revert to the wild type progenitor due to mutation of gene *B5R*. Fortunately, this gene can be eliminated without effect on protective immunity (Kidokoro M et al 2005 Proc Natl Acad Sci USA 102:4252). ▶*malaria*, ▶*Plasmodium falciparum*, ▶*variation*; Moss B, Shisler JL 2001 Semin Immunol 13:59; Takemura M 2001 J Mol Evol 52(5):419; Enserink M 2002 Science 296:1592; L1 protein: Su HP et al 2005 Proc Natl Acad Sci USA 102:4240; <http://www.poxvirus.org>.

POZ: Protein–protein interaction domain of Zinc finger-containing transcriptional regulatory proteins. ▶*Zinc finger*, ▶*αβ T cells*

PP-1, PP-2: Protein serine/threonine phosphatases that are inhibited by okadaic acid. PP-1 may be associated with chromatin through the nuclear inhibitor of PP-1 (NIPP-1). PP enzymes play key roles in many cellular processes. ▶*okadaic acid*, ▶*DARPP*

pp15: A protein factor required for nuclear import. ▶*membrane transport*, ▶*RNA export*

pp125^{FAK}: ▶*CAM*

PP2A: The proline-directed heterotrimeric protein serine-threonine phosphatase dephosphorylates proteins in the MAP pathway of signal transduction and thus balances the effect of kinases. Its deregulation seems to be associated with several types of cancers, Alzheimer disease, and susceptibility to infections by pathogens. The crystal structure of the holoenzyme has been determined (Cho US, Xu W 2007 Nature [Lond] 445:53). PP2A subunit B56 regulates β-catenin signaling and several metabolic processes. PP2A is very sensitive to okadaic acid, a tumor-inducing agent. The non-catalytic α4 subunit of PP2A is a regulator of apoptosis by dephosphorylating c-Jun and p53 transcription factors, which upon phosphorylation promote apoptosis (Kong M et al 2004 Science 306:695). ▶*Sit*, ▶*MAP*, ▶*signal transduction*, ▶*MAP kinase phosphatase*, ▶*okadaic acid*, ▶*catenins*, ▶*cyclin G*, ▶*apoptosis*, ▶*calcineurin*, ▶*TGF*

PPAR (peroxisome proliferator-activated receptor, 17q12): A transcription factor in the adipogenic (fat synthetic) pathways. The three types α, γ, and δ show different distribution in human tissues and associate with different ligands. PPARα is the target for the drugs and fibrates (amphipathic carboxylic acids) that reduce triglycerides. Type α also acts as a transcription

factor for several genes affecting lipoprotein and fatty acid metabolism. PPAR γ is a (3p25) regulator of glucose, lipid, and cholesterol metabolism, may be sensitized by thiazolidinediones (TZD), and offers some hope to be used for the treatment of diabetes mellitus type2 (IDDM). PPAR γ 2 deficiency dramatically reduces adipogenesis in mouse fibroblasts whereas PPAR γ 1 affects obesity and diabetes (Zhang J et al 2004 Proc Natl Acad Sci USA 101:10703). The PPAR γ 12Ala allele is associated with a small yet significant reduction in the risk for diabetes type II. PPAR γ agonists have a controversial—promoting and suppressing—effect on polyposis of the colon and other cancers. In human thyroid carcinoma, PAX8–PPAR γ 1 has been observed. PPAR- α agonists are also successful for the treatment of some autoimmune diseases. PPAR γ deficiency can also lead to hypertension. ▶[peroxisome](#), ▶[ROS](#), ▶[diabetes mellitus](#), ▶[polyposis](#), ▶[famesoid X receptor](#), ▶[leukotrienes](#), ▶[leptin](#), ▶[obesity](#), ▶[Krox20](#), ▶[hypertension](#), ▶[PAX](#), ▶[thiazolidinedione](#), ▶[dizygotic twins](#), ▶[sirtuin](#), ▶[mesenchyma](#), ▶[retinoic acid](#); Lowell BB 1999 Cell 99:239; Kersten S et al 2000 Nature 405:421; Willson TM et al 2001 Annu Rev Biochem 70:341; Michalik L et al 2004 Nature Rev Cancer 4:61; review: Lehrke M, Lazar MA 2005 Cell 123:993.

pPCV: Plasmid plant cloning vector, designation (with additional identification numbers and/or letters) of agrobacterial transformation vectors constructed by Csaba Koncz.

ppGpp: ▶[discriminator region](#)

PPI (peptidyl prolyl isomerase): An endoplasmic reticulum-bound protein assisting chaperone function. There are 3 PPI families: cyclophilins, FK506, and parvulins. ▶[chaperone](#), ▶[PDI](#); Dolinski K, Heitman J 1997, p 359 In: Gething MJ (Ed.) Guidebook to Molecular Chaperones and Protein Folding Catalysis, Oxford University Press, Oxford, UK.

ppm: Parts per million.

PP2R1B: PP2R1B at human chromosome 11q22-q24 encodes the β isoform of the PP2A serine/threonine protein phosphatase. The gene displays alterations (LOH) in a variable fraction of lung, colon, breast, cervix, head and neck, ovarian cancers and melanoma, and it is thus a suspected tumor suppressor gene. ▶[tumor suppressor gene](#), ▶[LOH](#); Mumby MC, Walter G 1993 Physiol Rev 73:673.

PPTs (palmitoyl-protein thioesterases): PPTs hydrolyze long chain fatty acyl CoA and PPT1 may cleave cysteine residues in the lysosomes. Its deficiency may lead to Batten disease. ▶[Batten disease](#)

Prader-Willi Syndrome (Prader-Labhart-Willi syndrome):

A very rare (prevalence 1/25,000) dominant defect involving poor muscle tension, hypogonadism, (hyperphagia [over-eating]) obesity, short stature, small hands and feet, mental retardation, compulsive behavior that sets in by the teens, caused by methylation of the paternal chromosome and by disomy for maternal chromosome 15 (see Fig. P121). The recurrence risk in affected families is about 1/1000. This and cytological evidence indicate that the condition is caused in about 60% of the cases by a chromosomal breakage in the so-called imprinting center (IC) in the long arm of human chromosome 15q11.2-q12. The same deletion (4–5 Mbp or sometimes shorter), when transmitted through the mother, results in the Angelman syndrome. At the breakpoints, the HERC2 gene (encoding a very large protein) may be repeated. The repeats may then recombine and generate the deletions. See two chromosomes shown in Figure P122, with different number of repeats, as detected by FISH. In some cases, there is no deletion but a mutation in an ubiquitin protein ligase gene (UBE3A). Mutations in the proximal part of IC lead to the Angelman syndrome and in the distal part to the Prader-Willi syndrome. Molecular studies indicated in many cases the missing (uniparental disomy) or silencing (imprinting) of a paternal DNA sequences in the patients.

Figure P121. Prader-Willi syndrome at age 15. (From Bergsma, D., ed. 1973 Birth Defects. Atlas and Compendium. By permission of the March of Dimes Foundation)

Figure P122. Duplications in the Prader-Willi syndrome. (Redrawn from Amos-Landgraf JM et al 1999 Am J Hum Genet 65:370)

The deletions of this syndrome usually involve the promoter of an snRPN gene, resulting in the silencing (imprinting) of flanking genes (ZNF127 encoding a Zn-finger protein, NDN [necdin], IPW and PAR) on either side. Necdin and Magel2 also interact with Fez (fasciculation) protein and BBS4 (Bardet-Biedl protein) and they affect centrosome function (Lee S et al 2005 Hum Mol Genet 14:627). Lack of expression of snRNP is the most reliable clinical criterion for the syndrome, although snRPN alone does not appear to be the major pathogenic factor in the syndrome. The snoRNA appears to control alternative processing of the serotonin receptor 2C (Kishore S, Stamm S 2006 Science 311:230). Also, exon 1 (1920 bp) includes more than 100 5'-CG-3' and 5'-GC-3' dinucleotides liable to methylation. Among the 19 methyl-sensitive restriction enzyme sites within the telomeric region were completely methylated in this syndrome but none of these were methylated in case of the Angelman syndrome. A 2.2 kb spliced and polyadenylated RNA is transcribed 150 kb telomerically to snRPN in human chromosome 15q11.2-q12 and the homologous mouse chromosome 7 region. The transcript is not translated, however. This gene (IPW) is not expressed in individuals with the Prader-Willi syndrome and is therefore said to be imprinted in Prader-Willi syndrome. In the mouse gene *Ipw*, multiple copies of 147 bp repeats are found with retroviral transposons (IAP) insertions. ►obesity, ►imprinting, ►imprinting box, ►epigenesis, ►disomic, ►serotonin, ►alternative splicing, ►Angelman syndrome, ►head/face/brain defects, ►snPRN, ►IAP, ►Bardet-Biedl syndrome; Fulmer-Smentek SB, Francke U 2001 Hum Mol Genet 10:645.

Prairie Dog (ground squirrel, *Sciuridae*): Burrowing mammals with five different species. They are rodents, and not canidae, inhabiting arid areas (see Fig. P123).

Figure P123. *Cynomys ludovicianus* Prairie dog

pRB: Retinoblastoma protein. ►retinoblastoma

PRC1: A spindle midzone-associated kinase. ►midzone

PRD1: An icosahedral, double-stranded-DNA phage (*Tectiviridae*) of Gram-negative bacteria. It lacks the common phage tail and it acquires an injection device from the host membrane during phage assembly. The mature virion is 66 Mda, containing 20 protein species. It is evolutionarily related to adenovirus. ►phage, ►adenovirus; Abrescia NGA et al 2004 Nature [Lond] 432:68.

Pre-Adaptive: A pre-adaptive trait or mutation is that which occurs before selection would favor it but it becomes important when the conditions become favorable for this genotype. ►adaptation, ►post-adaptive mutation, ►fluctuation test

Prebiotic: Prebiotic refers to the period before life originated. ►evolution prebiotic

Precambrian: ►Proterozoic, ►Cambrian, ►geological time periods

Precise Excision: In precise excision, the genetic vector or transposon leaves the target site without structural alterations; the initially disrupted gene or sequence can return to the original (wild type) form.

Precursor Ion Scanning: A powerful technique in proteomics in connection with MS/MS and TOF. ►MS/MS, ►TOFMS; Steen H et al 2001 J Mass Spectrom 36:782; Hager JW 2002 Rapid Commun Mass Spectrom 16:512.

Predetermination: In predetermination, the phenotype of the embryo is influenced by the maternal genotypic constitution but the embryo itself does not carry the gene(s) that would be expressed in it at that particular stage. ►delayed inheritance, ►maternal effect genes

Predictive Value: The true estimate of the number of individuals afflicted by a condition on the basis of the tests performed in the population.

Predictivity: The predictivity of an assay system is, e.g., the percentage of carcinogens correctly identified

among carcinogens and non-carcinogens, by indirect carcinogenicity tests, based mainly on mutagenicity. ►accuracy, ►specificity, ►sensitivity, ►bioassays for environmental mutagens

Predictome: A database of protein links and networks. ►genetic networks

Predictor Gene: The expression of a predictor gene signals difference(s) among phenotypically similar but functionally different forms of malignancies. ►cancer classification

Predisposition: Susceptibility to disease. It may be based on a large number of alleles and environmental factors may also have a major role. A predispositional testing, based on the genetic constitution, may or may not indicate the probability of a disease.

Preeclampsia: ►ecclampsia

Preferential Repair: Transcriptionally active DNA is repaired preferentially. ►DNA repair

Preferential Segregation: Non-random distribution of homologous chromosomes toward the pole during anaphase I of meiosis. There are four loci in the Abnormal 10 chromosome (carrying a terminal large knob) in maize that affect neocentromere activity, increased recombination, and preferential segregation (Hiatt EN, Dawe RK 2003 Genetics 164:699). If harmful combination of genes (gene blocks) is preferentially included in the gametes, this may constitute a genetic load. ►meiotic drive, ►neocentromere, ►polarized segregation; Rhoades MM, Dempsey E 1966 Genetics 53:989; Buckler ES et al 1999 Genetics 153:415.

Prefoldins (PFDN): Molecular chaperones built as hexamers from the α and β subunits and four β -related subunits in eukaryotes. Prefoldin 1 was assigned to human chromosome 5, and prefoldin 4 to chromosome 7. Prefoldins may be required for gene amplification in tumors. ►chaperone; Siegert R et al 2000 Cell 103:621; prefoldin-like Skp structure: Walton TA, Sousa MC 2004 Mol Cell 15:367.

Preformation: An absurd historical idea supposing that an embryo preexists in the sperm (spermists) or in the egg (ovists) of animals and plants, rather than developing by epigenesis from the fertilized egg. ►epigenesis; Richmond ML 2001 Endeavour 25(2):55.

Pre-Genome RNA: The replication intermediate in retroid viruses. ►retroid virus

Pregnancy, Male: In seahorses (*Hippocampus*, Syngnathidae), the female lays unfertilized eggs in the ventral pouch of the male where he fertilizes them and the fetus develops.

Pregnancy Test: Pregnancy is the formation of a fetus in the womb; there are about 40 known pregnancy tests, based on chemical study of blood and urine or other criteria. The currently used tests rely on estrogen level. ►Aschheim-Zondek test

Pregnancy, Unwanted: The estimated frequency of unwanted pregnancy in the human population of the whole world was estimated between 35 to 53 million per year. ►pregnancy test, ►abortion medical

Pregnenolone: A precursor in the biosynthesis of several steroid hormones: CHOLESTEROL PREGNENOLONE→PROGESTERONE→ANDROSTENEDIONE→TESTOSTERONE→ESTRADIOL. These steps are under the control mainly of several cytochrome P450 (CYP) enzymes and their deficiency or misregulation lead to pseudohermaphroditism, hermaphroditism, and various other anomalies of the reproductive system. ►steroid hormones

Preimmunity: ►host-pathogen relation

Preimplantation Genetics: Preimplantation genetics detects genetic anomalies either in the oocyte or in the zygote before implantation takes place. This can be done by molecular and biochemical analyses, and cytogenetic techniques. The status of the egg—in some cases of heterozygosity for a recessive gene—may be determined prior to fertilization by examining the polar bodies. Since the first polar bodies are haploid products of meiosis, if they show the defect, then presumably the egg is free of it. The purpose of this test is to prevent transmission of identifiable familial disorders. The technology permits selection for sex of the embryo but this is ethically controversial. ►gametogenesis, ►in vitro fertilization, ►ART, ►micromanipulation of the oocyte, ►polymerase chain reaction, ►sperm typing, ►PGD; Delhanty JD 2001 Am J Hum Genet 65:331; Wells D, Delhanty JD 2001 Trends Mol Med 7:23; Bickerstaff H et al 2001 Hum Fertil 4:24; Braude P et al 2002 Nature Rev Genet 3:941; ethical and legal considerations: Knoppers BM et al 2006 Annu Rev Genomics Hum Genet 7:201.

Preinitiation Complex: ►PIC, ►open promoter complex

Pre-mRNA (pre-messenger RNA): The primary transcript of the genomic DNA, containing exons and introns and other sequences. ►mRNA, ►RNA processing, ►introns, ►hnRNA, ►post-transcriptional processing, ►RNA editing, ►splicing enhancer exonic

Pre-Mutation: A genetic lesion, which potentially leads to mutation unless the DNA repair system remedies the defect before it is visually manifested. Pre-mutational lesions lead to delayed mutations. UV irradiation or chemical mutagens with indirect effects (that is the mutagen requires either activation or it induces the

Figure P124. Two molecules of farnesyl pyrophosphate are converted into 30-C squalene in the presence of NADPH

formation of mutagenic radicals, peroxides) frequently cause pre-mutations. Incomplete expansion of trinucleotide repeats may also be considered pre-mutational, e.g., in the fragile X chromosome. ▶chromosomal mutation, ▶chromosome breakage, ▶point-mutation, ▶telomutation, ▶trinucleotide repeats, ▶fragile X, ▶Sherman paradox under mental retardation; Auerbach C 1976 Mutation research. Chapman and Hall, London, UK.

Prenatal Diagnosis: Prenatal diagnosis determines the health status or distinguishes among the possible nature of causes of a problem with a fetus before birth. The results of cytological or biochemical analysis permit the parents to prepare psychologically and medically to the expectations. Although chromosomal abnormalities cannot be remedied, for metabolic disorders (e.g., galactosemia) advance preparations can be made. Similarly, fetal erythroblastosis may be prevented. In case of very severe hereditary diseases, abortion may be an option if it is morally acceptable to the parents and does not conflict with the existing laws. Prenatal diagnosis is now available for more than hundred anomalies. Until recently, prenatal diagnosis required mainly amniocentesis or sampling of chorionic villi, now in some instances the maternal blood can be scanned for fetal blood cells and by the use of the polymerase chain reaction, the DNA of the fetus can be examined. ▶genetic testing, ▶genetic screening, ▶genetic counseling, ▶amniocentesis, ▶polymerase chain reaction, ▶RFLP, ▶DNA fingerprinting, ▶DNA circulating, ▶plasma nucleic acid, ▶PUBS, ▶MSAFP, ▶sonography, ▶fetoscopy, ▶echocardiography, ▶hydrocephalus, ▶galactosemias, ▶chorionic villi, ▶pre-implantation genetics, ▶ART; Weaver DD, Brandt IK 1999 Catalog of prenatally diagnosed conditions, Johns Hopkins University Press, Baltimore, Maryland; Fetal Evaluation: <http://www.cpdx.com/>.

Prenylation: The attachment of a farnesyl alcohol, in thioether linkage, with a cystein residue located near the carboxyl terminus of the polypeptide chain. The donor is frequently farnesyl pyrophosphate.

Cytosolic proteins are frequently associated with the lipid bilayer of the membrane by prenyl lipid chains or through other fatty acid chains. Prenyl biogenesis begins by enzymatic isomerization of isopentenyl pyrophosphate ($\text{CH}_2=\text{C}[\text{CH}_3]\text{CH}_2\text{CH}_2\text{OPP}$) into dimethylallyl pyrophosphate ($[\text{CH}_3]_2\text{C}=\text{CHCH}_2\text{OPP}$). These then react to form geranyl pyrophosphate ($[\text{CH}_3]_2\text{C}=\text{CHCH}_2\text{CH}_2\text{C}[\text{CH}_3]=\text{CHCH}_2\text{OPP}$). Geranyl pyrophosphate is then converted into farnesyl pyrophosphate as shown in Figure P124.

Members of the RAS family proteins, involved in signal transduction, cellular regulation, and differentiation are prenylated at cysteine residues of the COOH-terminus. Prenylation determines the cellular localization of these molecules. Cellular fusions are mediated by prenylated pheromones. The cytoskeletal lamins attaching to the cellular membranes are farnesylated. Prenylation of the C-termini of proteins is generally mediated by farnesyltransferase, a heterodimer of 48 kDa α and 46 kDa β subunit. Protein farnesylation is essential for early embryogenesis and for the maintenance of tumorigenesis (Mijimolle N et al 2005 Cancer Cell 7:313). Squalene is a precursor of cholesterol and other steroids (see Fig. P125). ▶lipids, ▶abscisic acid, ▶lamin, ▶RAS, ▶cytoskeleton, ▶pheromone

Figure P125. Isoprene units

Prepatent: The period before an effect (e.g., infection) becomes evident.

Prepattern Formation: The distribution of morphogens precedes the appearance of the visible pattern of particular structures. ▶morphogen; Chiang C et al 2001 Dev Biol 236:421.

Prepriming Complex: A number of proteins at the replication fork of DNA involved in the initiation of DNA synthesis. ▶DNA replication, ▶replication fork

Preprotein: A preprotein is a protein molecule that has not completed yet its differentiation (trimming and processing).

Prereduction: In prereduction, the alleles of a locus separate during the first meiotic anaphase because there was no crossing over between the gene and the centromere. ▶tetrad analysis, ▶meiosis, ▶post-reduction

Pre-rRNA: The unprocessed transcripts of ribosomal RNA genes; they are associated at this stage with ribosomal proteins and are methylated at specific sites. The cleavage of the cluster begins at the 5' terminus of the 5.8S unit and proceeds to the 18S and 28S units. ▶rRNA, ▶rm, ▶ribosomal RNA, ▶ribosome

Presence-Absence Hypothesis: The presence-absence hypothesis was advocated by William Bateson during the first few decades of the 20th century as an explanation for mutation. The recessive alleles were thought to be losses whereas the dominant alleles were supposed to indicate the presence of genetic determinants. Similar views, in a modified form, were maintained for decades later and were debated in connection with the nature of induced mutations. ▶null mutation, ▶genomic subtraction; Bateson W et al 1908 Rep Evol Comm R Soc IV, London, UK.

Presenilins (PS): Proteins associated with precocious senility, such the presenilin 1 (S182/AD3) encoded at human chromosome 14q24.3 (442 amino acids) and presenilin 2 (STM2/AD4, 467 amino acids encoded at 1q31-q34.2) proteins of the Alzheimer's disease. Mutations in presenilins account for about 40% of familial cases of the Alzheimer's disease. Presenilins are integral membrane proteases. Presenilin 1 and presenilin 2 increase the production of β -amyloid either directly or most likely by their effect on secretases. They may also promote apoptosis. Presenilins control calcium ion channels of the endoplasmic reticulum and the disruption of these channels can lead to Alzheimer's disease (Tu H et al 2006 Cell 126:981). Mutant PS1 strongly affects both the amplitude of evoked excitatory currents as well as the frequency of spontaneous excitatory synaptic currents by decreasing the number of functional synapses (Priller C et al 2007 J Biol Chem 282:1119). p53 and p21^{WAF-1} promote inhibition of presenilin 1, and that may encourage apoptosis and tumor suppression as well. Presenilin 1 is associated with β -catenin and in the complex β -catenin is stabilized. Mutations in Presenilin 1 may destabilize β -catenin and the latter is usually degraded in

Alzheimer's disease. Thus, mutation in Presenilin 1 may predispose to early onset Alzheimer's disease. Presenilin also controls pigmentation of the retinal epithelium and epidermal melanocytes, and mutation may lead to aberrant accumulation of tyrosinase (Wang R et al 2006 Proc Natl Acad Sci USA 103:353). Presenilin 2 contains a domain that is similar to that of ALG3 (apoptosis linked gene) and inhibits apoptosis. Presenilin 1 may also affect various (non-neurodegenerative) cancer-related pathways. The presenilins are involved in the processing of the transmembrane domain of amyloid precursor proteins (APP), and they are essential for normal embryonal development. Protein TMP21 is a component of presenilin complexes and modulates selectively γ -secretase but not ϵ -secretase (Chen F et al 2006 Nature [Lond] 440:1208). Presenilins also control the transduction of Notch signals. A presenilin locus exists in the third chromosome also (77A-D) of *Drosophila melanogaster*. ▶Alzheimer disease, ▶prion, ▶apoptosis, ▶p53, ▶p21, ▶calsenilin, ▶catenins, ▶ubiquitin, ▶Notch, ▶secretase, ▶nicastrin; Sisodia SS et al 1999 Am J Hum Genet 65:7; Baki L et al 2001 Proc Natl Acad Sci USA 98:2381; Wolfe MS, Haass C 2001 J Biol Chem 276:5413; Marjaux E et al 2004 Neuron 42:189.

Present: The expressed open reading frames during particular times or conditions when analyzed by microarrays. ▶open reading frame, ▶microarray hybridization

Presenting: Behavioral signs shown by the female indicating receptivity to mating.

Presequence: A generic name for signal peptides and transit peptides.

Presetting: The penchant of a transposable element to undergo reversible alteration in a new genetic milieu. It may be caused by the methylation of the transposase gene. ▶Spm, ▶Ac-Ds

Presymptomatic Diagnosis: The identification of the genetic constitution before the onset of the symptoms. ▶prenatal diagnosis, ▶genetic screening

Pre-tRNA: ▶tRNA

Prevalence (K, λ): The proportion of a genetic or non-genetic anomaly or disease in a particular human population at a particular time. The percentage of hereditary diseases caused by presumably single nuclear genes in human populations: autosomal dominant 0.75, autosomal recessive 0.20, X-linked 0.05. Besides these, multifactorial abnormalities account for about 6% of the genetic anomalies. In case the general prevalence of the diseases in a population is x, the expected expression among sibs for autosomal

dominant is $1/2x$, for autosomal recessives it is $1/4x$, and for multifactorial control $1/\sqrt{x}$. ▶incidence, ▶mitochondrial diseases in humans

Prevention of Circularization of Plasmids: ▶circularization

Preventive Medicine: Preventive medicine studies the genetic and physiological conditions of individuals and societies in order to take measures to avoid the onset of diseases. ▶diseases in humans, ▶genetic counseling, ▶counseling genetic, ▶genetic risk, ▶recurrence risk, ▶empirical risk, ▶heritability

Prey: ▶two-hybrid system

Prezygotic: The DNA molecule in the prokaryotic cell before recombination (transduction or transformation); after integration it becomes postzygotic.

Pri: ▶cis-acting elements

PriA: Replication priming protein. ▶replication fork, ▶DNA replication, ▶primase

Priapism: An uncommon prolonged engorgement of the penis or erection of the penis or the clitoris. Phosphodiesterase-5A dysregulation is one cause (Champion HC et al 2005 Proc Natl Acad Sci USA 102:1661). It is generally called idiopathic but in some families it occurs repeatedly. It may be evoked by alcoholism or by certain drugs. Chronic hemoglobinopathies and genital cancer may also cause it. ▶idiopathic, ▶hemoglobinopathies, ▶nitric oxide, ▶phosphodiesterase

Pribnow Box (TATA box): 5'-TATAATG-3' (or similar) consensus preceding the prokaryotic transcription initiation sites by 5–7 nucleotides in the promoter region at about –10 position from the translation initiation site. Separated by 17 bp there is another conserved element (called extended promoter) in prokaryotes at –35 (TTGACA). The eukaryotic homolog of the Pribnow box is the Hogness box. ▶Hogness box, ▶open promoter complex, ▶σ; Gold L et al 1981 Annu Rev Microbiol 35:365.

Pride: A living and mating community of animals under the domination of a particular male(s).

Primary Cells: Primary cells are taken directly from an organism rather than from a cell culture.

Primary Constriction: The centromeric region of the eukaryotic chromosome (see Fig. P126).

Figure P126. Primary constriction

Primary Nondisjunction: ▶nondisjunction

Primary Response Genes: The induction of primary response genes occurs without the synthesis of new protein but requires only pre-existing transcriptional modifiers such as hormones. ▶sign transduction, ▶secondary response genes

Primary Sex Ratio: Ratio of males to females at conception. ▶sex ratio

Primary Sexual Characters: The female and male gonad, respectively. ▶secondary sexual characters

Primary Structure: The sequence of amino acid or nucleotide residues in a polymer.

Primary Transcript: The RNA transcript of the DNA before processing has been completed. ▶processing, ▶pre-mRNA, ▶pre-rRNA

Primase: Polymerase-α/primase synthesizes an about 30-nucleotide RNA primer for the initiation of replication of the lagging strand of the DNA. In prokaryotes, the primosome protein complex fulfills the function. In bacteriophage M13, an imperfect hairpin is formed at the origin of replication, which is recognized by *E. coli* RNA polymerase σ^{70} holoenzyme and it synthesizes a 18–20 nucleotide primer suitable for synthesis by DNA polymerase III. The RNA polymerase leaves a protruding 3'-end of the RNA but maintains an RNA-DNA hybrid molecule of 8–9 bp. This 3-end of the RNA can then interact with DNA polymerase III. Filamentous phages and bacterial plasmids probably use the priming mechanisms (Zenkin N et al 2006 Nature [Lond] 439:617). The function of the primase is much slower than the processing of the DNA polymerase. Since the Okazaki fragments need priming several times while the leading strand is synthesized by the DNA polymerase, there must be a molecular brake there to assure that the two (leading and lagging) strands are synthesized in concert (Lee J-B et al 2006 Nature [Lond] 439:621). In *E. coli*, gene *DnaG* (66 min) encodes it and it is associated with the replicative helicase. In eukaryotes, the ~60 and ~50 kDa subunits of DNA polymerase α represent the primase.

The latter complex is associated with proteins and forms a mass of ~300 kDa. The primases prime any single-stranded DNA but they are far more effective at specific sequences. DnaG recognizes the 5'-CTG-3' trinucleotide and synthesizes a 26–29 nucleotide RNA. The mouse primase works at ~17 sites that share either 5'-CCA-3' or 5'-CCC-3' at about 10 nucleotides downstream from the priming initiation site at the 3'-end. The active template is usually rich in pyrimidines. In eukaryotes, the primer is directly transferred to the DNA pol α without dissociating from the template. Primase inhibitors (cytosine or adenosine arabinoside, 2'-deoxy-2'-azidocytidine, etc.) have therapeutic potentials. Several binding proteins assist priming. ►replication fork, ►DNA replication, ►PriA, ►DNA polymerases, ►polymerase switching, ►Okazaki fragment, ►primosome, ►replication restart; Keck JL et al 2000 Science 287:2482; Arezi B, Kuchta RD 2000 Trends Biochem 25:572; Frick DN, Richardson CC 2001 Annu Rev Biochem 70:39; Augustin MA et al 2001 Nature Struct Biol 8:57.

Primates: The taxonomic group that includes humans, apes, monkeys, and lemur. To the higher primates, also called anthropoidea or simians, belong the old world monkeys (Cercopithecidae) such as the *Macaca*, *Cercopithecus*, etc., hominoidea (chimpanzee [*Pan*], gorilla [*Gorilla*], orangutan [*Pongo*], and humans, and also the now extinct early evolutionary forms. The anthropoidea includes also the new world monkeys (*Cebioidea*). The lower primates or prosimians mean the genera of the lemur, galago, etc. According to data of D.E. Kohne et al (1972 J Hum Evol. 1:627), on the basis of thermal denaturation of hybridized DNA the numbers in million years of divergence (and the % of nucleotide difference) of various primates from man was estimated to be: chimpanzee 15 (2.4), gibbon, 30 (5.3), green monkey 46 (9.5), capuchin 65 (15.8), galago 80 (42.0). Some of the DNA differences now need revisions (►chimpanzee). Humans have substantially lower variations in the DNA than the great apes, chimpanzees, and orangutan (see Table P2) (Kaessmann H et al 2001 Nature Genet 27:155).

Table P2. The expressed genes indicate relations among three primate species as follows

| | Chimpanzee | Orangutan | Rhesus macaque |
|------------|------------|-----------|----------------|
| Humans | 110 | 128 | 176 |
| Chimpanzee | - | 150 | 141 |
| Orangutan | - | - | 129 |

(Data from Gilad, Y. et al. 2006 Nature [Lond] 440:242)

The taxonomic tree of primates can be outlined as:

PRIMATES: *I. Catarrhini*. IA1 Cercopithecidae (Old World Monkeys). IA1a Cercopithecinae, IA1b Colobinae. IA1c Cercopithecidae. IB. Hominidae (Gorilla, Homo, Pan, Pongo). IC. Hylobatidae (Gibbons). *II. Platyrrhini* (New World Monkeys): IIA. Callitrichidae (Marmoset and Tamarins). IIA1. Callimico. IIA2. Callithrix. IIA3. Cebuella. IIA4. Callicebinae. IIA5. Cebinae. IIA6. Pitheciinae. *III. Strepsirhini* (Prosimians) IIIA Cheirogalidae. IIIA1 Cheirogaleus. IIIA2. Microcebus. IIIB. Daubentonidae (Ayeayes). IIIB1. Daubentonia. IIIC Galagonidae (Galagos). IIIC1. Galago. IIIC2. Otolemur. IIID. Indridae. IIID1 Indri. IIID2. Propithecus (Sifakas). IIIE. Lemuridae (Lemurs). IIIE1. Eulemur. IIIE2. Hapalemur. IIIE3. Lemur. IIIE4. Varecia. IIIF. Loridae (Lorises). IIIF1. Loris. IIIF2. Nycticebus. IIIF3. Perodicticus. IIIG Megalapididae. IIIG1. Lepilemur. *IV. Tarsii* (Tarsiers). IVA Tarsiidae (Tarsiers). IVA1. Tarsius. ►human races, ►apes, ►prosimii, ►Cebidae, ►Callithricidae, ►Cercopithecidae, ►Colobidae, ►Pongidae, ►Homo sapiens, ►Hominidae, ►evolutionary tree; DeRousseau CJ (ed) 1990 Primate Life History and Evolution, Wiley-Liss, New York; Enard W et al 2002 Science 296:340; <http://www.primat.wisc.edu/pin>; phylogeny database: <http://www.hvrbase.org/>.

Primatized Antibody: A chimeric antibody constructed using the variable region of monkey antibody linked to the human constant region. ►antibody chimeric

Primer: A short sequence of nucleotides (RNA or DNA) that assists in extending the complementary strand by providing 3'-OH ends for the DNA polymerase to start transcription. In some viruses (hepadna viruses, adenoviruses), the replication of viral DNA, and in some cases viral RNA is primed by proteins. The 3' OH group of a specific serine is linked to a dCMP and a viral enzyme drives the reaction. Replication may proceed from both ends of the linear molecules without being in the same replication fork. ►nested primers, ►primase, ►PCR, ►Vpg; <http://www.genome.wi.mit.edu>; primer identification: <http://ihg.gsf.de/ihg/ExonPrimer.html>; <http://web.ncicrf.gov/rtp/gel/primerdb/>; primer design for promoters and exons: <http://genepipe.ngc.sinica.edu.tw/primerz/>; may better opens by: http://www.citeulike.org/user/sebastien_vigneau/article/1357047; Primer3 primer selection: <http://www.bioinformatics.nl/cgi-bin/primer3plus/primer3plus.cgi>.

Primer Extension: RNA (or single-strand DNA) is hybridized with a single strand DNA primer (30–40 bases), which is 5'-end-labeled. Generally, the primers are complementary to base sequences within 100 nucleotides from the 5'-end of mRNA to avoid

heterogeneous products of the reverse transcriptase which is prone to stop when it encounters tracts of secondary structure. After extension of the primer by reverse transcriptase, the length of the resulting cDNA (measured in denaturing polyacrylamide gel electrophoresis) indicates the length of the RNA from the label to its 5'-end. When DNA (rather than RNA) is used as template DNA-DNA hybridization must be prevented. The purpose of the primer extension analysis is to estimate the length of 5' ends of RNA transcripts and identify precursors of mRNA and processing intermediates. The cDNA so obtained can be directly sequenced by the Maxam-Gilbert method or also by the chain termination methods of Sanger if dideoxynucleoside triphosphates are included in the reaction vessels. Primer extension preamplification (PEP) facilitates the preparation of multiple copies of the genome of a single sperm (Zhang L et al 1992 Proc Natl Acad Sci USA 89:5847). ▶DNA sequencing, ▶primary transcript, ▶post-transcriptional processing, ▶chimeric proteins, ▶PCR-based mutagenesis, ▶amplification; Reddy VB et al 1979 J Virol 30:279; Sambrook J et al 1989 Molecular cloning, Cold Spring Harbor Laboratory Press.

Primer Shift: The primer shift is used for confirmation that a PCR procedure indeed amplified the intended DNA sequence. For this purpose, a primer different from the one initially employed is chosen and attached to the template a couple of hundred bases away from the position of the first. After the completion of the PCR process, the amplified product is supposed to be as much longer as the difference between the position of the first and the second primer if the amplification involved the intended sequence. Such a procedure may be used when a DNA sequence corresponding to a deletion is amplified. ▶PCR, ▶primer

Primer Walking: A method in DNA sequencing whereby a single piece of DNA is inserted into a large-capacity vector. After a shorter stretch had been sequenced, a new primer is generated from the end of what has been already sequenced and the process is continued until the sequencing of the entire insert is completed. ▶DNA sequencing; Zevin-Sonkin D et al 2000 DNA Seq 10(4-5):245; Kaczorowski T, Szybalski W 1998 Gene 223:83.

Primitive Streak: The earliest visible sign of axial development of the vertebrate embryo when a pale line appears caudally at the embryonic disc as a result of migration of mesodermal cells. ▶organizer, ▶differentiation, ▶morphogenesis, ▶Hensen's node, ▶embryo node; Ciruna B, Rossant J 2001 Dev Cell 1:37.

Primordium: The embryonic cell group that gives rise to a determined structure.

Primosome: The complex of prepriming and priming proteins involved in replication of the Okazaki fragments (see Fig. P127). It moves along with the replication fork in the opposite direction to DNA synthesis. The primosome (containing helicase and primase) unwinds the double-stranded DNA and synthesizes RNA primers. ▶DNA replication, ▶replication fork, ▶Okazaki fragment, ▶primase; Marsin S et al 2001 J Biol Chem 276:45818; replication restart primosome PriB component structure: Lopper M et al 2004 Structure 12:1967; Zhang Z et al 2005 Proc Natl Acad Sci USA 102:3254; electron microscopic structure: Norcum MT et al 2005 Proc Natl Acad Sci USA 102:3623.

Primula (Primrose): An ornamental plant. *P. kewensis* ($2n = 36$) is an amphidiploid of *P. floribunda* ($2n = 18$) and *P. verticillata* ($2n = 18$).

Principal Component Analysis: The aim of the principal component analysis is to reduce the apparent complexity of the original variables and summarize the information in a simpler manner. The principal components are construed as linear functions of the original variables. ▶factorial analysis, ▶stratification; Jolliffe IT 1986 Principal Component Analysis, Springer, New York.

PRINS (primed in situ synthesis): An in situ hybridization technique bearing some similarities to other methods of probing (e.g., FISH). The PRINS procedure uses small oligonucleotide (18–22 nucleotides) primers from the sequence of concern. After the primer is annealed to denatured DNA (chromosomal or other polynucleotides), a thermostable DNA polymerase is employed to incorporate biotin-dUTP or digoxigenin-dUTP. The procedure is very sensitive to mismatches (because the primer is short) and a mismatch at the 3'-end may prevent chain extension. The concentration of the primer (C) = $Ab_{260}/\epsilon_{max} \times L$

where Ab_{260} = absorbance at 260 nm, ϵ_{\max} = molar extinction coefficient (M^{-1}) and L = the path length of the cuvette of the spectrophotometer. The molar extinction coefficients are determined $\epsilon_{\max} = (\text{number of A} \times 15,200) + (\text{number of T} \times 8400) + (\text{number of G} \times 12,010) + (\text{number of C} \times 7050) M^{-1}$. (A = adenine, T = thymine, G = guanine, C = cytosine). PRINS are useful for many purposes, including determination of aneuploidy, DNA synthesis, viral infection, etc. ►PCR, ►FISH, ►in situ hybridization, ►LISA, ►biotinylation, ►extinction, ►non-radioactive label; Hindkjaer J et al 2001 Methods Cell Biol 64:55.

PrintAlign: A computer program for graphical interpretation of fragment alignments in physical mapping of DNA. ►physical map

PrintMap: A computer program that produces a restriction map in PostScript code. ►PostScript

Prion (PrP^C , PrP^{Sc} , PrP^* , PrP^{Pres}): Infective, protease-resistant glycoprotein particles, responsible for the degenerative brain diseases such as scrapie in sheep, chronic wasting disease in deer and elk, BSE in cattle, kuru, Creutzfeldt-Jakob disease, Gerstmann-Sträussler syndrome, fatal familial insomnia of man and, possibly, also Alzheimer's disease. Protease-sensitive prions ($sPrP^{Sc}$) also exist. Prions are transmitted among various animal species although the expression may require a longer lag. Decreased transmission of the prion state between divergent proteins is termed "species barrier" and was thought to occur because of the inability of divergent prion proteins to co-aggregate. Species barrier can be overcome in cross-species infections, e.g., from "mad cows" to humans. The counterparts of yeast prion protein Sup35, originated from three different species of the *Saccharomyces sensu stricto* group exhibit the range of prion domain divergence that overlaps with the range of divergence observed among distant mammalian species. All three proteins were capable of forming a prion in *Saccharomyces cerevisiae*, although prions formed by heterologous proteins were usually less stable than the endogenous *S. cerevisiae* prion. Heterologous Sup35 proteins co-aggregated in the *S. cerevisiae* cells. However, in vivo cross-species prion conversion was decreased and in vitro polymerization was cross-inhibited in at least some heterologous combinations, thus demonstrating the existence of prion species barrier (Chen B et al 2007 Proc Natl Acad Sci USA 104:2791).

Mutations in the gene may result in prion potentiation. The non-familial Creutzfeldt-Jakob disease may be traced to infections by gonadotropins, human growth hormones extracted from cadavers, grafts, improperly-sterilized medical equipment contaminated by prions, or to eating the meat (primarily brain, lymphatic and nerve tissues) of infected animals. In case of chronic inflammation of the kidneys, scrapie-infected mice excrete prions by the urine (Seeger H et al 2005 Science 310:324). Normal prion protein, PrP^{Sen} (PrP^C protease sensitive), is expressed as a membrane-bound glycoprophosphatidylinositol (GPI)-anchored protein (see Fig. P128). The GPI anchor may be the requisite for infectious transmission of this protein and the expression of typical scrapie (Chesebro B et al 2006 Science 308:1435). Other amyloidogenic proteins, which are involved in brain degeneration but lack GPI anchor, are not infectious. GPI-anchorless proteins can be secreted from the blood and can form deposits in the amyloid or non-amyloid forms in the brain and heart endothelia. In infected non-transgenic mice, it appears mainly in the non-amyloid form but in transgenic animals, mainly in the amyloid form. The protease-resistant prion causes heart disease (Trifilo MJ et al 2006 Science 313:94).

Figure P128. The normal PrP^C protein is encoded in the nucleus by the PRNP gene and after transcription the RNA transcript is translated in the cytoplasm. Some of the PrP^C molecules decorate the surface of the nerve cells and others may be sequestered into the endosomes or lysosomes. Within these compartments, a conformational alteration may take place and the infectious PrP^* or PrP^{Sc} protein molecules are released. These altered molecules may then infect other, normal cells and initiate a process of degenerative protein accumulation. The conformational changes may be caused by mutations in PRNP and other genes located in several human chromosomes. (Modified after Weissmann C 1999 J Biol Chem 274:3)

On the basis of the degree and extent of glycosylation, about 400 prions have been distinguished. The N terminus of PrP contains a glycosaminoglycan (GAG)-binding motif. Binding of GAG is important in prion disease. Accordingly, all human mutant recombinant rPrPs bind more GAG, and GAG promotes the aggregation of rPrP more efficiently than wild-type recombinant normal cellular PrP (rPrP^C). Furthermore, point mutations in *PRNP* gene also cause conformational changes in the region between residues 109 and 136, resulting in the exposure of a second, normally buried, GAG-binding motif. Importantly, brain-derived PrP from transgenic mice, which express a pathogenic mutant with nine extra octapeptide repeats also binds more strongly to GAG than wild-type PrP^C (Yin S et al 2007 Proc Natl Acad Sci USA 104:7546).

Prions appear like virus particles but are free of nucleic acid. The 25 nm virus-like arrays in two cell lines with transmissible spongiform encephalitis (TSE) virions are structurally independent of pathological PrP in the intact cell (Manuelidis L et al 2007 Proc Natl Acad Sci USA 104:1965). It appears that a normal protein is structurally modified; the α helical structure is largely converted into β sheets, leading to the formation of these autonomous disease-causing proteins. Transmission of the disease in the absence of the protease-resistant prion is exceptional (Lasmézas CI 1997 Science 275:402). Although prions are infectious diseases of protein folding, some RNAs of mammals appear adjuvants of the pathogenic alterations in vitro whereas invertebrate RNA has no such effect (Deleault NR et al. 2003 Nature [Lond] 425:717). Experimental protein misfolding cyclic amplification (PMCA) reaction can yield in vitro generated prions that are indistinguishable from prions isolated from scrapie hamster brain in terms of proteinase K resistance, autocatalytic conversion activity, and, most notably, specific biological infectivity (Weber P et al 2006 Proc Natl Acad Sci USA 103:15818).

In order to develop prion disease in mice, the organism must have PrP^C, and if it is absent the animals become resistant to scrapie and show normal neuronal functions (Büeler H et al 1993 Cell 73:1339). PrP^C-deficient cattle produced by a sequential gene-targeting system over 20 months of age are clinically, physiologically, histopathologically, immunologically and reproductively normal. Brain tissue homogenates are resistant to prion propagation in vitro (Richt JA et al 2007 Nature Biotechnol 25:132). Also, microglia (cells that surround the nerves and phagocytize the waste material of the nervous tissue) must be present to develop prion disease. Depletion of the endogenous neuronal PrP^C from mice by the Cre recombinase prevents the

progression of the disease. The non-neural accumulation of PrP^{Sc} is not pathogenic but leads to an arrest of PrP^C→PrP^{Sc} conversion within neurons and prevents neurotoxicity (Mallucci G et al 2003 Science 302:871). Depletion of endogenous neuronal prion protein (PrP^C) in mice with early prion infection reversed spongiform change and prevented clinical symptoms and neuronal loss. Thus, early functional impairments precede neuronal loss in prion disease and can be rescued. Further, they occur before extensive PrP^{Sc} deposits accumulate and recover rapidly after PrP^C depletion, supporting the concept that they are caused by a transient neurotoxic species, distinct from aggregated PrP^{Sc} (Malucci GR et al 2007 Neuron 53:325).

If microglia are destroyed by L-leucine-methylester, the neurotoxic PrP fragment, containing amino acids 106–126, does not harm the neurons. The transition from the normal PrP^C→PrP^{Sc} (the insoluble scrapie prion) conformation involves changes in amino acid residues 121–231, involved two antiparallel β -sheets and in three α -helices (see Fig. P129).

Figure P129. The nuclear magnetic resonance-revealed structure of the PrP^C protein. The amino end displays an about 100 residue flexible sequence that is modified when PrP^{Sc} is formed. (Modified after Riek R et al 1997 FEBS Lett 413:282. By Permission of Elsevier Science and Authors)

Monoclonal antibody 15B3 (Peretz D et al 2001 Nature [Lond] 412:739) and the anti-DNA antibody OCD4 as well the gene 5 protein (Zou W-Q et al 2004 Proc Natl Acad Sci USA 101:1380), both DNA-binding proteins, discriminate between the PrP^C and PrP^{Sc} and may help in the diagnosis of prion diseases or perhaps cure. Early diagnosis of prions (CJD) is possible because two peptides of PrP^C bind 3800 fold more effectively to PrP^{Sc} than to PrP^C (Lau AL et al 2007 Proc Natl Acad Sci USA 104:1151). The Tyr-Tyr-Arg monoclonal antibodies discriminate between PrP^C and PrP^{Sc} and hold promise that immunoprophylaxis and/or immunotherapy may eventually

become available (Paramithiotis E et al 2003 Nat Med 9:893). Conformation-dependent immunoassay (CDI) can discriminate among different prion strains. This assay quantifies PrP isoforms by simultaneously following antibody binding to the denatured and native prion protein. When the denatured/native PrP is graphed as the function of PrP^{Sc} concentration, each strain occupies a different position indicating a unique conformation (Safar J et al 1998 Nature Med 4:1157). The CDI test is extremely reliable (Safar JG et al 2005 Proc Natl Acad Sci USA 102:3501).

It has been hypothesized—on the basis of experimental observations—that the toxicity of this protein is based on increased oxidative stress. The inactivation of the *PrP* gene in mice does not lead to an immediate deleterious condition, but by the age of 70 weeks, an extensive loss of the Purkinje cells (large neurons in the cerebellar cortex) takes place and the animals have problems with movement coordination (ataxia). In case the normal PrP protein accumulates in the cytosol, a self-perpetuating PrP^{Sc}-like transformation takes place and neurodegeneration results (Ma J et al 2002 Science 298:1781). The disrupted *PrP* genes make them resistant to prions. Susceptibility in mice is affected also by QTLs in chromosomes 4, 6, 8, and 17 (Moreno CR et al 2003 Genetics 165:2085). On the basis of some genetic tests, it was concluded that the period of incubation of the mouse scrapie is controlled by allelic forms of a separate gene (*Sinc/Prni*). Molecular evidence indicates, however, that codons 108 and/or 109 of the *Prp* gene control incubation. In the mouse, there is a second *PrP* locus 16 kb down-stream. This *Prnd* (d for Doppelgänger [alterego in German], downstream prion protein-like) is truncated at the amino end domain and encodes only 179 amino acids.

Although its amino acid sequence shows only 25% homology with PrP, the structure of Prnd is quite similar. Prnd originated probably as an ancient duplication. Mice homozygous knockouts for Prnd and PrC are sterile. Its expression is normally limited to the testes, but if it is expressed in the brain, it causes neurodegeneration.

In case the *PrP* (*Prnp*) exons are deleted, Doppelgänger exons can be spliced into the PrP mRNAs. In ataxic animals, this intergenic splicing is highly expressed. Apparently, the manifestation of ataxia, the loss of Purkinje cells, and the degeneration of cerebellar granule cells is correlated with the alteration of a ligand-binding site.

A mutant form of PrP, ^{C_{tm}}PrP, a trans-membrane protein, can also cause prion disease in the absence or presence of PrP^{Sc}. The latter may also modulate the synthesis of the transmembrane form. Actually “the ability of polypeptide chains to form amyloid structures is not restricted to the relatively small

number of proteins associated with recognized clinical disorders, and it now seems to be a generic feature of polypeptide chains” (Dobson CM 2003 Nature [Lond] 426:884). PrP^{Sc} molecules could be formed *de novo* from defined components in the absence of preexisting prions. PrP^{Sc} can be formed from a minimal set of components including native PrP^C molecules, co-purified lipid molecules, and a synthetic polyanion. Inoculation of samples containing either prion-seeded or spontaneously generated PrP^{Sc} molecules into hamsters caused scrapie, which was transmissible on second passage (Deleault NR et al 2007 Proc Natl Acad Sci USA 104:9741).

PrP^C may be involved in signal transduction in nerve function. PrP^{Sc} apparently binds plasminogen that selectively imparts neurotoxicity to the prion protein.

In budding yeast, two non-nuclear elements [*URE3*] and [*PSI*] appear (among others) to be the infectious prion forms of the Ure2p protein that is also a regulator of nitrogen catabolism. When Urep was overexpressed in wild type strains, the frequency of occurrence of the [*URE3*] increased 20–200 fold. If the overexpression of Urep was limited only to the amino ends of this protein, the frequency of occurrence of [*URE3*] increased 6000 times. The carboxyl domain of Urep seemed to carry out nitrogen catabolism whereas the amino end induced the prion formation. Both [*URE3*] and [*PSI*] are the prion causing forms of nuclear genes *URE2* and *SUP35*, respectively. The *URE2* gene is involved in the control of utilization of ureidosuccinate as a nitrogen source, while the *SUP35* nuclear gene encodes a subunit (eRF3, eukaryotic release factor) of the yeast translation termination complex. Mutations in both the nuclear genes involve derepression of nitrogen catabolism that is normally repressed by nitrogen. The propagation of [*URE3*] and [*PSI*] depends on *URE2* and *SUP35* nuclear genes, respectively. Guanidine-HCl blocks the propagation of *PSI*⁺. Gdn-HCl-induced loss of the [*PSI*⁺] prion is due to a failure to segregate propagons from daughter cells and not because of degradation of the preexisting propagons (Byrne LJ et al 2007 Proc Natl Acad Sci USA 104:11688). In vitro, the Sup35 protein may show prion-like properties. Normally, translation terminates at a stop codon by an interaction between Sup35 and other proteins such as Sup45. If the Sup35 proteins aggregate, they may assume prion conformation and the translation continues beyond the stop codon and an additional protein sequence is formed (►eRF). The conformation of the SUP35 prion motif varies among different fungal species and is important for its transmissibility. The amyloid fiber morphology and size may vary in different yeast prion strains (Diaz-Avalos R et al 2005 Proc Natl Acad Sci USA 102:10165). A certain conformation of SUP35 of *Saccharomyces cerevisiae* permits transmission to

Candida albicans and such *Candida* can then infect *Saccharomyces*. Thus strain conformation is critical for cross-species transmission (Tanaka M et al 2005 Cell 121:49; Tanaka M et al 2006 Nature [Lond] 442:585). A similar conclusion has been reached in mammals where a single or two residues determine critical requirement for amyloid transmission, yet preformed fibrils may overcome sequence-based structural preferences. For transmission, the amyloid protein conformation is the critical factor (Jones EM, Surewicz WK 2005 Cell 121:63). The cross- β spine structure explains the critical features of stability and self-perpetuation of the amyloid fibers (►cross- β spine). Heat shock protein Hsp104 catalyzes the formation and also the destruction of this yeast prion (Shorter J, Lindquist SW 2004 Science 304:1793). Deletion of Hsp104 eliminates Sup35 and Ure2 prions, whereas overexpression of Hsp104 purges cells of Sup35 prions, but not Ure2 prions. For both Sup35 and Ure2, Hsp104 catalyzes de novo prion nucleation from soluble, native proteins. Hsp104 fragments both prions to generate new prion-assembly surfaces. For Sup35, however, the fragmentation endpoint is an ensemble of noninfectious, amyloid-like aggregates and soluble proteins that cannot replicate conformation (Shorter J, Lindquist S 2006 Mol Cell 23:425). Five glutamine/asparagine-rich oligopeptide repeats at the N-terminus of Sup35 stabilize the aggregated form, and for replication, a chaperone-dependent element is also required (Osherovich LZ et al 2004 PLoS Biol 2(4): E86). In a somewhat different amyloid disease associated with transthyretin, only the highly destabilized molecules are degraded in the endoplasmic reticulum and only in certain tissues, indicating that endoplasmic reticulum-assisted folding depends on energetics, chaperone distribution, and metabolites (Sekijima Y et al 2005 Cell 121:78).

The human PrP repeat (PHGGGWGQ) can substitute for the yeast peptides (Parham SN et al 2001 EMBO J 20:111). This feature of prions allows the development of diversity and may have evolutionary significance. Structurally, neither [URE3] nor [PSI] are similar to the mammalian PrP protein, indicating that there is more than one way for prions to arise. In the fungus *Podospora anserina*, the heterokaryosis incompatibility locus (*Het*) also makes prion-like proteins. The infectious forms of the normal Prp are also called PrP*, and the PrP^{Sc} is designated also PrP^{res} (protease-resistant prion). PrP^C and PrP^{Sc} appear to be conformational isomers. PrP* is the misfolded pathological core form. The yeast prion [PSI⁺] can be reversibly removed, “cured” to [psi⁻] 100% in seven to eight generations when exposed to guanine hydrochloride or methanol. Guanidin inactivates Hsp104 and Sup35 depolymerizes without a need for cell division (Wu Y-X et al 2005 Proc Natl

Acad Sci USA 102:12789). The denaturants induce the expression of chaperones, giving further support to the notion that the prion functions are based on conformational changes. Recent evidence indicates that the PrP^C→PrP^{Sc} transition may involve the chemical thiol/disulphide exchange between the terminal thiolate of PrP^{Sc} and the disulfide bond of a PrP^C monomer and not only a conformational change (Welker E et al 2001 Proc Natl Acad Sci USA 98:4434). The protein chaperones HSP104, and to a lesser extent, HSP70, can affect the expression and transmission of [PSI⁺] and its conversion to [psi⁻]. In silico screening for compounds that fitted into a “pocket” created by residues undergoing the conformational rearrangements between the native and the sparsely populated high-energy states (PrP*) and that directly bind to those residues identified 2-pyrrolidin-1-yl-N-[4-[4-(2-pyrrolidin-1-yl-acetylamino)-benzyl]-phenyl]-acetamide (GN8), which efficiently reduced PrP^{Sc} and improved the survival of affected mice (Kuwata K et al 2007 Proc Natl Acad Sci USA 104:11921).

When the *URE2* and *SUP35* genes or the N-terminal domain of their products are deleted, the [URE3] and [PSI⁺] elements permanently disappear. These yeast proteins are different from each other and from the prion proteins of higher eukaryotes, except the N-terminal region where homology exists. The NH₂ domain of SUP35, when fused to the rat glucocorticoid receptor protein, can interact with the endogenous Sup35 protein and it undergoes a prion-like change of state. Self-replication requires a conformational conversion of initially unstructured Sup35 protein. Thus, the prion-like behavior is transmissible to another protein (Derkatch IL et al 2001 Cell 106:171). More recently, additional yeast proteins (RNQ1, NEW1) with prion-like properties have been identified (Tuite MF 2000 Cell 100:289; Derkatch IL 2000 EMBO J 19:1942). The *het-s* gene product of *Podospora anserina*, responsible for spore killer properties, also meets the criteria of being a prion (Perkins DD 2003 Proc Natl Acad Sci USA 100:6292). The so-called C hereditary units in *Podospora* have a nature similar to prions; they contain the MAPK cascade and trigger cell degeneration (Kicka S et al 2006 Proc Natl Acad Sci USA 103:13445).

The vCJD (variant of Creutzfeldt-Jakob disease) prions appear to have either single amino acid differences or differences in glycosylation which may also be the cause or consequence of conformational differences. The differences in electrophoretic mobility of the protease-digested prions are expected to shed light upon the problems of tracing the transmission of prions from cattle to man or among different animal species. The PrP gene in humans is in chromosome 20p12, and encodes 253 amino acids by a single exon.

The corresponding mouse gene is in chromosome 2. Other mammalian genes display very substantial homologies, although they may be transcribed by up to three exons. The NH²-end of the protein displays an 8 amino acid repeat consensus (PHGGGW) in five to six copies, depending on the species. Deletions in these repeats do not involve disease symptoms. Short conserved amino acids downstream of the last repeats are important for PrP^C→PrP^{Sc} conversion. Another unique feature of PrP is an alanine-rich tract (AGAAAAGA). The transmission of prions among different species prolongs the incubation period. Mice lacking the gene for PrP^C cannot develop the disease even when inoculated (Büeler H et al 1993 Cell 73:1339). The PrP^C deficient mouse appears normal. Knocking out PrP^C from larger mammals would be an approach to avoid prion formation but because of technical difficulties, the use of shRNA is a viable alternative to block PrP expression and prevent encephalitis. Transgenic goats and cows produced by nuclear transplantation of the cognate shRNA gene resulted in more than 90% reduction in PrP expression (Golding MC et al 2006 Proc Natl Acad Sci USA 103:5285). The most infectious property was attributed to 300–600 kDa particles (14–28 PrP molecules) and less than five molecules, as well as very large aggregates, were much less effective in evoking neurodegenerative disease (Silveira JR et al 2005 Nature [Lond] 437:257). Also, immunodeficient mice, despite the fact that they may accumulate plaques upon scrapie infection, fail to develop the disease. It appears that human individuals who might have been exposed to the same BSE source may not all respond with the development of the disease.

PrP^C→PrP^{Sc} conversion by infection with a prion from another species (heterotypic conversion), especially when the inoculum is small or the inoculation occurs rarely, is less likely. The amino acid sequence in the 125–231 sequence displays differences among cow, sheep, dog, cat, pig, mouse, Syrian hamster, and human PrP^Cs and the structure varies as well (Lysek DA et al 2005 Proc Natl Acad Sci USA 102:640). Similarly, structural differences exist in elk compared to cow PrP^C (Gross AD et al 2005 Proc Natl Acad Sci USA 102:646). The chicken, turtle, and *Xenopus* PrP^Cs display only about 30% identity with the mammalian protein amino acid sequence, yet the molecular architectures are similar (Calzolari L et al 2005 Proc Natl Acad Sci USA 102:651).

Wild type mice brain infected with hamster prions did not develop scrapie, although a low level of maintenance of the hamster protein was detectable and reintroduced into hamsters; encephalitis followed. When the human prion is transferred to an animal, the PrP sequences in the new host are determined by the recipient and not by the donor, except when the animal

is transgenic for the human PrP. Thus, the prion inoculum acts as a catalyst or as a chaperone. It is known that in Prp-deficient mice the immune system eliminates the PrP^C. It is also conceivable that in mice the hamster PrP^{Sc} is immunologically tolerated. The presence of the PrP gene is a requisite for the development of the PrP^{Sc} protein. PrP^{Sc} exists in multimeric rather than monomeric forms but PrP may become part of the interacting PrP^{Sc} molecular network. There are indications that prion and DNA interaction may modulate the harmful aggregation of the protein (Cordeiro Y et al 2001 J Biol Chem 276:49400). Hamster-adapted prion protein heated up to 600°C for 5 to 15 min (actually ashed) still retained some infectivity and points to the role of an inorganic template in the replication of scrapie. Heating to 1000°C abolished all activity. In case of relatedness between these two proteins, PrP^{Sc} may easily facilitate the conversion to prion. The expression of the PrP^{Sc} may require chaperones. One such protein was named X but its role is unclear. In vitro assay is available for fast and relatively inexpensive assaying of prions using mouse neuroblastoma cell line N2a (Klöhn P-C et al 2003 Proc Natl Acad Sci USA 100:11666).

According to some views, the “protein only” mechanism requires further proof, although all current evidence indicates a “protein only” basis. There is definite proof that the prions of yeast can be caused by the amino-terminal fragment of the Sup-35 protein without the help of any other substance (King C-Y, Diaz-Avalos R 2004 Nature [Lond] 428:319; Tanaka M et al 2004 *ibid.* 323). Additional recent evidence further supports this protein-only principle. A synthetic peptide (free of nucleic acids), containing mutation at site 102 leucine (see Fig. P130) folded into a β -conformation-rich form, was introduced into mice; and animals developed disease homologous to the Gerstmann-Sträussler syndrome in humans (Tremblay et al 2004 J Virol 78:2088). Furthermore, the peptide-induced disease was serially passed into healthy mice, which developed symptoms indistinguishable from those appearing spontaneously in PrP^{Sc} leucine mutants. Similarly, recombinant protein consisting of the mouse prion sequence 89–231, rich in β -sheets, was cloned in *Escherichia coli* and then introduced into the brain of animals that over-expressed the normal PrP^C. Mice developed neuropathological symptoms characteristic of specific encephalopathy, and their protease-resistant extract evoked disease symptoms in other animals. There were two essential differences from the normal infection. The responding recipients produced excessive amounts of PrP^C before inoculation, and the period of incubation was substantially extended compared with the normal course of disease development (Legname et al 2004 Science 305:673).

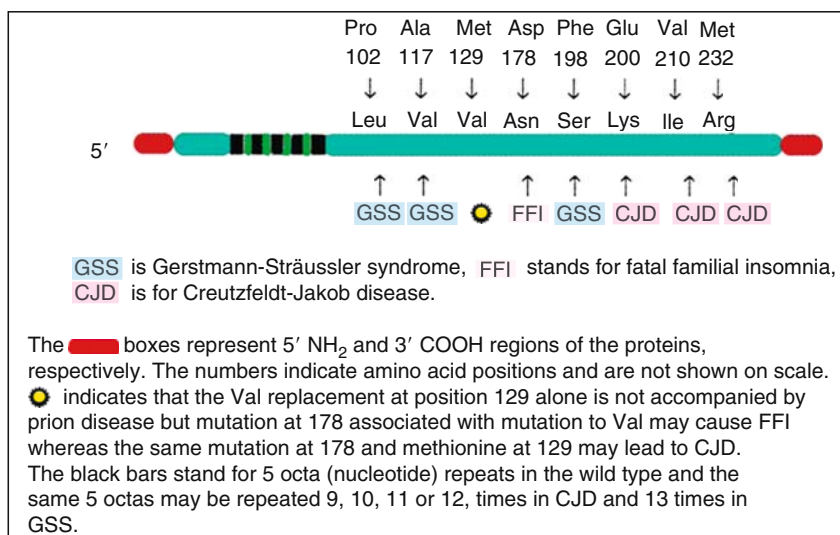

Figure P130. Prion mutations (Redrawn after Weissmann, C. 1999. J. Biol. Chem. 274:3.)

Cyclic amplification of protein misfolding (PMCA) in vitro produced protein identical to the protease resistant form in the brain of sick animals. Furthermore, this in vitro produced prion when introduced into healthy hamster caused the same type of disease as infection by PrP^{Sc} (Castilla J et al 2005 Cell 121:195). PMCA amplification technology can be automated and in 140 cycles leads to a 6600-fold increase in sensitivity compared to older techniques. Two successive rounds of PMCA increase the sensitivity of detection 10-million fold and can detect as few as 8000 molecules of PrP^{Sc} at 100% specificity (Castilla J et al 2005 Nature Med 11:982) and permit the detection of prions in the blood before the disease symptoms manifest (Saá P et al 2006 Science 313:92).

The existence of prions seems to be an exception to the “nucleic doctrine.” Some evidence seemingly contradicts the infectious nature of the prions and points to accumulation of protein waste. The prion diseases may be familial, with an onset at about 50 years of age in humans. The sporadic forms are attributed to dominant somatic mutations. From cultured scrapie-infected mouse (but not of hamster) neuroblastoma cells, the branched polyamines (polyamidoamide dendrimers, polypropyleneimine, polyethyleneimine) purged PrP^{Sc} prions at non-toxic concentrations. Bis-acridines and a few other compounds appear inhibitory to prion replication in cell cultures (May BCH et al 2003 Proc Natl Acad Sci USA 100:3416). Kastellopaolitrine, phenanthridines, 6-aminophenanthridine, quinacrine, and chlorpromazine appear effective in yeast against mammalian prions (see Fig. P131) (Bach S et al 2003 Nat

Biotechnol 21:1075). By 2003, no real cure or preventive measures had emerged for prion diseases. There are some positive cues that proline-rich oligopeptides may restore the conformation of PrP^{Sc} to normal PrP. Preliminary results indicate that the lymphotoxin-β receptor may delay the onset of the symptoms temporarily in mice.

Figure P131. Kastellopaolitrine 1 (left) is one of the other similar compounds, which have different substitutions at other positions at the right ring. Phenanthridine (right) basic structure

It seems that the complement component C3 is important for the prions to attach to the follicular dendritic cells, which mediate infection. Antibodies generated against the μ chain of PrP are a promising approach for the prevention of pathogenesis. ▶Creutzfeldt-Jakob disease, ▶Gerstmann-Sträussler disease, ▶presenilin, ▶kuru, ▶encephalopathies, ▶fatal familial insomnia, ▶protein structure, ▶Protein X, ▶tau, ▶curing plasmids, ▶plasmin, ▶chaperones, ▶PSI⁺, ▶PIN⁺, ▶quinacrine mustard, ▶Cre/loxP, ▶virino hypothesis, ▶conformation-dependent immunoassay, ▶transthyretin, ▶PMCA,

Prior Distribution: A probability distribution of variables or parameters before empirical information was obtained. Generally, it is part of Bayesian inference. ►Bayes' theorem, ►posterior distribution

Prior Probability: The suspected incidence of a disease before a diagnostic test or change of environmental effects or other extrinsic factors before the onset of a condition are identified.

Prisoner's Dilemma: A game theory, applicable to the interpretation of pairwise competition between two types of organisms using conflicting strategies. The two may cooperate, or either may "defect" for selfish reasons(s) and exploit the other and consequently the fitness may decrease to $1 - s_1$. In case both of them defect (are uncooperative), the population has to pay a cost (c), and the fitness becomes $1 - c$. In case the defector gains a fitness advantage ($1 + s_2$), it may invade the cooperators territory. If c is high ($[1 - c] < [1 - s_1]$), a stable polymorphism may result. This theory is applicable also to studies on economic activities and to other fields. ►snowdrift game, ►cooperation, ►tragedy of the common; Page KM, Nowak MA 2001 J Theor Biol 209:173; Neill 2001 J Theor Biol 211(2):159; Doebeli M et al 2004 Science 306:859; Imhof LA et al 2005 Proc Natl Acad Sci USA 102:10797.

Pristionchus pacificus: The *Pristionchus pacificus* nematode is somewhat similar to *Caenorhabditis elegans* <http://www.pristionchus.org>. ►Caenorhabditis

Privacy Rule: An individual's privacy is legally protected against unwanted disclosures, yet medical research has a legitimate need to use, access, and disclose protected health information with certain limitations. ►GWA; <http://privacyrulesandresearch.nih.gov>; http://privacyruleandresearch.nih.gov/pr_02.

asp; European guidelines for human data: http://ec.europa.eu/justice_home/fsj/privacy/docs/wpdocs/2007/wp136_en.pdf; recommended confidentiality certificate of the US National Institutes of Health: <http://grants.nih.gov/grants/policy/coc>; human molecular genetic data: Lowrance WW, Collins FS 2007 Science 317:600.

Private Blood Groups: A collective name of various blood groups with low frequencies compared to *public blood* group systems that occur frequently.

Private Mutation: Private mutation occurs very rarely in a very limited number of families.

Privilege: ►immune privilege

PRL: ►prolactin

PRL-3 (PTP4A3, 8q24.3): A 22 kDa tyrosine protein phosphatase situated at the cytoplasmic membrane; its elevated expression is associated with metastasis of colorectal cancer. ►colorectal cancer, ►metastasis; Saha S et al 2001 Science 294:1343.

PRM (pattern recognition proteins): PRMs are involved in the regulation of transcription.

PRMT: Protein-arginine methyltransferase. (See Boisvert FM et al 2003 Mol Cell Proteomics 2:1319).

P_{RNP}: The human gene encoding the normal isoform of the prion protein; the same in mouse is P_{rnp}.

Proaccelerin: A labile blood factor (V); its deficiency may lead to parahemophilia and excessive bleeding during menstruation or after surgery or bruising. ►antihemophilic factors

Probabilistic Graphical Models of Cellular Networks: In biological modeling we may be interested in different attributes, e.g., in the random expression of the genes observed and the hidden attributes of the model, such as the cluster assignment of a gene. The model includes the joint probability distribution of all relevant random attributes. The probabilistic graphical model represents multivariate joint probability distributions by a product of terms, each involving only a few variables. In Bayesian Networks, the joint distribution is represented as a product of conditional probabilities of the genotype of each individual, given the genotypes of its two parents. In pedigree analysis, the joint distribution of genotypes is the product of conditional probabilities. In phylogenetic models, the probability, over all evolutionary sequences, is the product of the conditional probability of each sequence, given its latest ancestral sequence in the phylogeny. Another classes of models are Markov Networks representing joint distribution as product of potentials. Cellular networks are based upon gene expression data observed on thousands of genes over a large number of microarrays. Then *GeneCluster_g* denotes the cluster assignment of gene g and

ArrayCluster_a denotes the cluster assignment of array *a*. Co-expression of genes is assumed to be due to co-regulation. The regulation is mediated by the transcription factors attached to specific sequences of the promoter during transcription, and to interaction of protein products of the gene clusters. The interaction of the proteins may be dependent on modifications. The regulatory networks can be partitioned to expression modules rather than to the study of individual genes. Because of the large number of factors involved, appropriate statistics are necessary to evaluate the reality of the observations and the evaluations. Validation of the models against all biochemical information available is highly desirable. New experimental procedures, high-throughput systems, and bioinformatics are under continuous development. This field is impossible to summarize adequately in the frame of this work. A good overview of the status of the field in 2004 is provided by Nir Friedman in Science 303:799. ▶joint probability, ▶multivariate analysis, ▶Bayes' theorem, ▶Markov chain statistics, ▶microarray hybridization, ▶networks, ▶genetic networks, ▶model, ▶small-world networks

Probability: The statistical measure of chance on a scale between 0 to 1, inclusive. 0 means the lack of chance for an event to occur, 1 indicates a certainty that it will occur, and any value expressed as a decimal or fraction indicate the intermediate chances. The probability function indicates the value of a frequency predicted from the observations related to the parameter. The *simple probability* reveals the chance of a single event; the *compound probability* is the chance of multiple events. When two events are independent, their *joint probability* is the product of their independent probabilities. *Alternate probability* exists in case of sex in dioecious species, when an individual is either female or male; no intermediates are considered. One must keep in mind that probability does not absolutely prove or disprove a point; it simply indicates the chance of its occurrence. ▶binomial probability, ▶conditional probability, ▶likelihood, ▶maximum likelihood

Proband: Person(s) through which a family study of the inheritance of a human trait is initiated (also called propositus if male, or proposita if female). Determining the pattern of inheritance on the basis of families chosen by probands may display an excess of affected individuals relative to Mendelian expectations because of the bias in sampling of the population. ▶ascertainment test, ▶pedigree analysis

Probasin: A secreted and nuclear protein abundant in the prostate epithelium. Its expression is regulated by androgens (two receptors at 5' of the 17.5 kb gene) and zinc. Its promoter is extensively used with

various modifications for the study of prostate function/cancer. ▶androgen, ▶prostate cancer; Logg CR et al 2002 J Virol 76:12783.

Probe: A labeled nucleic acid fragment used for identifying or locating another segment by hybridization. Similarly, immunoprobes using primarily monoclonal antibodies or enzyme probes or enzymes linked to antibodies can also be employed (see Fig. P132). The probe binds a reporter protein and another binding protein (binding p). For enzymatic detection of a probe, most commonly alkaline phosphatase or horseradish peroxidase are used. The tissue is incubated with the appropriate substrate of the enzyme and the colored precipitate formed through its action identifies its location. ▶synthetic DNA probes, ▶heterologous probe, ▶recombinational probe, ▶immunoprobe, ▶labeling, ▶nick translation, ▶padlock probe, ▶histochemistry

Figure P132. Protein-mediated detection of probe

Probe (primer oligo base extension, PO-BE): A diagnostic procedure for the identification of localized variation in DNA. It is a primer extension procedure using a polymerase, three different deoxyribonucleotide triphosphates, and a dideoxynucleotide triphosphate (ddNTP). The primer is extended until the variable SNP site is reached where the ddNTP is incorporated. The synthetic product is then analyzed by matrix-assisted laser desorption time of flight mass spectrometry. ▶primer extension, ▶MALDI-TOF, ▶SNIP, ▶dideoxyribonucleotide; Braun A et al 1997 Clin Chem 43:1151.

Probe Arrays: Oligonucleotides immobilized on silicon wafers in order to study simultaneously the functions of many genes. ▶DNA chips, ▶microarray

ProbeMaker: A computer program that converts DNA sequence files in FASTA format to digital restriction maps used for MapSearch Probes.

Probiotics: Beneficial bacteria in the body.

Probit: A cumulative normal frequency distribution is represented by an S curve. A cumulative curve can become a straight line by *probit transformation*. We

may represent the probability scale in units of standard deviations. Thus the 50% point is the 0 standard deviation, the 84.13 unit becomes +1, and the 2.27 point the -2 standard deviations. The cumulative percentages are also called *normal equivalent deviates* (NED). If the ordinates are in NED units and we plot the cumulative normal curve, a straight line results. Probits are thus the NEDs with 5.0 added and thus we do not get negative values for the majority of deviates. The probit value of 5.0 indicates a cumulative frequency of 50% and a probit value of 6.0 means a cumulative frequency of 84.13% whereas probit 3.0 indicates a cumulative frequency of 2.27%. Probit value tables are available (Fisher RA, Yates F 1963 Statistical Tables. Hafner, New York). Probit transformations are frequently used for dosage mortality responses to chemicals indicating the regression of cumulative mortalities on dosage. The graphs can be plotted on probit papers with abscissa on logarithmic scale. ▶normal distribution, ▶logit

Proboscis: Tubular snout (nose-like emergence) on the head such as the feeding apparatus of *Drosophila*, elephant trunk, snout of tapirs, shrews, etc. ▶morphogenesis in *Drosophila*

Procaine Anesthetics: Benzoic acid derivatives with local numbing of nerves or nerve receptors.

Procambium: The primary meristem that gives rise to the cambium and the primary vascular tissue of plants. ▶cambium, ▶meristem, ▶root

Procapsid: The empty capsid precursor of phage into which the DNA can be packaged. ▶development, ▶phage

Procarcinogen: A procarcinogen requires chemical modification to become carcinogenic. ▶carcinogen, ▶phorbol esters, ▶activation of mutagens

Procaryote: ▶prokaryote

Procentriole: An immature centriole that upon maturing becomes the anchoring site of the spindle fibers, cilia, and flagella. ▶centriole, ▶centromere, ▶spindle fibers

Process, Genetic: Gene product(s) mediated changes to reach a certain goal in the cell.

Processed Genes: Processed genes are obtained by reverse transcriptase from mRNA and therefore are free of all elements (e.g., introns) removed during processing of the primary transcript. They are widely expressed, highly conserved, and short and low in GC. ▶cDNA, ▶intron, ▶primary transcript

Processed Pseudogene (retropseudogene): A processed pseudogene is similar to mRNA, lacks introns, and

may have a polyA tail, yet it is non-functional. The faulty reverse transcription of mRNA may have produced processed pseudogenes. Pseudogenes are widely expressed, generally short, highly conserved, and low in GCs. Many of the processed pseudogenes lack promoters and cannot be transcribed. About half of the human pseudogenes are the processed type. Some of processed pseudogenes are actually retro-elements. Processed pseudogenes can be mapped in the genome and provide information on ancestral transcripts (Shemesh R et al 2006 Proc Natl Acad Sci USA 103:1364). ▶reverse transcriptases, ▶cDNA, ▶processed genes, ▶pseudogene, ▶LINE; Gonçalves I et al 2000 Genome Res 10:672; <http://pbil.univ-lyon1.fr/>.

Processing: The trimming and modifying of the primary transcripts of the DNA into functional RNAs or cutting and modifying polypeptide chains prior to becoming enzymes or structural proteins. ▶primary transcripts, ▶protein synthesis, ▶postranslational modification

Processing Body: ▶P body

Processivity: Processivity defines the number of nucleotides added to the nascent DNA chain before the polymerase is dissociated from the template. The processivity for *E. coli* DNA polymerase I, II, and III is 3–200, >10,000, >500,000, respectively. ▶error in aminoacylation, ▶clamp-loader, ▶DNA polymerases, ▶polymerase switching, ▶replication fork

Processor: Data-processing hardware or a computer program (software) that compiles, assembles, and translates information in a specific programming language.

Prochiral Molecule: An enzyme substrate that after attaching to the active site undergoes a structural modification and becomes chiral. ▶chirality, ▶active site

Prochloron: ▶evolution of organelles

Pro-Chromatin: A state of the chromatin that is conducive to transcription.

Prochromosome: Heterochromatic blocks detected during interphase. In this interphase nucleus of *Arabidopsis*, the centromeric heterochromatin was stained by fluorescent isothiocyanate and displayed yellow-green color (see Fig. P133). Courtesy of Drs. Maluszinszka J, Heslop-Harrison JH. ▶heterochromatin, ▶Barr body, ▶mitosis

Figure P133. Prochromosomes

Procollagen: Precursor of collagen. ▶collagen

Proconsul: A fossil ape that lived about 23–17 million years ago.

Proconvertin: Antihemophilic factor VII, and the deficiency of which may lead to excessive bleeding and hypoproconvertinemia. ▶hypoproconvertinemia, ▶antihemophilic factors

Proctodeum: An invagination of the embryonal ectoderm where the anus is formed later.

Procyclic: The stage at which *Trypanosoma* is in the gut of the intermediate host (tse-tse fly) and at is not infectious to higher animals. ▶metacyclic *Trypanosoma*, ▶*Trypanosoma*

Prodroma (prodrome): Ominous sign(s) of a looming disease before the actual onset.

P

Prodrug: A prodrug is processable to a biologically active compound. ▶suicide vector, ▶activation of mutagens, ▶ADEPT

Producer Cell: An infected cell continuously produces recombinant retrovirus.

Product-Limit Estimator: The product-limit estimator is based on a number of conditional probabilities, e.g., the probability of survival after surviving for one day, then for the next day, and so on. Where $\hat{S}(t)$ the survival function at subsequent times, r_j = the number of individuals at risk at time $t_{(j)}$, d_j = the number of individuals involved in the event at risk time $t_{(j)}$.

$$\hat{S}(t) = \prod_{j|t_{(j)} \leq t} \left(1 - \frac{d_j}{r_j}\right)$$

Product-Moment Correlation (Pearson's product-moment correlation coefficient): The correlation coefficient of a sample that is used as an estimator for the correlation coefficient of the population:

$$r_{XY} = \frac{\sum_i (X_i - M_X)(Y_i - M_Y)}{N s_X s_Y}, \quad s_X = \sqrt{\frac{\sum_i (X_i - M_X)^2}{N}},$$

$$s_Y = \sqrt{\frac{\sum_i (Y_i - M_Y)^2}{N}}$$

Where the N pairs of values (X_i , Y_i) represent the size of the sample and s_X and s_Y are the standard deviation of the respective variables as shown above.

▶correlation

Product Ratio Method: ▶F₂ linkage estimation

Product Rule: ▶joint probability

Productive Infection: In productive infection, the virus is not inserted into the eukaryotic chromosome and can propagate independently from the host DNA and can destroy the cell while releasing progeny particles.

▶lysis

Proembryo: The minimally differentiated fertilized egg.

Profile: A nucleotide or amino acid sequence probability motif. ▶motif

Profilin: Profilin mediates actin polymerization. ▶actin, ▶Bni1, ▶cytoskeleton, ▶formin; Carlsson L et al 1977 J Mol Biol 115:465.

Proflavin: An acridine dye, capable of inducing frameshift mutations. ▶acridine dye, ▶frameshift mutation; Brenner S et al 1958 Nature [Lond] 182:933.

Progenitor: An ancestor or an ancestral cell of a lineage. Progenitor cells—unlike stem cells—may lose their ability of self-renewal yet they retain their mitotic ability and may generate one or different types of differentiated cells. ▶stem cells, ▶cancer stem cell; Reya T et al 2001 Nature [Lond] 414:105; Weissman IL et al 2001 Annu Rev Cell Dev Biol 17:387.

Progenote: The evolutionarily common, primitive ancestor of the eukaryotic cytoplasm and the bacterial cell (Woese CR, Fox GE 1977 J Mol Evol 10:1).

Progeny Test: A procedure for determining the pattern of inheritance. ▶Mendelian segregation, ▶Mendelian laws

Progeria (premature aging): ▶aging, ▶Hutchinson–Gilford syndrome

Progeroid Syndromes: ▶aging

Progesterone: ▶animal hormones, ▶steroid hormones, ▶testosterone, ▶estradiol, ▶progesterin (see Fig. P134), formula

Figure P134. Progesterone (progestin)

Progesterone Receptors (PR): PRs are assembled with the cooperation of at least eight chaperones, including Hsp40, Hsp70, Hsp90, Hip, p60, p23, FKBP, and cyclophilins. PRs are transcriptional regulators of progesterone-responsive genes. named proteins under separate entries; Hernández P et al 2002 J Biol Chem 277:11873.

Progestin: A steroid hormone, used as medication for the prevention of repeated spontaneous abortion. When added to estrogen, it reduces the risk of endometrial cancer. ►[progesterone](#)

Prognosis: The prediction of the course or outcome of a process, e.g., disease, cancer, etc.

Program: A set(s) of instructions in computer language (software) that permits the user to carry out specified tasks. In biology, program refers to the development proceeds according to a genetically determined pattern, realized by environmental effects.

Programmed Cell Death: ►[apoptosis](#)

Programming, Dyanamic: In dynamic programming, large groups of data are broken down to subsets to facilitate programming of the complex. ►[genetic networks](#)

Progression: A process involved in oncogenic transformation; after the initial mutation of a proto-oncogene progression changes it into an active oncogene. ►[cancer](#), ►[phorbol esters](#)

Prohibitin: A 30 kDa tumor-suppressor protein localized mainly in the mitochondria, although it is encoded at human chromosome 17q21. The well-conserved protein is present in other mammals, *Drosophila*, the plant *Arabidopsis*, and several microbes (*Pneumocystis carinii*, the cyanobacterium *Synechocystis*).

Projectin: A myosin-activated protein kinase. ►[myosin](#)

Projection Formula: Modeling configurations of groups around chiral centers of molecules. ►[chirality](#)

Prokaryon: Same as prokaryote.

Prokaryote: An organism without membrane-enveloped (cell nucleus) genetic material (such as the case in bacteria). The majority of prokaryotic bacteria have circular double-stranded DNA chromosomes. However, *Borrelia*, *Streptomyces*, and *Agrobacterium tumefaciens* have a linear chromosome. The GC content varies between ~72% to ~27%. The genome size of prokaryotes varies 20-fold. The majority of bacteria carry their genes in the leading strand of the DNA. The pathogenic strain may have reduced genome size and/or increased number of pseudogenes. (<http://www.cbs.dtu.dk/databases/DOGS/>). ►[cell comparisons](#), ►[GC skew](#), ►*Borrelia*, ►*Streptomyces*, ►*Agrobacterium tumefaciens*; Bentley SD, Parkhill J 2004 Annu Rev Genet 38:771; regulation: <http://regtransbase.lbl.gov>.

Prolactin (PRL): A 23 kDa mitogen, stimulating lactation and the development of the mammary glands. Prolactin receptors are present on human lymphocytes and prolactin may form complexes with IgG subclasses. A prolactin releasing peptide was identified in the hypothalamus. ►[lymphocytes](#), ►[immunoglobulins](#), ►[mitogen](#), ►[brain](#), ►[cathepsins](#); Mann PE, Bridges RS 2001 Progr Brain Res 133:251.

Prolamellar Body: The crystalline-like, lipid-rich structure in the immature plastids that upon illumination develops into the internal lamellae of the proplastids and into the thylakoids of the chloroplasts (see Fig. P135). ►[chloroplast](#)

Figure P135. Prolamellar body

Prolamine: ►[zein](#), ►[high lysine corn](#)

Proliferating Cell Nuclear Antigen: ►[PCNA](#)

Proliferation: The multiplication of cells or organisms. In cells, cytotoxic agents that may induce first cell death may cause proliferation and then regenerative growth, or it may be the result of the action of mitogens. ►[mitogen](#), ►[cancer](#)

Proline Biosynthesis: Proline biosynthesis proceeds from glutamate through enzymatic steps involving glutamate kinase, glutamate dehydrogenase, and finally Δ^1 -pyrroline-5-carboxylate, which is converted to proline by pyrroline carboxylate reductase (see

Fig. P136). In some proteins, e.g., collagen, prolyl-4-hydroxylase generates 4-hydroxyproline from proline. The latter enzyme is coded in human chromosomes 10q21.3-q23.1 (α -subunit) and 17q15 (β -subunit).
 ▶amino acid metabolism, ▶hyperprolinemia

Figure P136. Proline

Prolog: A database management and query system in physical mapping of DNA. (See <http://portal.acm.org/citation.cfm?id=711875&dl=ACM&coll=&CFID=15151515&CFTOKEN=6184618>).

Prolyl Isomerase: ▶PPI, ▶immunophilin

Promastigote: ▶*Trypanosoma*

Prometaphase: Early metaphase. ▶mitosis

Prominin: ▶CD133

Promiscuous DNA: Homologous nucleotide sequences occurring in the various cell organelles (nucleus, mitochondrion, plastid). They are assumed to owe their origin to ancestral insertions during evolution.
 ▶insertion elements; Ayliffe MA et al 1998 Mol Biol Evol 15:738; Lin Y, Waldman AS 2001 Nucleic Acids Res 29:3975.

Promiscuous Plasmids: ▶plasmids promiscuous

P

Promiscuous Protein: A promiscuous protein has affinity to more than one substrate. ▶conformational diversity; Copley SD 2003, Curr Opin Chem Biol 7:265.

Promitochondria: Organelles in anaerobically grown (yeast) cells that can differentiate into mitochondria in the presence of oxygen. ▶mitochondria

Promoter: The site of binding of the transcriptase enzyme (RNA polymerase), transcription factor complexes, and regulatory elements, including also the ribosome-binding untranslated sequences (see Fig. P137). Usually, the basal promoter is situated in front of the genes although pol III may rely on both upstream and downstream promoters.

The promoters of the 5S and tRNA genes are internal. Also, some *E. coli* genes have some weak promoters within open reading frames (Kawano M et al 2005 Nucleic Acids Res 33:6268). The arrangement of the promoter used by pol II is outlined.

The promoters used by RNA polymerase II may encompass several hundred nucleotides in yeast but in higher eukaryotes it may extend to several thousand bases. In yeast, UAS (upstream activating sequences) and URS (upstream repressing sequences) are regular binding sites. The transcription start site is usually within a stretch of 30 to 120 nucleotides downstream of the TATA box (see Fig. P138). The pol II enzyme frequently uses in mammals multiple promoters, within which there are multiple start sites, and alternative promoter usage generates diversity and complexity in the mammalian transcriptome and proteome (Sandelin A et al 2007 Nature Rev Genet 8:424). Some of the mammalian promoters are localized more than 100 kb upstream or located downstream, may be multiple, may overlap several genes, and are shared by other genes (Denoed F et al 2007 Genome Res 17:746).

At the ends of the genes, insulators (boundary elements) separate the genes or the used promoters from the others. The DNase hypersensitive site(s) (also called locus control region) may permit the attachment of sequence-specific transcriptional activators, making the gene competent for transcription. The competence may involve histone acetylation.

Among 1031 human protein-coding genes, the Pol II-like enzymes commonly (~32%) use a TATA box both in prokaryotes and eukaryotes. The TATA box ca. 25 bp upstream from the initiation point of transcription is usually surrounded by GC-rich tracts (97%). Near the transcription initiation site (−3 to +5), there may be an initiator (Inr, 85%) with an ~average type of sequence: (Pyrimidine)₂CA(Pyrimidine)₅. Many eukaryotic genes do not have Inr but the TATA box directs the initiation. CAAT box is also a frequent (64%) element in the promoter. Some large eukaryotic genes utilize more than one promoter and the transcripts may vary. Some housekeeping and RAS genes do not use the TATA box. DNA-dependent RNA polymerase I synthesizes ribosomal RNAs; it has a core sequence adjacent to the transcription initiation site and upstream regulator binding sites (UCE). Pol III promoters facilitating the transcription of tRNA usually have split

enhancer - PROMOTER - leader - exons - introns - termination signal - polyadenylation signal - downstream regulators

Transcription factor-binding sites, DNase hypersensitive site, TATA box, transcription start

Figure P137. Organization of the promoter and other genic elements

Figure P138. The promoter usually includes several regulatory boxes to which protein factors are recruited. (Modified after Guo, J. *et al.* 2001 J. Biol. Chem. 276:48871)

Figure P139. Arrows symbolize promoters; boxes represent structural genes

promoters with an A-box and a B-box about 40 bases apart, situated inside the transcription unit 20 and 60-bases downstream from the transcription initiation site. The pol III promoter of some U RNAs has, however, a TATA box 30–60 bases upstream from the transcription initiation site and further upstream a proximal sequence element (PSE) near the TATA box. Synthetic promoters can be constructed with increased activity. The Promoter Scan II program identifies pol II promoters in genomic sequences and is available through Internet: <http://www.cbs.umn.edu/software/software.html>.

Promoters (→) may be of different types and some genes may rely on multiple promoters (see Fig. P139): TFD, TRANSFAC, or IMD databases can use the Signal Scan to find transcription factor binding sites. A high-resolution analysis revealed 10,567 promoters corresponding to 6763 genes in the human genome. Almost half of all mammalian genes have evolutionarily conserved alternative promoters (Baek D *et al* 2007 Genome Res 17:145). About 11% of the human promoters are bidirectional/divergent, are more active in transcription than other promoters, and are involved with RNA polymerase II and the modified histones H3K4me2, H3K4me3, and H3ac (Lin JM *et al* 2007 Genome Res 17:818). This information resulted by mapping the preinitiation complexes labeled by the attached TATA box associated protein and analysis by microarray hybridization of immunoprecipitated complexes (Kim TH *et al* 2005 Nature [Lond] 436:876). Libraries of engineered promoters can provide a fruitful approach for quantitative study of gene expression (Alper H *et al* 2005 Proc Natl Acad Sci USA 102:12678). The promoter of the *lac* operon of *E. coli* is controlled by cis elements that integrate signals coming from the cAMP receptor and the Lac repressor (Mayo AE *et al* 2006 PLoS Biol 4:e45).

Active promoters are marked by trimethylation of Lys4 of histone H3 (H3K4), whereas enhancers are

marked by monomethylation, but not trimethylation, of H3K4. Computational algorithms, using these distinct chromatin signatures to identify new regulatory elements, predicted over 200 promoters and 400 enhancers within the 30 Mb region of the vertebrate genome (Heintzman N *et al* 2007 Nature Genet 39:311).

In vivo spatiotemporal analysis for approximately 900 predicted *C. elegans* promoters (~5% of the predicted protein-coding genes), each driving the expression of green fluorescent protein (GFP) using a flow-cytometer adapted for nematode profiling, generated “chronograms,” two-dimensional representations of fluorescence intensity along the body axis and throughout development from early larvae to adults. Automated comparison and clustering of the obtained in vivo expression patterns show that genes coexpressed in space and time tend to belong to common functional categories (Dupuy D *et al* 2007 Nature Biotechnol 25:663).

Promoter Bubble: ►promoter clearance

Promoter Clearance (promoter escape): In promoter clearance, the RNA polymerase complex (promoter bubble) starts moving forward from the promoter as the first ribonucleotides are transcribed. The RNA polymerase can synthesize a few bases without leaving the promoter site, but after that tension develops, which discontinues the contact between the DNA and the RNA polymerase. Clearance is regulated by both positive and negative elongation factors. Negative elongation requires four polypeptides and two polypeptides sensitivity inducing factor (DSIF). Inhibition takes place when about 18 nucleotides were added to the growing transcript. The transcript length is regulated also by the inhibition of the transcript cleavage factor TFIIS; the latter can be active along the entire length of the transcript (Palangat M et al 2005 Proc Natl Acad Sci USA 102:15036).

The movement may be represented by an inch-worm model or a moving domain model (the translocation involves the entire transcription box with minimal stretching) or the tilting model without a flexible polymerase, which is tilted along the axis of the DNA. ►bubble, ►replication bubble, ►inch-worm model; Pal M et al 2001 Mol Cell Biol 21:5815; Liu C, Martin CT 2002 J Biol Chem 277:2725.

Promoter Conversion (Pro-Con): Promoter conversion changes the promoter to a heterologous one.

Promoter Escape: ►promoter clearance

Promoter, Extended: ►Pribnow box

Promoter, Inducible: Inducible promoters turn on genes in response to biological, chemical, or physical signals. ►metallothionein, ►Lac

Promoter Interference: Promoter interference may occur when within a single viral vector two genes

are placed under separate controls, e.g., the strong promoter within the long terminal repeat (LTR) may suppress the function of an internal promoter irrespective of its orientation. This problem may be overcome by utilizing an IRES for the second gene in the common transcript:

LTR — 1st Gene — IRES — 2nd Gene —. ►IRES

Promoter Melting: In promoter melting, the double-stranded DNA unwinds (forms a promoter bubble) to allow access to the template strand for the RNA polymerase enzyme. In *E. coli*, the N-terminal 1–314 amino acids of the β' subunit and the 94–507 amino acids of the σ subunit cooperate in the melting. ►RNA polymerase, ►promoter; Young BA et al 2004 Science 303:1382.

Promoter Occlusion: Promoter occlusion occurs when, in retroviral elements with direct LTR repeats, the promoters at the 3'-end are inactivated and prevented from binding enhancers or transcription factors because they cannot facilitate transcription due to their wrong orientation. ►LTR, ►enhancer, ►transcription factors

Promoter Swapping: An exchange of promoter by, e.g., reciprocal chromosome translocation. ►translocation, ►pleiomorphic adenoma

Promoter, Tissue-Specific: A tissue-specific promoter permits the transcription of genes only or mainly in specific tissue(s) (see Fig. P140). ►promoter, ►tissue specificity

Figure P140. Tobacco seedlings segregating for kanamycin resistance on a root-tissue-specific promoter. Transformation was made by a promoter-less vector construct. The non-transgenic plants cannot grow roots on kanamycin medium. (From Y. Yao & G.P. Rédei)

Promoter Trapping: ▶trapping promoters, ▶transcriptional gene fusion vectors, ▶translational gene fusion vectors, ▶gene fusion, ▶promoter; Medico E et al 2001 Nature Biotechnol 19:579.

Promoters of Tumorigenesis: Environmental substances or gene products that guide a group of precancerous cells toward malignant growth. The promoters themselves do not initiate cancer. ▶carcinogenesis, ▶phorbol esters, ▶cancer, ▶conversion

Promutagen: A promutagen requires chemical modification (activation) to become a mutagen. ▶mutagen, ▶activation of mutagens

Promyelocytic Body (PML): A nuclear product of the promyelocytic leukemia gene; it mediates the degradation of ubiquitinated proteins and is regulated by the nucleolus. PMLs contain also TRF1 and TRF2 telomeric proteins required for the maintenance of telomeres. PMLs may be targeted by viruses, may act as suppressors of growth and tumors, and mediate apoptosis. PML body may also occur in the cytoplasm and modulates TGF- β signaling. The PML protein also regulates centrosome duplication by the suppression of the Aurora protein. ▶leukemia, ▶ubiquitin, ▶telomerase, ▶apoptosis, ▶transforming growth factor β , ▶centrosome

Pronase: A powerful general (non-specific) proteolytic enzyme isolated from *Streptomyces*.

Pronucleus: The male and female gametic nucleus to be involved in the sexual union.

Proof-of-Concept (proof of principle): Experimental evidence that an idea works in practical application. ▶validation

Proofreading: Bacterial DNA polymerase I (and analogous eukaryotic enzymes) can recognize replicational errors and remove the inappropriate bases by its editing 3' - 5' exo-nuclease function. In case the editing function is diminished by mutation, mutator activity is gained. In case of gain in editing, function antimutator attributes are observed. In bacteria, proofreading is performed also by the *dnaQ* gene encoding the ϵ subunit (an exonuclease) of the DNA polymerase III holoenzyme. The product of gene

dnaE carries out the base selection. The enzymes MutH, MutL, and MutS and the corresponding homologs in higher organisms repair mismatches. The fidelity of replication due to the combined action of the sequentially acting bacterial genes was estimated to be in the range of 10^{-10} per base per replication. During the process of translation, the EF-Tu•GTP \rightarrow EF-Tu•GDP change releases a molecule of inorganic phosphate (P_i) and allows a time window to dissociate the wrong tRNA from the ribosome. A similar correction is made also by the aminoacyl synthetase enzyme, by virtue of its active site specialized for this function. DNA polymerase η lacks exonuclease function required for proofreading, but correction is still accomplished by recruiting an extrinsic exonuclease to the error site. ▶DNA polymerase I, ▶DNA polymerase III, ▶DNA polymerases, ▶exonuclease, ▶proofreading paradox, ▶DNA repair, ▶error in replication, ▶error in aminoacylation, ▶ambiguity in translation, ▶protein synthesis, ▶DNA repair; Friedberg EC et al 2000 Proc Natl Acad Sci USA 97:5681; Livneh Z 2001 J Biol Chem 276:25639; Shevelev IV, Hübscher U 2002 Nat Rev Mol Cell Biol 3:364.

Propagule: A part of an organism that can be used for propagation of an individual by asexual means.

Propeller Twist in DNA: The surface angle formed between individual base-planes viewed along the C⁶-C⁸ line of a base pair.

Properdin (Factor P): A serum protein of three to four subunits (each ca. 56 kDa, encoded in human chromosome 6p21.3). It is an activator of the complement of the natural immunity system that works by stabilizing the convertase. ▶convertase, ▶complement, ▶complement, ▶immune system; Perdikoulis MV et al 2001 Biochim Biophys Acta 1548:265.

Prophage: The proviral phage is in an integrated state in the host cellular DNA and it is replicated in synchrony with the host chromosomal DNA until it is induced and thus, becomes a vegetative virus (see Fig. P141). ▶prophage induction, ▶temperate phage, ▶lysogeny, ▶lambda phage

Figure P141. Phage DNA incorporated into bacterial DNA becomes prophage

Prophage Induction: Treating the bacterial cells by physical or chemical agents that cause the moving of the phage into a vegetative lifestyle resulting in asynchronous, independent replication from the host and eventually the lysis and liberation of the phage. ▶prophage, ▶lysogeny, ▶zygotic induction

Prophage-Mediated Conversion: In prophage-mediated conversion, the integrated prophage causes genetic changes in the host bacterium, and it is expressed as an altered antigenic property, etc.

Prophase: ▶meiosis, ▶mitosis

Prophylaxis: Disease prevention.

Propionicacidemia: ▶glycinemia ketotic, ▶methylmalonicaciduria, ▶isoleucine-valine biosynthetic pathway, ▶tiglicacidemia; Chloupkova M et al 2002 Hum Mut 19:629.

Propionyl-CoA-Carboxylase Deficiency: ▶glycinemia ketotic

Proplastid: The young colorless plastid without fully differentiated internal membrane structures; it may differentiate into a chloroplast (see Fig. P142). ▶etioplast, ▶chloroplasts

Figure P142. Proplastid

Proportional Counters: Proportional counters are used for measuring radiation-induced ionizations within a chamber. The voltage changes within are proportional to the energy released. It may be used for measuring neutron and α radiations with an efficiency of 35–50%. The equipment must be calibrated to the radiation source. ▶radiation measurement, ▶radiation hazard assessment

Propositus (Proposita): ▶proband, ▶pedigree analysis

Propyne ($\text{CH}_3\text{-C}\equiv\text{CH}$): An alkyne used as a modifier at the C-5 position of pyrimidines in antisense oligonucleotides, frequently in combination with other

modifications such as phosphorothioate. ▶antisense technologies

Prosimii (prosimians): A suborder of lower primates, including Galago, Lemur, Tarsius, and Tupaia. Lorisidae. ▶primates, ▶Lemur, ▶Tupaia, ▶Lorisidae

Prosite: A protein sequence database, searchable by PROSCAN (Bairoch A et al 1977 Nucleic Acid Res 25:217); <http://pbil.univ-lyon1.fr/pbil.html>; PROSITE for uncharacterized proteins: <http://www.expasy.org/prosite/>; improved PROSITE: <http://www.expasy.org/tools/scanprosite/>.

Prosody: The inability of sensing or expressing variations of the normal rhythm of speech. It seems to be independent of processing musical pitch. ▶amusia, ▶musical talent, ▶pitch

Prosome: Small ribonucleoprotein body. It is identical with the $\sim 20\text{S}$ multifunctional protease complex of the proteasome of eukaryotes and prokaryotes. ▶proteasome

Prospective Study: Prospective study involves the epidemiological surveillance of a population after the occurrence of a disease or other harmful exposure. The exposed or involved individuals are compared with a concurrent control cohort. Prospective cohort studies improve on case control information. ▶case control, ▶concurrent control, ▶cohort

PROST (pronuclear state embryo transfer): Basically, very similar to intrafallopian transfer of zygotes but the zygote here is at a very early stage. ▶intrafallopian transfer, ▶ART

Prostacyclins: Prostacyclins may be derived from arachidonic acid or prostaglandins, regulate blood platelets, cause vasodilation, and are antithrombotic. ▶thrombosis, ▶prostaglandins, ▶COX

Prostaglandins: Long-chain fatty acids in different mammalian tissues with hormone-like muscle-regulating, inflammation-regulating, and reproductive functions; they exist in several forms. They occur in the majority of the cells and act as autocrine and paracrine mediators. Fever development is controlled by prostaglandin E_2 and EP_3 receptors. Prostaglandin synthesis is regulated by cyclooxygenases. Prostaglandin E (cyclopentenone prostaglandins) appears to be an inhibitor of I κ B kinase. ▶animal hormones, ▶autocrine, ▶paracrine, ▶cyclooxygenases, ▶I κ B, ▶leukotrienes, ▶eicosanoids, ▶pain-sensitivity, ▶implantation, ▶misoprostol, ▶colorectal cancer; Rudnick DA et al 2001 Proc Natl Acad Sci USA 98:8885.

Prostanoids: Bioactive lipids such as the prostaglandins, prostacyclin, and thromboxane. Aspirin-like

drugs may inhibit prostanoid biosynthesis, reduce fever and inflammation, and interfere with female fertility. ►prostaglandins, ►prostacyclins

Prostate Cancer (HPC): About 9–10% of USA males eventually develop prostate cancer. The autosomal dominant gene has a high penetrance: about 88% of the carriers become afflicted by the age of 85. Several other genes involved in prostate function may mutate and cause cancer. Recurrent fusion of the androgen-responsive promoter element of TMPRSS2 (a transmembrane protease serine 2, 21q22.3) with members of the ETS oncogene family ETV1 at 7p21.2 leads to prostate cancer (Tomlins SA et al 2005 *Science* 310:6744). Relative to low-grade prostate cancer (Gleason pattern 3) and high-grade cancer (Gleason pattern 4) shows an attenuated androgen signaling signature, similar to metastatic prostate cancer, which may reflect dedifferentiation and explain the clinical association of grade with prognosis (Tomlins SA et al 2007 *Nature Genet* 39:41). Androgen receptor and PTEN–AKT signaling may initiate and maintain prostate cancer. For therapeutic intervention, androgen receptor and AKT and/or growth factor receptor tyrosine kinases that activate AKT can be targeted (Xin L et al 2006 *Proc Natl Acad Sci USA* 103:7789). The high level of testosterone may increase the chances for this cancer. Reduced level of testosterone may not slow down advanced prostate cancer growth and metastasis. There is a possible therapeutic approach to prostate cancer in overexpressing an androgen receptor by ligand-independent activation of the N-terminal domain peptide to create decoy molecules that competitively bind the interacting proteins required for activation of the endogenous full-length receptor.

A genetic variant in the 8q24 region, identified by GWA, in conjunction with another variant, accounts for about 11–13% of prostate cancer cases in individuals of European descent and 31% of cases in African Americans (Gudmundsson J et al 2007 *Nature Genet* 39:631). Seven risk variants, five of them previously unreported, spanning 430 kb and each independently predicting risk for prostate cancer ($P = 7.9 \times 10^{-19}$ for the strongest association, and $P < 1.5 \times 10^{-4}$ for five of the variants, after controlling for each of the others). The variants define common genotypes that span a more than fivefold range of susceptibility to cancer in some populations. None of the prostate cancer risk variants aligns to a known gene or alters the coding sequence of an encoded protein (Haiman CA et al 2007 *Nature Genet* 39:638).

There is evidence that in vivo expression of the receptor decoys decreased tumor incidence and inhibited the growth of prostate cancer tumors (Quayle SN et al 2007 *Proc Natl Acad Sci USA*

104:1331). Growth hormone-releasing hormone (GHRH) antagonists increased the intracellular Ca^{2+} and activated tumoral GHRH receptors and induced apoptosis (Rékási Z et al. 2005 *Proc Natl Acad Sci USA* 102:3435). Metastatic prostate cancer cells may show high levels of caveolin-1 and reduced amount of testosterone. Caveolin-1 antisense RNA promoted apoptosis and increased testosterone. A metastasis suppressor gene, KAI1, in human chromosome 11p11.2, has been identified. The KAI1 protein appears to contain 267 amino acids with four transmembrane hydrophobic and one large hydrophilic domains. This glycoprotein is expressed in several human tissues and also in rats. A negative regulator of the MYC oncogene, MXI1 (encoded in human chromosome 10q24-q25), is frequently lost in prostate cancer. KAI1 is involved in chromatin remodeling by suppressing Tip60, β -catenin, and reelin, and in metastasis of prostate cancer cells (Kim JH et al 2005 *Nature [Lond]* 434:921). Cytokine-activated IKK α controls metastasis by repressing Maspin (Luo J-L et al 2007 *Nature [Lond]* 446:690). In the chromosome 10pter-q11 region, a prostate cancer suppressor gene, causing apoptosis of carcinoma, has been detected from loss of heterozygosity mutations (LOH). A major susceptibility locus was identified in human chromosome 1q24-q25 and at Xq27-q28. Candidate genes are expected in human chromosomes 3p, 4q, 5q, 7q32, 8p22-p23 and 8q, 9q, 10p15 (KLF6), 13q, 16q, 17p11, 18q, 19q12, 20q13, and 22q12.3. At 16q22 the transcription factor ATBF1 is transcribed, which negatively regulates AFP and MYB but transactivates CDKN1A and it may be reduced in about a third of the prostate cancer cells (Sun X et al 2005 *Nature Genet* 37:407). Insulin-like growth factor (IGF-1) levels may be predictors of prostate cancer risks before cancerous growth is observed but some other data are at variance with the claim. In prostate tumors, the prostate-specific cell-surface antigen (STEAP), in human chromosome 7p22.3, is highly expressed in different organs and tissues, except the bladder. A predisposing gene in 17p has been cloned. The various types of prostate cancers can be classified on the basis of DNA microarray and the result may assist treatment and prognostication (Lapointe J et al 2004 *Proc Natl Acad Sci USA* 101:811). In Northern Europe, about 42% of the cases were found to be hereditary and 58% were sporadic (Lichtenstein P et al 2000 *N Engl J Med* 343:78). The first-degree relative risk is 1.7–3.7 or more. American blacks have higher and Asians lower risks than Caucasians (Stanford JL, Ostrander EA 2001 *Epidemiol Rev* 23:19).

Prostate stem cell antigen (PSCA) may be the target for immunological therapy. About 11–12% of all prostate cancer patients harbored mitochondrial mutations in cytochrome oxidase I subunit; mutations

inhibiting oxidative phosphorylation can increase ROS and tumorigenicity (Petros JA et al 2005 Proc Natl Acad Sci USA 102: 719). Prostate cancer is the second most frequent cause of cancer mortality in the US but it is very rare in other animals, except dogs. ▶PSA, ▶cancer, ▶tumor suppressor gene, ▶IKK, ▶Maspin, ▶MYC, ▶MYB, ▶fetoprotein- α , ▶CDKN1A, ▶insulin-like growth factor, ▶caveolin, ▶antisense technology, ▶automaton, ▶testosterone, ▶apoptosis, ▶microarray hybridization, ▶gene fusion, ▶probasin, ▶ROS, ▶mitochondrial genetics, ▶mitochondrial diseases in humans, ▶Gleason score, ▶automaton, ▶chromatin remodeling, ▶*erbB*, ▶androgen, ▶PTEN, ▶AKT; Ostrander EA, Stanford JL 2000 Am J Hum Genet 67:1367; Xu J et al 2001 Am J Hum Genet 69:341; Stephan DA et al 2002 Genomics 79:41; Ostrander EA et al 2004 Annu Rev Genomics Hum Genet 5:151; susceptibility markers: <http://cgems.cancer.gov/>.

Prostates (prostata): Gland in the animal (human) male surrounding the base of the bladder and the urethra; upon ejaculation injects its content (acid phosphatase, citric acid, proteolytic enzymes, etc.) into the seminal fluid. ▶PSA, ▶prostate cancer; <http://www.pedb.org>.

Prosthesis: Any type of mechanical replacement of a body part, such as artificial limbs, false teeth, etc.

Prosthetic Group: A non-peptide group (iron or other inorganic or organic group) covalently bound (conjugated) to a protein to assure activity.

Prot: Na^+/Cl^- -dependent proline transporter that also transports glycine, GABA, betaine, taurine, creatine, norepinephrine, dopamine, and serotonin in the brain. ▶transporters

Protamine: The basic (arginine-rich) protein occurring in the sperm substituting for histones.

The protamine gene cluster is in human chromosome 16p13.2 and it includes genes PRM1, PRM2, and TNP2 (transition protein 2). They are transcribed at the postmeiotic round spermatid stage of spermatogenesis and translated in elongating spermatids (see Fig. P143). These messages are bound as cytoplasmic messenger ribonuclear protein particles until histone replacement is initiated with the transition proteins in late elongating spermatids. At this time the mRNAs are activated and then translated

into the peptides that will repackage and compact the male genome in terminally differentiated spermatozoa. In humans and mice, the genes first acquire a DNase I-sensitive conformation in pachytene spermatocytes that is even maintained in human spermatozoa and transcription is facilitated (Martins RP, Krawetz SA 2007 Proc Natl Acad Sci USA 104:8340). Protamine 4 is a minor protein and it is different from PRM2 and PRM3 only by a short extension. The genes are potentiated at late pachytene before the haploid (n, 1C) spermatids are formed. In the mature spermatozoon, the histones are replaced by protamines. Protamine controls both condensation and decondensation of the DNA by anchoring to it at about each 11 bp. After fertilization it is removed. In *Drosophila*, the *Hira* gene is involved in the decondensation. The HIRA gene of mammals is essential for chromatin assembly in the male pronucleus and it uses histone variant H3.3 (Lappin B et al 2005 Nature [Lond] 437:1386). In the somatic cells, protamines constitute less than 5% of the nucleus. The majority of mammals have only a single protamine but mice and men have four. If protamines are deleted missing functional sperm is not produced because of haplo-insufficiency. ▶histones, ▶transition protein, ▶haploinsufficiency, ▶spermiogenesis, ▶gametogenesis, ▶C amount of DNA; Cho C et al 2001 Nature Genet 28:82.

Protandry: in monoecious plants the pollen is shed before the stigma is receptive. ▶monoecious, ▶stigma, ▶protogyny, ▶self-sterility

Protanope: ▶color blindness

Protease (proteinase): Enzyme, which hydrolyzes proteins at specific peptide bonds; for *protease 3* see antimicrobial peptides. The human genome codes for at least 553 proteases. Proteases may either facilitate or reduce the expression of enzymes. ▶proteasome, ▶peptidase; Ehrmann M, Clausen T 2004 Annu Rev Genet 38:709; <http://cutdb.burnham.org>.

Protease Inhibitors: Protease inhibitors, such as leupeptin, antipain, and soybean trypsin inhibitors are credited with anticarcinogenic effects and potential cures for asthma, schistosomiasis. Proteases process the primary proteins into their functional role in viral/microbial or other systems. If this processing

Figure P143. Development of the nuclear DNA in spermatozoa

is prevented, infectious or other agents may not or may have reduced adverse effect to the cells. ►carcinogen, ►cancer, ►AIDS, ►schistosomiasis, ►asthma

Proteasomes: Tools of degradation of intracellular proteins (see Fig. P144). Proteasomes have non-degradatory functions too, such as in transcription, DNA repair, and chromatin remodeling. ATP-dependent ubiquitinated proteins process intracellular antigens into short peptides that are then transported to the endoplasmic reticulum with the aid of TAP, and are responsible for MHC class I-restricted antigen presentation. Proteasomal polymorphism is determined, among others, by LMP2 and LMP7 genes encoded within the MHC class II region in the vicinity of TAPs that are upregulated by interferon γ . The 26S (~2500 kDa) proteasomes (~31 subunits) are hollow cylinders engulfing ubiquitinated proteins and degrade them with proteases. The lid and the base each are 19S (890 kDa). The ATP-dependent dissociation of the 19S subunits from the 26S complex leads to the protein degradation (Babbitt SE et al 2005 Cell 121:553). The ~20S (720 kDa) middle section barrel of the proteasomes contain multiple peptidases. Their active site is at the hydroxyl group of the N-terminal threonine in the β subunit. The PA proteins are proteasome activators. The 26S proteasome is associated with at least 18 ancillary and essential proteins (PSM proteins, including ATPase) and many of these are now genetically mapped to different human chromosomes. Chymostatin, calpain, and leupeptin, etc., are inhibitors. The proteases of the 20S proteasome are activated by the heptameric 11S regulators, which also control the opening of the barrel-shaped structure. The assembly of the 28 subunits of the 20S mammalian proteasomes is mediated by the heteromeric chaperones PAC1 and PAC2 (Hirano Y et al 2005 Nature [Lond] 437:13481). Proteasomes have also ubiquitin-independent function, such as the degradation of the excess amounts of ornithine decarboxylase, a key enzyme in polyamine biosynthesis. The proteasomes have important—although not fully understood—roles in differentiation and development by mediating protein turnover. Proteasomes control also apoptosis and carcinogenesis (Adams J 2004 Nat Rev Cancer 4:349). According to

Figure P144. Proteasome and its function

Princiotta MF et al 2003 (Immunity 18:343) each cell of the immune system contains 800,000 proteasomes (immunoproteasomes). The product peptides of the immunoproteasome are different from the regular proteasomes. They degrade 2.5 viral translation product substrates per minute and thus generate one MHC class I peptide complex for each 300 to 5000 viral translation product degraded. The misfolded proteins are removed from the endoplasmic reticulum and in the cytoplasm, after ubiquitination and de-glycosylation, they are degraded by the proteasome. On the average cellular proteins are degraded in about two days and about a third of the new proteins of mammals have less than 10 min half-life. The majority of these have a synthetic defect. In active mammalian cells, about 10 million polypeptides are formed per minute and within seconds these are degraded to amino acids by peptidases (Yewdell JW 2005 Proc Natl Acad Sci USA 102:9089). Membrane proteins US11 and Derlin-1 mediate MHC molecule dislocation from the endoplasmic reticulum (Lilley BN Ploegh HL 2004 Nature [Lond] 429:834; Ye Y et al 2004 *Ibid.* 841). In case the proteasome function is inhibited or lost, inhibitor resistant cells may grow out of the cultures that have a compensating mechanism for proteasome function. The Cop9 signalosome of *Arabidopsis* is functionally homologous to the lid element of the proteasome. It appears that the various elements of the proteasome complex are co-regulated by the RPM4 putative transcription factor. The yeast activators Gcn4, Gal4, and Ino2/4 are actually activated by exposure to the ubiquitin–proteasome system. It appears that after the transcription has started, the removal of the promoter-bound activators is beneficial for the continuation of transcription (Lipford JR et al 2005 Nature [Lond] 438:113). ►ubiquitin, ►LID, ►TAP, ►N-end rule, ►antigen presenting cell, ►MHC, ►antigen processing, ►JAMM, ►DRiP, ►immune system, ►polyamine, ►Skp1, ►tripeptidyl peptidase, ►Clp, ►photomorphogenesis, ►signalosome, ►lysosomes, ►unfolded protein response, ►immunoproteasomes, ►Gcn4, ►Gal4, ►exosome; Voges D et al 1999 Annu Rev Biochem 68:1015; Bochtler M et al 1999 Annu Rev Biophys Biomol Struct 28:295; Klotzel P-M 2001 Nature Rev Mol Cell Biol 2:179; Ottosen S et al 2002 Science 296:479; Liu C-W et al 2003 Science 299:408; Puente XS et al 2003 Nature Rev Genet 4:544; Goldberg AL 2003 Nature [Lond] 426:895; lid structure: Sharon M et al 2006 PLoS Biol 4(8):e267; minireview: DeMartino GN, Gillette TG 2007 Cell 129:659.

Protectin (CD59): A protein component of the complement encoded at 11p13. ►complement, ►paroxysmal nocturnal hemoglobinuria; Kawano M 2000 Arch Immunol Ther Exp 48(5):367.

Protein: A large molecule (polymer) composed of one or more identical or different peptide chains. The distinction between protein and polypeptide is somewhat uncertain; generally a protein has more amino acid residues (50–60) and therefore can fold. In animal cells, there are about 1×10^5 protein species. ►protein synthesis, ►protein structure, ►amino acid sequencing, ►subcellular localization; protein data Bank [PDB]: Westbrook J et al 2002 Nucleic Acids Res 30:245; <http://www.rcsb.org/pdb/>; <http://pir.georgetown.edu/>; <http://www.ncbi.nlm.nih.gov/gquery/gquery.fcgi>.

Protein 14-3-3: A family of 28–33 kDa acidic chaperone proteins named after their electrophoretic mobility. The proteins occur in many forms in different organisms and have roles in signal transduction (RAS-MAP), apoptosis, exocytosis, the regulation of the cell cycle (checkpoint), DNA repair, and oncogenes. They generally bind to phosphoserine/threonine domains. Protein 14-3-3 σ isoform binds tumor suppressor p53, regulates translation through eukaryotic translation initiation factor 4B, and reduces the mitotic endogenous ribosomal entry site (IRES)-dependent cyclin Cdk1 (PITSLRE), among performing other functions. In the absence of this isoform, mitotic exit is impaired and causes aneuploidy and tumorigenesis (Wilker EW et al 2007 Nature [Lond] 446:329). ►Chk1, ►cell cycle, ►Cdc25, ►p53, ►CaM-KK, ►checkpoint, ►chaperone, ►longevity, ►PITSLRE, ►IRES, ►cdk, ►eIF-4B; Muslin AJ, Xing H 2000 Cell Signal 12(11–12):703; Masters SC, Fu H 2001 J Biol Chem 276:45193; Tzivion G, Avruch J 2002 J Biol Chem 277:3061; Sehnke PC et al 2002 Plant Cell 14:S339.

Protein A: Protein A is isolated from *Staphylococcus aureus*; it binds the Fc domain of immunoglobulins without interacting with the antigen-binding site. It is used both in soluble and insoluble forms for the purification of antibodies, antigens, and immune complexes. ►antibody, ►immunoglobulins

Protein Abundance: ►genome-wide location analysis

Protein Alignment: <http://mozart.bio.neu.edu/topofit/index.php>.

Protein Arrays: Protein arrays are used in a manner analogous to microarrays of DNA. On specially treated microscope slide or microtiter plates, samples of a protein or proteins are lined up and exposed to other proteins or to drug molecules or molecular fragments in order to assess their interaction. This new procedure is expected to be useful for analytical purposes and particularly for the development of new drugs. ►microarray hybridization, ►protein chips,

►reverse array; Avseenko NV et al 2001 Anal Chem 73:6047; Brody EN, Gold L 2000 J Biotechnol 74:5.

Protein Assays: ►Bradford method, ►Lowry test, ►Kjeldhal method; for analysis with single cell resolution: Zhang HT et al 2001 Proc Natl Acad Sci USA 98:5497; detection on magnetic nanoparticle-bio-barcode and antibody at 30 attomolar concentration: Nam J-M et al 2003 Science 301:1884.

Protein C (2q13-q14): A vitamin K-dependent serine protease, which selectively degrades antihemophilic factors Va and VIIIa, and it is thus, an anticoagulant. ►protein C deficiency, ►antihemophilic factors, ►thrombin, ►anticoagulation, ►thrombophilia

Protein C Deficiency (thrombotic disease): Protein C deficiency is human chromosome 2q13-q14 dominant and may be a life-threatening cause of thrombosis. ►thrombosis, ►protein C

Protein Chips: A protein mixture (e.g., serum) applied to an about 1 mm² surface containing a “bait” that is an antibody, a specific receptor, or other kind of specific molecule, which selectively binds a particular protein (tagged by fluorescent dye) and thus facilitates its isolation even when present only in minute amounts. Alternatively, recombinant proteins are immobilized on the chips and then putative interacting proteins (cell lysates) are applied to it. The unbound material is removed by washing and the bound one(s) are analyzed by mass spectrometry, or phage display or two-hybrid method may be used. These procedures can handle speedily huge number of samples and bear similarity to DNA chips. ►microarray hybridization, ►ELISA, ►DNA chips, ►mass spectrum, ►MALDI, ►electrospray, ►phage display, ►two-hybrid method, ►gene product interaction, ►proteomics, ►protein microarray; Zhu H et al. 2001 Science 293:2101.

Protein Classification for Machine Learning: ►machine learning; <http://hydra.icgeb.trieste.it/benchmark>.

Protein Clock: ►evolutionary clock

Protein Complexes: Protein complexes usually play an important role in protein and cellular function. Their study requires enrichment of the complex either by chromatography, co-immunoprecipitation, co-precipitation by affinity-tagged proteins, and SDS-PAGE separation of the components before additional analytical techniques are employed. One study involving 1739 yeast genes, including 1143 human homologous, revealed 589 protein assemblies. Among these, 51% included up to five proteins, 6% more than 40 proteins, 4% 31–40, 6% 21–30, 15% of the complexes 11–20 proteins, and 18% displayed interactions among 6–10 proteins. The technology did not reveal interactions of very short durations.

Obviously, within the cells even more proteins interact. The modules of the interacting systems are better conserved during evolution than are random samples of other proteins. This indicates their importance in specific functions (Wuchty S et al 2003 *Nature Genet* 35:176). ▶immunoprecipitation, ▶immunolabeling, ▶SDS-PAGE, ▶LC-MS, ▶mass spectrometry, ▶TAP, ▶two-hybrid method, ▶genetic networks, ▶SAGE, ▶TAP; Gavin A-C et al 2002 *Nature [Lond]* 415:141; Ho Y et al 2002 *Nature [Lond]* 415:180; global surveys of budding yeast cell machineries: Gavin A-C et al *Nature [Lond]* 440:631; Krogan NJ et al 2006 *Nature [Lond]* 440:637; <http://www.biond.org/>; protein-DNA complexes: <http://gibk26.bse.kyutech.ac.jp/jouhou/readout/>.

Protein Conducting Channel: Membrane passageways for proteins that interact with the membrane protein and lipid components. ▶protein targeting, ▶SRP, ▶translocon, ▶translocase, ▶TRAM, ▶ABC transporters, ▶Sec61 complex; Spahn CM et al 2001 *Cell* 107:373.

Protein Degradation: ▶proteasome, ▶ubiquitin, ▶anti-zyne, ▶lysosomes, ▶endoplasmic reticulum, ▶endocytosis, ▶major histocompatibility complex, ▶TAP, ▶F-box, ▶microRNA, ▶RNAi, ▶half-life

Protein Degradation within Cells: In protein degradation, endogenous proteins are digested primarily by the proteasomes and exogenous proteins are cleaved mainly by the lysosomal system, although the compartmentalization is not rigid. ▶proteasome, ▶lysosome, ▶N-end rule

Protein Design: Computer programs exist now to design new proteins for physico-chemical potential function and stereochemical arrangements using combinatorial libraries of amino acids. The *designability of a protein* is determined by the amino acids that permit alterations without loss of structure or function. (See Dahiat BI, Mayo SL 1997 *Science* 278:82).

Protein, Disordered: A disordered protein contains at least one experimentally determined disordered region and lacks fixed structure. Such proteins and regions can carry out important biological functions and may be involved in regulation, signaling, and control. (See <http://www.disprot.org/>).

Protein Domains: Protein domains are generally formed by the folding of 50–350 amino acid sequences for carrying out particular function(s). Small proteins may have only a single domain but larger complexes may have multiple modular units. The

alternations of α helices and β sheets constitute a characteristic *motif*. The two β -sheet motifs are shown in Figure P145 in black and red, respectively. The compact motifs are generally covered by polypeptide loops. Domain similarities among proteins from different organisms indicate possible functional relationship (homology) of those proteins. ▶protein structure- β sheets, ▶ α helices, ▶helix-turn-helix, ▶helix-loop-helix, ▶zinc finger, ▶binding proteins, ▶motif; Ponting CP, Russell RR 2002 *Annu Rev Biophys Biomol Struct* 31:45; Pearl FM et al 2003 *Nucleic Acids Res* 31:452; http://smart.embl-heidelberg.de/help/smart_about.shtml; <http://www.ebi.ac.uk/interpro>; <http://smart.embl.de/>; domain homology: <http://genespeed.uchsc.edu/>; conserved domains: <http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=cdd>; conserved domains in new sequences: <http://www.ncbi.nlm.nih.gov/Structure/cdd/wrpsb.cgi>; three-dimensional structures: <http://www.toulouse.inra.fr/prodom.html>; domain search on the basis of sequence: <http://www.icgeb.trieste.it/sbase>; Superfamily domains: <http://supfam.org>; protein domain prediction: <http://www.bioinfotool.org/domac.html>.

Protein Engineering: Constructing proteins with amino acid replacements at particular domains and positions (e.g., substrate-binding cleft, catalytic and ligand-binding sites, etc.) or adding a label or another molecule, etc., to explore their effect on function. Incorporation of unnatural amino acids into particular proteins is a common way to accomplish it (Nowak MW et al 1998 *Methods Enzymol* 293:504). ▶directed mutation, ▶semisynthesis of proteins, ▶DNA shuffling, ▶iterative truncation, ▶nonsense suppression, ▶suppressor tRNA, ▶expressed protein ligation, ▶proteomics, ▶enzyme design; Tao H, Cornish VW 2002 *Curr Opin Chem Biol* 6:858; Brennigan JA, Wilkinson AJ 2002 *Nature Rev Mol Cell Biol* 3:964; Wang L et al 2003 *Proc Natl Acad Sci USA* 100:56.

Protein, Essential: Essential for the viability of the organism in an environment.

Protein Families: Protein families share structural and functional similarities; generally share more than 30% sequence identity. The number of different families in vertebrates is about 750, in invertebrates and plants ~670, in yeast and larger bacteria ~550, and in small parasitic bacteria ~220 (Chotia C et al

2003 Science 300:1701). The average family size in higher organisms is about 20 whereas in lower forms it is 8 to 2. *Superfamilies*: (i) catalyze the same chemical reaction or (ii) different overall reactions that share common mechanistic properties (partial reaction, intermediate or transition state) and share 20 to 50% sequence identity. *Suprafamilies*: homologous enzymes but catalyze different reactions. Mutations affecting amino acid sequences in three different evolutionary groups (mammals, chickens, bacteria) are strikingly similar. For categories with the same divergence, common accepted mutations have similar frequencies and rank orders in the three groups. With increasing divergence, mutations increase at different rates in the buried, intermediate, and exposed regions of protein structures in a manner that explains the exponential relationship between the divergence of structure and sequence. This work implies that commonly allowed mutations are selected by a set of general constraints that are well defined and whose nature varies with divergence (Sasidharan R, Chothia C 2007 Proc Natl Acad Sci USA 104:10080). ►*gene family*, ►*PRINTS*; Enright AJ et al 2002 Nucleic Acids Res 30:1575; Aravind L et al 2002 Curr Opin Struct Biol 12:392; <http://pfam.wustl.edu/>; <http://www.ebi.ac.uk/interpro>; <http://www.biochem.ucl.ac.uk/bsm/cath>; <http://mia.sdsc.edu/mia/html/bioDBs.html>; <http://systems.molgen.mpg.de>; shifts in subfamilies: <http://funshift.cgb.ki.se/>; families in evolution: <http://www.pantherdb.org/>.

Protein Folding: The majority of proteins fold to acquire functionality, although some (mainly) surface proteins do not require folding. The pattern of hydrophobic and polar residues of a relatively small number may be required for folding. The native conformation is reached through intermediate stage(s) (see Fig. P146) (Sadqi M et al 2006 Nature [Lond] 442:317). Even at high (88%) amino acid identity, two proteins may have different structures and functions (Alexander PA et al 2007 Proc Natl Acad Sci USA 104:11963).

The native structure is stabilized primarily by hydrogen bonding between amide and carbonyl groups

of the main chain. Glycosylation in the endoplasmic reticulum may affect the conformation of proteins.

The folding is determined by the amino acid sequence, however other factors (chaperones) may be needed to facilitate the process. the energetics of backbone hydrogen bonds dominate the folding process, with preorganization in

Besides the primary structure of amino acids, the energetics of backbone hydrogen bonds can dominate the folding process, with pre-organization in the unfolded state. Then, under folding conditions, the resultant fold is selected from a limited repertoire of structural possibilities, each corresponding to a distinct hydrogen-bonded arrangement of α -helices and/or strands of β -sheets (Rose GD et al 2006 Proc Natl Acad Sci USA 103:16623).

The classical diffusion–collision and nucleation–condensation models may represent two extreme manifestations of an underlying common mechanism for the folding of small globular proteins. Characterization of the folding process of the PDZ domain, a protein that recapitulates three canonical steps, is involved in a unifying mechanism, namely: (1) the early formation of a weak nucleus that determines the native-like topology of a large portion of the structure, (2) a global collapse of the entire polypeptide chain, and (3) the consolidation of the remaining partially structured regions to achieve the native state conformation. Classical kinetic analysis identified two activation barriers along the reaction coordinate, corresponding to a more unfolded transition state *TS1* and a more native-like transition state *TS2*. The PDZ2 (PDZ repeat from Protein Tyrosine Phosphatase-Bas Like folding process; Bas for basophil) provides evidence that its folding mechanism is distinct from the pure diffusion–collision as well as from the nucleation–condensation mechanism, but displays characteristic features of both models (Gianni S et al 2007 Proc Natl Acad Sci USA 104:128).

Prokaryotic proteins (which are generally smaller, two to three hundred amino acid residues) fold correctly only after the completion of the entire length of the amino acid chain. Eukaryotic proteins (usually on the average over four to five hundred residues) may

Figure P146. Protein folding

fold the separate domains in a sequential manner during their translation. Both prokaryotic and eukaryotic proteins may start folding before their translation is completed, i.e., co-translationally. Because of this, fusion proteins can also fold and this might have been of an evolutionary advantage. There is evidence that α helices fold faster than β sheets. Local interactions may facilitate speedier folding.

The global pattern of co-evolutionary interactions of amino acids is relatively sparse and a small set of positions in the proteins mutually co-evolves. The co-evolving residues are spatially organized into physically connected networks linking distant functional sites through packing interactions. By the method of statistical coupling analysis (SCA), it was revealed that the amino acid interactions specifying the atomic structure are conserved among the members of protein families. The conservation is not site independent and it occurs due to energetic interactions. The statistical energy functions can be appropriately estimated by the SCA method (Socolich M et al 2005 Nature [Lond] 437:512; Russ WP et al 2005 Nature [Lond] 437:579). Certainly many factors may affect the rate of folding and the rate among different proteins may be nine orders of magnitude. Besides folding, intrinsic plasticity of the enzyme proteins is a characteristic feature of catalysis. The motion is not limited to the active site but a more dynamic network is also involved (Eisenmesser EZ et al 2005 Nature [Lond] 438:117). Diseases may occur due to the misfolding of protein(s) such as in cystic fibrosis, Parkinsonism, prion, Alzheimer's disease, sickle cell anemia, etc. Some of the misfolding problems can be alleviated by inhibitors of the enzyme or by aiding its degradation by small molecules or by stabilizing the conformation (Cohen FE, Kelly JW 2003 Nature [Lond] 426:905). ▶chaperones, ▶chaperonins, ▶conformation, ▶calnexin, ▶calreticulin, ▶protein structure, ▶amyloidosis, ▶prion, ▶encephalopathies, ▶GroEL, ▶trigger factor, ▶endoplasmic reticulum, ▶Sec61 complex, ▶protein synthesis, ▶folding, ▶SCA; Bukau B et al 2000 Cell 101:119; Baker D 2000 Nature [Lond] 405:39; Parodi AJ 2000 Annu Rev Biochem 69:69; Klein-Seetharaman J et al 2002 Science 295:1719; Hartl FU, Hayer-Hartl M 2002 Science 295:1852; Myers JK, Oas TG 2002 Annu Rev Biochem 71:783; Gianni S et al 2003 Proc Natl Acad Sci USA 100:13286; Dobson CM 2003 Nature [Lond] 426:884; Selkoe DJ 2003 Nature [Lond] 426:900; evolutionary implications: DePristo MA et al 2005 Nat Rev Genet 6:678; protein misfolding and amyloid disease: Chiti F, Dobson CM 2006 Annu Rev Biochem 75:333; protein misfolding-human disease: Gregersen N et al 2006 Annu Rev Genomics Hum Genet 7:103; <http://bioresearch.ac.uk/browse/mesh/D017510.html>; protein refolding: [http://refold.med.](http://refold.med.monash.edu.au/)

Protein Function: Protein function is generally determined by biochemical and genetic analyses such as enzyme assays, two-hybrid system, etc. Many proteins are involved in complex functions and interact with several other proteins. These complex functions can be inferred from the known role of proteins in evolutionarily different organisms, from amino acid sequence information, by the rosetta stone sequences, the correlation of mRNA expression, and gene fusion information from sequence data. During evolution, some structural and functional properties of the diverging proteins are retained in the protein families but some groups have acquired new function such as substrate-specificity. These shifts can be analyzed by: <http://FunShift.cgb.ki.se>. ▶rosetta stone sequences, ▶microarray hybridization, ▶two-hybrid system; <http://biozon.org>; functional sites, ligands: <http://firedb.bioinfo.cnio.es>.

Protein G: An immunoglobulin-binding (IgG) streptococcal extracellular cell surface protein.

Protein Grafting: The transfer of a binding epitope in biologically active conformation unto the surface of another protein. Such a procedure may produce an effective antiviral protein or may be used for other biological purposes. ▶epitope; Sia SK, Kim PS 2003 Proc Natl Acad Sci USA 100:9756.

Protein H: Streptococcal IgG-binding protein. ▶immunoglobulins

Protein Index: Guides to the main databases on proteomes such as Swiss-Prot, RefSeq, Ensembl, etc. ▶protein classification; <http://kinemage.biochem.duke.edu/~jsr/html/anatax.3a4.html>.

Protein Information Resource: ▶PIR; <http://pir.georgetown.edu>; the largest and most comprehensive source is the Swiss-Prot: <http://www.expasy.ch/>; ▶databases

Protein Interactions: Interaction density (PID) is calculated as observed protein interaction/total number of possible pair-wise combinations. Conformational switches detectable by nuclear magnetic resonance relaxation experiments at the microsecond to millisecond time scale may modulate protein interactions (Koglin A et al 2006 Science 312:273). The various proteins may interact in many different ways and the ~6000 proteins of yeast may display about 100,000 relations. In a preliminary attempt to develop a human genome-wide interaction network,

~8100 Gateway-cloned ORFs allowed the detection of 2800 interactions (Rual J-F et al 2005 Nature [Lond] 437:1173). A new method permits prediction of interactions on the basis of protein sequence (Shen J et al 2007 Proc Natl Acad Sci USA 104:4337). Bioinformatic technology is required to separate the genuine from the spurious interactions (Jansen R et al 2003 Science 302:449). In *Drosophila* a draft of 7048 proteins and 20,405 interactions were detected and at a high confidence level 4679 proteins and 4780 interactions were verified by the two-hybrid method and mapped (Giot L et al 2003 Science 302:1727).

Photo-cross-linking permits detection of protein–protein interactions in living cells. Photoreactivable amino acids (e.g., photomethionine, as shown in Figure P147, the critical change is circled by dashed line) are very similar to natural counterparts and can be incorporated into the protein by the translation machinery. Activation by ultraviolet light results in cross-linking of the interacting proteins and it can be detected by western blotting (Suchanek M et al 2005 Nature Methods 2:261).

Figure P147. Photomethionine (left); methionine (right). (After Suchanek, M. et al. 2005 Nature Methods 2:261)

The bimolecular fluorescence complementation (BiFC) method permits the visualization of interaction *in situ* within living cells using yellow fluorescent protein variants (Hu C-D, Kerppola TK 2003 Nature Biotechnol 21:539). Protein interaction networks are largely preserved during evolution from prokaryotes to eukaryotes, although some specialization is also evident (Kelley BP et al 2003 Proc Natl Acad Sci USA 100:11394). A recent analysis of more than 70,000 binary interactions in humans, yeast, *Caenorhabditis*, and *Drosophila* showed only 42 were common to human, worm, and fly and only 16 were common to all. An additional 36 were common between fly and worm but not to humans, although by co-immunoprecipitation 9 were present in humans. Proteins known to be involved in similar disorders in humans showed interaction (Gandhi TKB et al 2006 Nat Genet 38:285). ►gene product interaction, ►two-hybrid method, ►protein-DNA interaction, ►affinity tagging, ►protein chips, ►networks, ►genetic networks, ►GRID, ►BIND,

Protein Intron: ►intein

Protein Isoforms: Closely related polypeptide chain family, encoded by a set of exons, which share structurally identical or almost identical subset of exons. ►family of genes

Protein Kinase: A protein kinase phosphorylates one or more amino acids (frequently threonine, serine, tyrosine) at certain positions in a protein, and thus two negative charges are conveyed to these sites, altering the conformation of the protein. This alteration then involves a change in the ligand-binding properties. The catalytic domain of this large family of enzymes is usually 250 amino acids. The amino acids outside the catalytic domains may vary substantially and specify the recognition abilities of the different kinases and serve in responding to regulatory signals. During the last three to four decades, hundreds of protein kinases have been discovered that can be classified into serine/threonine (TGF- β [transforming growth factor]), tyrosine (EGF [epidermal growth factor receptor], PDGF [platelet-derived growth factor receptor] protein kinases, SRC [Rous sarcoma oncogene product], Raf [product of the Moloney and MYC oncogenes]), MAP kinase, cell cyclin-dependent kinase (Cdk), cell division cycle (Cdc), cyclic-AMP- and cyclic-GMP-dependent kinases, myosin light chain kinase, Ca^{2+} /calmodulin dependent kinases, etc. Protein kinase R (PKR, dsRNA-dependent protein kinase) down-regulates protein synthesis in virus-infected cells. In the N-terminal region, two double-stranded RNA binding domains activate PKR by binding to dsRNA

and recruit it to the ribosome where it phosphorylates the eukaryotic elongation factor eIF2 α . The consensus sequences for a few protein kinases are shown below:

Protein kinase A
(?)-Arg-(Arg/Lys)-(?)-(Ser/Thr)-(?)
Protein kinase G
(?)-{[Arg/Lys] 2x or 3x}-(?)-(Ser/Thr)-(?)
Protein kinase C
(?)-([Arg/Lys] 1-3x)-([?] 0-2x)-(Ser/Thr)-([?]0-2x)-(Ser/[Thr]1-3x)-(?)
Ca⁺⁺/calmodulin kinase II
(?)-arg-(?)-(?)-(?)-(Ser/Thr)-(?)
Insulin receptor kinase
Thr-Arg-Asp-Ile-Tyr-Glu-Thr-Asp-Tyr-Tyr-Arg-Thr
EGF receptor kinase
Thr-Ala-Glu-Asn-Ala-Glu-Tyr-Leu-Arg-Val-Arg-Pro

(?) indicates any amino acid, the numbers after the amino acid with an "x" indicate how many times it may occur.

The majority of protein kinases require phosphorylation in their activation loop to perform their function. The human genome apparently includes 518 protein kinase genes. Protein kinases play an important role in signal transduction as well in the development of diseases (cancer), behavior and memory. Protein kinase inhibitors have therapeutic potentials. The inhibitors must pass the gatekeeper function of selectivity filters at the site of one or more amino acids (Cohen MS et al 2005 Science 308:1318).
►cAMP-dependent protein kinase, ►epinephrine, ►phosphorylase b kinase, ►signal transduction, ►obesity, ►PKB, ►kinase, ►TGF, ►EGF, ►PDGF, ►RAF, ►MYC, ►MAP, ►tyrosine kinase, ►selectivity filter; Plowman GD et al 1999 Proc Natl Acad Sci USA 96:13603; Ung TL et al 2001 EMBO J 20: 3728; Cohen P 2002 Nature Cell Biol 4:E127; Huse M, Kuryan J 2002 Cell 109:275; Manning G et al 2002 Science 298:1912; Noble MEM et al 2004 Science 303:1800; regulation: Nolen B et al 2004 Mol Cell 15:661; drug targets: Sebolt-Leopolt JS, English JM 2006 Nature [Lond] 441:457; protein kinase locking server: http://abcis.cbs.cnrs.fr/LIGBASE_SERV_WEB/PHP/kindock.php.

Protein Binding: Protein binding involves binding protein to protein, to RNA, and to DNA. Induced fit, van der Waals interactions, electrostatic interactions, hydrogen bonds, and aromatic stacking (involving mainly tyrosine and phenylalanine) have been implied. Organic chemistry also uses pi-pi (π - π) stacking. terms mentioned; Mignon P et al 2005 Nucleic Acids Res 33:1779; Hunter CA 2004

Angew Chem Int Ed Engl 43:5310; protein ligands: <http://www.bindingdb.org>.

Protein Knots: Structural sites for ligand binding and enzyme activity.

Protein L: *Peptostreptococcus* bacterial protein binding to the framework of immunoglobulin κ chains.
►immunoglobulins, ►framework amino acids

Protein Length: Protein length shows great differences among individual molecules by the number of amino acids. There is a statistically significant increase along the advancement in the evolutionary rank, e.g., in Archaeobacteria 270 ± 9 , in bacteria 330 ± 5 , and in eukaryotes (budding yeast and *Caenorhabditis*) 449 ± 25 . Some of the mammalian proteins are huge, e.g., dystrophin.

Protein Likelihood Method: The protein likelihood method is used to determine evolutionary distance when the organisms are not closely related and when the non-synonymous base substitutions are higher than the synonymous ones. In such cases, the protein method may provide more reliable information.
►evolutionary distance, ►evolutionary tree, ►least square methods, ►four-cluster analysis, ►un-rooted evolutionary trees, ►transformed distance, ►Fitch-Margoliash test, ►DNA likelihood method; Whelan S Goldman N 2001 Mol Biol Evol 18:691.

Protein Machines: Multimolecular interacting systems such as metabolic circuits, intracellular signal transduction, or cell-to-cell communication. These systems are operated under process control strategies involving integrated feedback control. The input and output of the circuits or modules are coordinated to assure the normal or adaptive function of the cell or organism. ►feedback control, ►microarray hybridization; Baines AJ et al 2001 Cell Mol Biol Lett 6:691; Tobaben S et al 2001 Neuron 31:987.

Protein Mapping: Protein mapping localizes the pattern of expression of genes by identifying the sites of proteins within cells. An automated, multidimensional fluorescence microscopy technology permits mapping and interaction of hundreds of different proteins in a single cell (Schubert W et al 2006 Nat Biotechnol 24:1270). ►gene expression map; Huh W-K et al 2003 Nature [Lond] 425:686; Ghaemmaghami S et al 2003 Nature [Lond] 425:737.

Protein Microarray: Microspots of proteins immobilized on solid support and exposed to samples of binding molecules. In such a system, enzyme-substrate and protein-ligand relations can be visualized by the use of fluorescence, chemiluminescence, mass spectrometry, radioactivity, or electrochemistry.
►protein chips, ►protein profiling, ►antibody microarray, ►chemiluminescence, ►fluorescence,

►mass spectrum; Templin MF et al 2002 Trends Biotechnol 20:160.

Protein Network: The protein network detects functional organization of genomes. Two proteins may be related to other in the cell in case the presence of one seems to affect the presence or absence of another. Such a relation exists if both are required to form a structural complex or if they carry out sequential steps in an unbranched pathway. Under natural, biological conditions the presence or absence of multiple proteins exists. Another simple situation is where three proteins are followed. These may display eight different relations, such as C being present only if both A and B are present or A being present if only either B or A are present and so on. The various probabilities or uncertainties of the clusters can then be calculated in a single genome and in phylogenetic relatives to obtain information of the protein network organization (Bowers PM et al 2004 Science 306:2246). ►genetic networks; <http://www.cellcircuits.org>.

Protein 4.1N: 4.1 N binds to the nuclear mitotic apparatus protein NuMA, a non-histone protein that is associated with the mitotic spindle. It regulates the antimitotic function of the nerve growth factor NGF. ►NGF, ►PIK; Kontragianni-Konstatonopoulos A et al 2001 J Biol Chem 276:20679; Scott C et al 2001 Eur J Biochem 268:1084.

Protein-Nucleic Acid Interaction: ►transcription factors, ►two-hybrid method; thermodynamics of interactions: <http://gibk26.bse.kyutech.ac.jp/jouhou/pronit/pronit.html>.

P

Proteins, Number of in a human cell: may exceed that of the number of genes by a factor 5 or more but at this stage it is not known.

Protein Phosphatases: Protein phosphatases remove phosphates from proteins. They include enzymes that reverse the action of protein kinases and have an important role, together with the kinases, in signal transduction. ►protein kinases, ►membrane fusion, ►FK506; Barford D et al 1998 Annu Rev Biophys Biomol Struct 27:133; Terrak M et al 2004 Nature [Lond] 429:780.

Protein pI: isoelectric point of proteins varies between <3 to >12. ►isoelectric point

Protein Profiling: The characterization or identification of proteins on the basis of sequence, structure, mass spectrum, MALDI, MS/MS, high-performance liquid chromatography, protein microarrays, two-dimensional gel electrophoresis, etc. ►proteomics, ►protein chips, ►antibody microarray

Protein Purification: To purify proteins, disrupt cells→separate subcellular organelles by differential centrifugation→wash by buffer the separated bodies→

treat the fraction(s) needed by denaturing agents→dialyze to remove the denaturing agent→use reducing agents for protection→concentrate→remove the unneeded or improperly folded protein fractions by ion-exchange chromatography, gel filtration, immunoaffinity, isoelectric focusing, high performance liquid chromatography or other steps→the wanted pure protein. Quantitate the amount or yield of the protein obtained by UV absorption or by the Lowry or Bradford methods. Each of these steps may need detailed operations. ►UV spectrophotometry of proteins, ►Lowry test, ►Bradford method

Protein Quality Control: ►unfolded protein response, ►endoplasmic reticulum-associated degradation

Protein Repair: Protein repair can be managed with assistance of chaperones. If the refolding is not feasible, proteolytic enzymes destroy proteins either directly or by the mediation of ubiquitins. Nascent polypeptides, transcribed from truncated mRNAs without a stop codon, acquire a C-terminal oligopeptide (Ala, Ala, Asn, Asp, Glu, Asn, Tyr, Ala, Leu, Ala, Ala or a variant), encoded by an *ssrA* transcript. The *ssrA* is a 362-nucleotide tRNA-like molecule that can be charged with alanine. The addition of the peptide tag takes place on the ribosome by cotranslational switching from the truncated mRNA to the *ssrA* RNA. The polypeptide chain so tagged is degraded in the *E. coli* cytoplasm or periplasm by carboxyl-terminal-specific proteases. The Clp chaperone recognizes the peptides by the *ssrA* tag of AANDENYALAA and targets the proteins to the ClpX and ClpA ATPases. ►amino acids, ►chaperone, ►ubiquitin, ►periplasm, ►protease, ►DNA repair, ►tmRNA, ►Clp, ►ssrA; Wawrzynow A et al 1996 Mol Microbiol 21:895.

Protein S (PROS): The human chromosome 3p11 vitamin K-dependent plasma proteins preventing blood coagulation and a cofactor for Protein C. Their deficiency and dysfibrinogenemia are genetically determined causes of thrombosis. ►protein C, ►anti-thrombin, ►dysfibrinogenemia, ►thrombosis, ►APC, ►anticoagulation, ►thrombophilia, ►tissue factor

Protein Sequencing: ►amino acid sequencing

Protein Shuttling: The flow of protein within cells or cellular organelles. (See Ando R et al 2004 Science 306:1370).

Protein Similarity Matrix: <http://mips.gsf.de/simap/>.

Protein Sorting (protein traffic): The mechanism by which the polypeptides synthesized on the ribosomes in the endoplasmic reticulum reach their destination in the cell through secretory pathways by transport, with the aid of endocytotic vesicles. ►endocytosis, ►clathrin, ►Golgi apparatus, ►COP transport vesicle, ►RAFT, ►Sec, ►Fts; Tormakangas K et al 2001 Plant Cell

Figure P149. Cyclic permutations of the secondary structure or domain swapping of the α and β strands is tolerated in many proteins. The essential feature of a protein fold is the complementary packing of the secondary structural elements and not the precise manner of connection of the elements. Some of these changes retain stability of the protein and binding ability and can be used in protein engineering. (Diagram is modified after Tabtiang RK et al 2005 Proc Natl Acad Sci USA 102:2305)

Protein Synthesis: Has many basic requisites and a large number of essential regulatory elements. It intertwines with all cellular functions. The blueprint for protein synthesis in the vast majority of organisms (DNA viruses, prokaryotes and eukaryotes) is in the nucleotide sequences of the DNA code. In RNA viruses the genetic code is in RNA. However, the viruses do not have their own machinery for the actual synthesis of protein, rather they exploit the host cell for this task. The genetic code specifies individual amino acids by nucleotide triplets, using one or several synonyms for each of the 20 natural amino acids. The triplet codons are in a linear sequence of the nucleic acid genes. In the organisms with DNA as the genetic material, the process of transcription produces a complementary RNA sequence from one or both strands of the anti-parallel strands of the DNA. The double-strands unwind and the RNA polymerase(s) synthesize(s) a complementary RNA copy of the sequence in the DNA. In the single stranded DNA and RNA viruses, the DNA or RNA may serve both purposes of being the genetic material and the transcript for protein synthesis. In cellular organisms three main classes of RNAs are made, messenger RNA (mRNA), transfer RNA (tRNA) and ribosomal RNA (rRNA), and all three are indispensable for protein synthesis. In addition to these RNAs, a large number of proteins are required for the transcription process (transcription factors), for the organization of the ribosomes (50–80 ribosomal proteins), for the termination of transcription, for the activation of the tRNAs, etc. A broad overview (without details) is shown in Figure P150. Some of the details of the transcriptional process are different in prokaryotes from that in eukaryotes. In the latter group, one DNA-dependent RNA polymerase is responsible for the synthesis of all RNAs. In eukaryotes, pol I synthesizes rRNAs with the exception of the 5S and 7S rRNA, pol II transcribes mRNA and the small nuclear RNAs (snRNA) and pol III synthesizes tRNAs and 5S and 7S rRNA.

Figure P150. An over-simplified view of the protein synthesizing machinery

In prokaryotes, the process of transcription and translation are *coupled*, i.e., as soon as the chain of mRNA unwinds from the DNA it is associated with the ribosomes and protein synthesis begins. The primary RNA transcripts must be processed to functional size molecules in all categories that may require splicing and other post-transcriptional modifications (capping, formylation, etc.).

In eukaryotes when the mRNA is released from its DNA template it moves into the cytosol where protein synthesis takes place. A small fraction of polypeptides may be synthesized also in the nucleus of eukaryotes (Iborra FJ et al 2001 Science 293:1058). There is evidence for the association of ribosomal

components into ribonucleoprotein complexes at the transcription sites of salivary gland chromosomes (Brognia S et al 2002 Mol Cell 10:93). The fate of the mRNA can be monitored by electronmicroscopy in both groups and these pictures show the elongation of RNA and protein strands (see Fig. P151). The first products of both display long strands and the short ones indicate the stage and place where they were started. The ribosomes are captured by the mRNA and form an association of multiple units in the form called *polysomes* (see Fig. P152).

The prokaryotic mRNA is directed to the proper position in the 30S ribosomal subunit by the Shine-Dalgarno nucleotide sequence within 8 to 13-base

Figure P151. Classical model of translation on ribosomes

area upstream from the initiation codon. In eukaryotes, such a sequence does not exist and the mRNA is simply scanned by the ribosome until the first methionine codon is found.

The ribosomal units then slide from the 5'-end of the mRNA toward the 3'-end and thus, the amino end of the polypeptide chain corresponds to the 5'-end of the mRNA. The ribosomes in both prokaryotes and

Figure P152. Transcription and translation coupled in *E. coli*. The thin thread is the DNA, the dark round structures are polysomes. The transcriptase attachment → is indicated. (From Hamkalo BA et al 1974 Stadler Symp 6:91)

eukaryotes are composed of a small and a large subunit. The size of these units is somewhat different in the two major taxonomic categories. The small and large subunits of the ribosomes jointly form two compartments, the so-called P (peptidyl-tRNA binding site) and the A (aminoacyl-tRNA binding site). A newer *hybrid-states model* of the translational process is described under the entry “ribosomes.” The ribosomes actually do not look like as shown in these diagrams, because they are three-dimensional and have a more elaborate structure. Before protein synthesis (translation) begins and the primary structure of the mRNA is translated from the nucleotide triplet codon words into the singular amino acid word language of the protein, the tRNA molecules must be charged with amino acids. This process is also called activation of tRNA. (► [aminoacyl-tRNA synthetase](#)).

The amino-acid-charged methionine-tRNA (tRNA^{Met}) in eukaryotes and the formylated $\text{tRNA}^{\text{fMet}}$ in prokaryotes seek out the cognate codon in the mRNA at the P site of the ribosome through the complementary anticodon. This event requires the presence of protein initiation factor(s) and GTP as energy source. The GTP is cleaved to GDP + inorganic phosphate (Pi) and thus liberates some of the needed energy. The elongation factor proteins and GTP and GDP complexes also police the system to prevent the wrong charged tRNA to go to an A site (proofreading function). Actually a similar correction mechanism is carried out earlier in the process by one of the active sites of the aminoacyl synthetase (activating) enzyme that usually dissociates the amino acid—tRNA link in case of a misalliance. With the double checks available, misincorporation of amino acids is approximately in the 10^{-4} range. Protein synthesis in the mitochondria and chloroplasts is essentially patterned after the prokaryotic systems.

The 5'-base of the anticodon triplet may not be the exact and conventional base, yet it may function

normally (► [wobble](#)). The two subunits of the ribosomes are combined and the second charged tRNA can now land at the A ribosomal site. The carboxyl end of the methionine forms a peptide bond with the amino terminus of the next incoming amino acid at the A site. This process is mediated by the enzyme peptidyl transferase. For this transferase function a 23S rRNA in the large subunit (a ribozyme) is responsible and not a protein. Again energy donors and elongation protein factors are cooperating in the process of peptide chain growth (► [initiation and elongation factors IF](#), ► [eIF](#), ► [EF](#), ► [EF-T](#), ► [EF-Tu](#)). When each peptide bond is completed the tRNA is released and recycled for another tour of duty. The *open reading frame* of the gene is terminated by a nonsense or chain-termination codon. When the ribosome slides to this point the mRNA is released from the ribosomes with the assistance of release factors (► [transcription termination in eukaryotes](#), ► [transcription termination in prokaryotes](#)). Protein synthesis proceeds at a rather rapid rate; it has been estimated that in *E. coli* 50–200 amino acids may be incorporated into peptides in 5–10 s. The process is slower in eukaryotes (3–8 s) (see Fig. [P153](#)). According to Princiotta MF et al 2003 (Immunity 18:343), the cells of the immune system produce 40 million proteins/min on the 6 million ribosomes.

The ribosomes have an important role in the regulation of protein synthesis. It appears that the availability of active ribosomes is controlled at the level of the transcription of the rRNA genes. In most of the cases, the number of ribosomes is not a limiting factor of translation. Some of the bacterial ribosome proteins have dual roles and participate in transcription and translation (Squires CL, Zaporjets D 2000 Annu Rev Microbiol 54:775). When the supply of ATP and GTP is adequate, rRNA genes are activated for transcription. In case the level of these nucleotide triphosphates is low, rRNA transcription is reduced or halted. Abundance of free ribosomal proteins may feedback-inhibit ribosomal production. The ribosome-associated Rel-A protein may mediate the formation of ppGpp from GTP (and possibly from other nucleotides). Then ppGpp may shut off rRNA and tRNA synthesis by binding to the promoter of RNA polymerase or to its antitermination signal.

Some of the nascent peptides are segregated into the endoplasmic reticulum through the Sec61 conductance opening of the large subunit of the ribosomes. Within the endoplasmic reticulum, the translation continues and the protein is folded by the appropriate chaperones. In prokaryotes, only the completed polypeptide chains are folded whereas in eukaryotes, the separate domains of the large polypeptides are folded as the chain grows.

Figure P153. An overview of eukaryotic translation

The dimeric NAC (nascent-polypeptide associated complex) interacts with the emerging polypeptide chains before 30 or fewer residue long chain is formed, and protects the nascent chain from becoming associated with other cytosolic proteins until the signal peptide fully emerges and then the signal recognition particle (SRP) crosslinks to the polypeptide. The purpose of the NAC is to assure that the polypeptide would be oriented to the proper SRP and the endoplasmic reticulum. Alternatively, if the protein does not carry a signal peptide, the nascent chain may be folded by chaperones such as heatshock proteins Hsp40 Hsp70 and TRiC. The completed amino acid sequences, the polypeptides, must be then converted to biologically active forms. This post-translational process may involve trimming (removal of some amino acids), proteolytic cleavage, folding to a tertiary structure, aggregation of different

polypeptide chains to form the quaternary structure, addition of prosthetic groups (such as heme, lipids, metals), and other non-amino-acid residues such as acyl, phosphate, methyl, isoprenyl and sugar groups.

Some proteins are expressed at very low level and by the classical methods of biochemistry or molecular biology the synthesis may not be detectable. A microfluidic device can, however, detect protein expression at the level of a single molecule (Cai L et al 2006 Nature [Lond] 440:358).

Protein Synthesis, Chemical: Building proteins from peptide domains by non-biological means. The peptides may be synthesized by the methods of organic chemistry and then ligated, spliced and folded in order to assure some specific function. Changing individual amino acids in the sequence may lead to new proteins. This procedure may become cumbersome because aggregation may create problems for proper folding. In contrast, solid phase synthesis is practical and any type of non-natural protein can now be produced using synthetic amino acids and peptides. Chemical synthesis of peptides requires stepwise addition of amino acids on solid support. Unfortunately, with the current technology (2005), routinely the synthetic proteins can be made only of about 40 residues although, e.g., 238-residue precursor of the green fluorescent protein has been made years ago (Nishiuchi Y et al 1998 *Proc Natl Acad Sci USA* 95:13549. [Bradley L et al. 2005 reviewed the principles of the various available peptide ligation techniques in *Annu Rev Biophys Biomol Struct* 34:91]. See Dawson PE, Kent SBH 2000 *Annu Rev Biochem* 69:923; Wei Y et al 2003 *Proc Natl Acad Sci USA* 100:13270).

Protein Synthesis Inhibitors: ►antibiotics, ►toxins, ►interferons

Protein Targeting: Can be co-translational, i.e., newly synthesized proteins are delivered to specific sites (endoplasmic reticulum) in the cell before the chain is completed or post-translational when the transport takes place after the polypeptide is completed. ►signal hypothesis, ►signal sequence recognition particle, ►translocon, ►TRAM, ►protein conducting channel, ►mitosome; Bachert C et al 2001 *Mol Biol Cell* 12:3152; Zaidi SK et al 2001 *J Cell Sci* 114:3093; Takayama S, Reed JC 2001 *Nature Cell Biol* 3:E237.

Protein Trafficking: ►protein sorting

Protein Transduction: The introduction of protein into the blood stream or organs for experimental or

therapeutic purposes. This procedure is usually limited to small size (<600 Da) molecules. When, however, the 120 kDa β -galactosidase was fused to an 11-amino acid NH₂ domain of the Tat protein of HIV and introduced into the intraperitoneal cavity of the mouse, the protein was detected in a biologically active form in several organs including the brain. ►AIDS, ►BBB, ►galactosidase, ►protein targeting; Embury J et al 2001 *Diabetes* 50:1706.

Protein Transport: ►protein sorting

Protein Truncation Test: The test may be used to detect the effects of several mutations that do not permit the completion of a polypeptide chain. The gene is transcribed by using polymerase chain reaction and the RNA is translated in vitro and the polypeptide is analyzed in SDS minigels. ►PCR, ►SDS-polyacrylamide gel, ►rabbit reticulocyte in vitro translation; Lutz S et al 2001 *Nucleic Acids Res* 29:E16.

Protein Tyrosine Kinases (PTK): The phosphorylate tyrosine residues in some proteins. This function is frequently coded for by v-oncogenes of retroviruses but cellular oncogenes and other proteins may be involved and are controlling signal transduction and other cellular processes such as cell proliferation and differentiation. Cytosolic tyrosine kinases preferentially phosphorylate their own SH2 domains or related SH2 domains with hydrophobic amino acids at key positions, e.g., Ile or Val at -1 and Glu, Gly or Ala at the +1 position. Receptor tyrosine kinases prefer Glu at -1 position. These preferences specify their signaling role. The RET oncogene's receptor tyrosine kinase product can shift substrate specificity and thereby cause multiple endocrine neoplasia. Quercetin, genistein, lavendustin A, erbstatin and herbimycin are all natural plant products and inhibitors of these enzymes. ►tyrosine kinase, ►receptor tyrosine kinase, ►protein kinases, ►SH2, ►endocrine neoplasia multiple, ►signal transduction; Hubbard SR, Till JH 2000 *Annu Rev Biochem* 69:373; Blume-Jensen P, Hunter T 2001 *Nature [Lond]* 411:355.

Protein Tyrosine Phosphatase: ►tyrosine phosphatases

Protein X: A hypothetical chaperone facilitator of the PrP^C → PrP^{Sc} conversion in prion diseases. ►prion

Protein Zero: A major part of the nerve cell myelin sheath of vertebrates. Its defect may lead to neurological anomalies.

Proteinase A: An endopeptidase involved in protein folding. ►endopeptidase, ►protein folding

Proteinase K: A proteolytic enzyme, frequently used to remove nucleases during the extraction of DNA and

RNA. With appropriate heat treatment any DNase associated with it can be safely removed. ►protease

Proteinoid: A polymerized mixture of amino acids formed during prebiotic stage of evolution (or simulated conditions in the laboratory). They may resemble primitive cells and display fission like phenomena (see Fig. P154). ►prebiotic

Figure P154. Proteinoid (From S. W. Fox., 1964 BioScience 14(12):13, © Am Inst Biol Sci)

Proteinosis: Anomalous accumulation of protein at particular structures of the body.

Protein-DNA Interaction: Takes place between transcription factors and the DNA template of the RNA. These interactions have been mapped in vivo over the entire mammalian genome (Johnson DS et al 2007 Science 316:1497). ►transcription factors, ►regulation of gene activity

Protein-Protein Interaction: Mediates structural and functional organization of the cells. The knowledge of these processes reveals the essential nature of the biology of organisms. The two-hybrid method may reveal the pair-wise interactions, and by sequential and systematic analysis the interacting systems, the metabolic modules can be identified. ►two-hybrid method, ►microarray hybridization, ►networks, ►gene product interaction, ►networks

Protein-RNA Recognition: Almost all RNA functions involve RNA-protein interactions such as regulation of transcription, translation, processing, turnover, viral transactivation and gene regulatory proteins in general, tRNA aminoacylation, ribosomal proteins, transcription complexes, etc.

Proteobacteria: Gram-negative purple bacteria, putative ancestors of mitochondria. ►NUMTs

Proteoglycan: Heteropolysaccharides with a peptide chain attached through O-glycosidic linkage to a serine or threonine residue. Such molecules are enzymes, animal hormones, structural proteins, basement membranes, cellular lubricants (such as mucin), extracellular matrix proteins and the “antifreeze proteins” of Antarctic fishes. They control plant and animal growth, differentiation, development and signal transduction. The proteoglycan-like xylogen accumulates in the meristem of plants and directs continuous vascular

development (Motoso H et al 2004 Nature [Lond] 429:873). ►antifreeze proteins, ►amyloids, ►glypican, ►syndecan, ►glycosaminoglycan, ►glycoprotein, ►phloeme, ►xyleme; Selleck SB 2000 Trends Genet 16:206.

Proteolipid Protein: A major part of myelin in the brain. ►myelin

Proteolysis: The hydrolyzing peptide bonds of proteins. The tobacco etch virus (TEV) NIa protease recognizes a seven-residue consensus (Glu-X-X-Tyr-X-Gln/Ser) sequence and does not affect proteins not containing it. The protease attached to the ribosomal exit site is most efficient and permits selective cleavage special target proteins (Heinrichs T et al 2005 Proc Natl Acad Sci USA 102:4246). ►proteasome, ►ubiquitin; Ciechanover A 2005 Nature Rev Mol Cell Biol 6:79.

Proteolytic: Enzymes hydrolyze peptide bonds in proteins. ►proteolysis, ►peptide bond, ►peptidase

Proteome: All the cellular proteins encoded by the cellular DNA; it is the protein complement of the genome. In bacteria 10% of the genes encode 50% of the bulk of the protein in eukaryotes ~90% of the proteome is contributed by 10% of the cellular proteins (Humphery-Smith I 2004, p 5 In: Albala JS, Humphery-Smith I (Eds.) Protein Arrays, Biochips, and Proteomics, Marcel Dekker, New York). The genome is very stable (except rare mutations) and it is the same in practically all cells of an organism. The proteome displays variations according to the developmental stage, organs, metabolic rate and health of the organism, etc. Since the proteins are organized and expressed in interacting systems, their study may be very complicated. While the genome does not reveal the detail of the function of a cell(s), proteomics has exactly this goal. The immediate products of the genome, the RNA is frequently processed in more than one way (alternative splicing and combinatorial assembly) to be translated into more than a single type of polypeptide. The translated product can be further modified by trimming, docking, forming multimeric associations, recruitment of ligand, phosphorylation and/or dephosphorylation, acetylation, glycosylation and various other epigenetic mechanisms. Because of alternatives in transcription (using different promoters and processing of the transcripts) there are in general substantially more proteins than genes in the cells. The proteins have also various regulatory roles at the levels of replication, transcription, translation, etc. The amount and kind of RNAs are correlated with the amount of polypeptides yet this correlation is variable. Proteins may undergo substantial post-translational modifications. Although the genome is essentially constant,

the encoded proteins may display great variations during differentiation and development. There are no well-established procedures “fit for all” proteins such as DNA sequencing after cloning, PCR or microarray hybridization. Two-dimensional gel electrophoresis is powerful for the separation of thousands of proteins and monoclonal antibody techniques can be used for the localization of proteins. Although definitive information on the proteome may not come easily it should permit an insight into the function of cells, organisms, evolution and disease that cannot be matched by other means. The size of the human proteome much exceeds that of the number of genes determined by sequencing the genome. The size of the human proteome has been estimated by the formula $N_{\text{CDS}} = f_1 \cdot f_2 \cdot N_{\text{genes}}$ where f_1 is the proportion of non-pseudogenic genes and f_2 is the ratio of the total number of protein-coding transcripts to the total number of genes, including those that are spliced alternatively. The estimates so obtained also vary within a wide range (see Harrison PM et al 2002 Nucleic Acids Res 30:1083). ►genome, ►genomics, ►metabolic pathway, ►transcriptome, ►monoclonal antibody, ►two-dimensional gel electrophoresis, ►two-hybrid method, ►protein chips, ►MALDI/TOF/MS, ►electrospray, ►ICAT, ►ACESIMS, ►MS/MS, ►microarray hybridization, ►networks, ►genetic network, ►TOGA, ►core proteome; protein–protein interaction: HUPO: <http://www.hupo.org>; ►Uniporter; <http://www.expasy.ch>; <https://www.proteome.com/proteome/>; <http://us.expasy.org>; human proteome: <http://www.hprd.org/>; mass spectrometric characterization of peptide fragments: <http://nwsr.bms.umist.ac.uk/cgi-bin/pepseeker/pepseek.pl?Peptide=1>; mass spectrum of body proteome: <http://www.mapuproteome.com>; ►protein, ►genomic sequences, ►exon structure, ►polarity, ►hydrophobicity; Ito T et al 2001 Proc Natl Acad Sci USA 98:4569; Walhaut AJM, Vidal M 2001 Nature Rev Mol Cell Biol 2:55; Harrison PM et al 2002 Nucleic Acids Res 30:1083; Auerbach D et al 2002 Proteomics 2:611; Burley SK, Bonnano JB 2002 Annu Rev Genomics Hum Genet 3:243; Rost B 2002 Curr Opin Struct Biol 12:409.

Proteomic Profiling: Uses chemical labels for the identification of active groups of enzymes in complex mixtures and attempts the identification of the functional role of these groups of proteins. The procedure may reveal the role of protein arrays in the development of disease and may suggest targets for intervention. (See Adam GC et al 2002 Nature Biotechnol 20:805).

Proteomics: The study of the system of the proteome, the modules of metabolism as they carry out cellular functions of the organisms. The new technologies

detect the composition/structure of proteins, isoforms, conformational changes, modulatory alterations during development, post-transcriptional and post-translational modifications (phosphorylation, glycosylation), interactions with other proteins or drugs, etc. With low mass tolerance, e.g., 10 ppm single proteins can be identified in a mixture among thousands of molecules. Proteomics has modified the basic approach to investigating biological function. Earlier the experimental design was based on hypotheses. With the aid of the proteomics technologies more direct approaches are possible based on the simultaneous expression patterns of interacting genetic networks. *Expression Proteomics* analyses proteins of the cells by two-dimensional gel electrophoresis (Wagner K et al 2002 Anal Chem 74:809). *Cell-Map Proteomics* is interested in the interaction between/among proteins at various phases of the cell function (Blackstock WP, Weir MP 1999 Trends Biotechnol 17(3):121). *Functional Proteomics* targets specific functions rather than the entire proteome (Graves PR, Haystead TA 2002 Microbiol Mol Biol Rev 66:39). *Structural Proteomics* seeks understanding of protein function on the basis of three-dimensional analysis and modeling (Norin M, Sundstrom M 2002 Trends Biotechnol 20:79; Sali A et al 2003 Nature [Lond] 422:216). *Reverse Proteomics* starts with the genes and proceeds to proteins. Liquid chromatography, two-dimensional polyacrylamide gel electrophoresis and tandem mass spectrometry are important tools of proteomics at large scale. Proteomics is concerned not only with the variability and interactions of proteins but may assist in modifying proteins for new types of interactions. The α -carboxyl group and preceding residues at the C-end of polypeptides may offer a useful target for modifications. The PDZ and TPR domains are well qualified for interactions with the C-termini and may facilitate temporal and spatial interactions, degradation, neuronal signaling and other functions (Chung JJ et al 2002 Trends Cell Biol 12:146). The proteome data are expected to be much more complex than that of the genome sequences. The number of proteins and their isoforms far exceeds that of the number of genes. There is a need to develop computer programs that can properly assist in interpreting the “mountain” of information. One of the most complete sources of information on the *E. coli* metabolic system is at: <http://ecocyc.org/>. The increasing amount of information is fast becoming impossible to integrate for a single human mind and advanced computer models are indispensable. Now proteomic information has important impact of applied biology such as medicine, drug development and agriculture. In painted artwork protein (egg white) has been used since the fourteenth century and before then as

binding material. These old paintings now need restoration and for doing the best work, it is necessary to determine in a minimally invasive way the material the artists used. Modern proteomics technology can reveal the nature of the binder used in Renaissance paintings in ~10 µg samples (Tokarski C et al 2006 Anal Chem 78:1494). ▶proteome, ▶PFAM, ▶Atlas human cDNA, ▶genomics, ▶annotation, ▶MALDI, ▶HMS-PCI, ▶TAP, ▶PDZ domain, ▶TPR, ▶peptide mass fingerprints, ▶NMR, ▶post-translational modification, ▶quadrupole, ▶LC-MS, ▶FTMS, ▶MS/MS, ▶ion trap mass analyzer, ▶linear ion trap analyzer, ▶two-dimensional gel electrophoresis, ▶two-hybrid system, ▶protein chips, ▶protein microarray, ▶X-ray crystallography, ▶genetic networks, ▶networks, ▶gene product interaction, ▶nucleolomics, ▶laser-capture microdissection, ▶MCA, ▶mass-coded abundance tagging, ▶display technologies, ▶MudPIT, ▶PEDRO, ▶protein engineering, ▶semisynthesis of proteins, ▶bioinformatics, ▶International Protein Index; Washburn MP et al 2001 Nature Biotechnol 19:242; Mann M et al 2001 Annu Rev Biochem 70:437; MOWSE 2001 Trends Biotechnol 19(10):Suppl; Fraunfelder H 2002 Proc Natl Acad Sci USA 99(Suppl 1):2479; Altman RB, Klein TE 2002 Annu Rev Pharmacol Toxicol 42:113; Regnier FE et al 2002 J Mass Spectrom 37:133; Laurell T, Mako-Varga G 2002 Proteomics 2:345; Auerbach D et al 2002 Proteomics 2:611; Petricoin EF et al 2002 Nature Rev Drug Discov 1:683; Huber LA 2003 Nature Rev Mol Cell Biol 4:74; Patterson SD, Aebersold RH 2003 Nature Genet 33 (Suppl):311; analytical methods: Phizicky E et al 2003 Nature [Lond] 422:208; Zhu H et al 2003 Annu Rev Biochem 72:783; de Hoog CL, Mann M 2004 Annu Rev Genomics Hum Genet 5:267; mass spectrometry methods: Domon B, Aebersold R 2006 Science 312:212; <http://www.ebi.ac.uk/interpro>; <http://dip.doe-mbi.ucla.edu/>; Proteomics Identification Database: www.ebi.ac.uk/pride/.

Proterozoic (precambrian): The geological period five billion to 570 million years ago. Aquatic forms of living systems appeared during this era. ▶geological time periods

ProtEST: A bioinformatics program tool for protein alignments. ▶UniGene; Wasmuth JD, Blaxter ML 2004 BMC Bioinformatics 5:187.

Proteus Syndrome: Involves gigantism of parts of the body probably caused by lipomatosis (abnormally large local fat accumulation). The genetic control is unclear. ▶PTEN; Cohen MM Jr 1993 Am J Med Genet 47:645.

Prothallium: The haploid gametophyte generation of ferns.

Prothrombin Deficiency: Caused by autosomal recessive, semidominant defects in the formation of anticoagulation factor VII, Stuart factor, Christmas factor and prothrombin. The human gene for prothrombin was assigned to chromosome sites 11p11-q12. Prothrombin is normally generated in sequential reactions by prothrombinase (Bianchini EP et al 2005 Proc Natl Acad Sci USA 102:10099). These proteins have similar proteolytic properties and the synthesis of all four depends on the presence of vitamin K. The patients have a tendency of bleeding similarly to hemophiliacs. Hereditary deficiency of factor VII itself is rare but it may be fatal if bleeding affects the central nervous system. Stuart factor deficiency has symptoms similar to those in deficiency of factor VII. All of these conditions can be treated by transfusion with blood plasma. ▶antihemophilia factors, ▶hemophilia, ▶vitamin K dependence, ▶coumarin-like drug resistance

Protist: A general term for single-cell eukaryotic organisms. The *Monera* including bacteria, blue green algae, viruses are also sometimes called protists although these are prokaryotes.

Protocell: Abiotic ancestor of living cells under prebiotic conditions. ▶origin of life

Protochlorophyll: The precursor of chlorophyll ($C_{55}H_{70}O_5N_4Mg$); if the magnesium is removed protophaeophytin results. The NADPH:protochlorophyllide oxidoreductases in the prolamellar body of the etioplast are required for the establishment of the photosynthetic apparatus (deetiolation) and for photoprotection in plants. ▶chloroplast, ▶etioplast, ▶NADP, ▶photomorphogenesis, ▶photosynthesis; Reinbothe S et al 2003 J Biol Chem 278:800.

Protogyny: In monoecious plants, the stigma is receptive before the pollen is shed. ▶protandry, ▶monoecious, ▶stigma, ▶self-incompatibility

Protomer: A polypeptide subunit of an oligomeric protein encoded by a cistron of a gene. ▶cistron, ▶oligomer

Proton: The positive nucleus of the hydrogen atom. The proton carries a positive charge equal to the negative charge of an electron but its mass is 1837 times larger.

Proton Acceptor: An anion capable of accepting protons. ▶anion, ▶proton

Proton Donor: An acid

Proton Pump: Mediates transport or exchange of protons across cellular membranes; energy is supplied usually by ATP or light. ▶proton, ▶ion pumps; Ferreira T et al 2001 J Biol Chem 276:29613.

Protonema: A filamentous stage in the formation of the gametophyte of mosses.

Protonoma: A red-color insensitive color blindness; an X-chromosomal anomaly. ▶color blindness

Proto-Oncogenes: These are cellular c-oncogenes, which after genetic alteration(s) may initiate or predispose to cancerous transformation. They generally have their counterparts in oncogenic viruses (v-oncogenes). Also, they may be involved in processes of signal transduction in a variety of organisms in fungi, plants and animals. ▶oncogenes, ▶signal transduction, ▶carcinogenesis, ▶tumor suppressors, ▶cell cycle

Protoperithecium: ▶ascogonia, ▶perithecium

Protoplasia: Formation of a new tissue.

Protoplasm: The viscous “live” content of the eukaryotic cell. ▶cytoplasm

Protoplast: A cell surrounded by the cell membrane but stripped of the cell wall, generally by a combination of pectin and cellulose digesting enzymes. Protoplasts under appropriate conditions may be regenerated into normal cells and intact plants (see Fig. P155). The bacterial protoplasts are generally called spheroplasts and may have some parts of the cell wall still attached. ▶cellulase, ▶macerozyme, ▶pectinase

Figure P155. Plant protoplast (Durand J et al 1973 Z. Pflanzenphys. 69:26)

Protoplast Fusion: Protoplasts may fuse in the presence of polyethylene glycol (and some other agents). The fusion may take place within sister cells or with the cells (protoplasts) of any taxonomically distant organisms such as mammalian and plant cells (see Fig. P156). These somatic hybrids, unlike the zygotes derived from the fusion of eggs and sperm, contain all the contents of the two cells, nuclei and cytoplasm, although some cytoplasmic organelles may be lost eventually.

In certain rodent-human cell hybrids even the human chromosomes may be eliminated; similar observations are available for carrot and parsley cell hybrids. When the genetic differences between the

Figure P156. Human HeLa cells attached to tobacco protoplast (a), the HeLa nucleus (larger) inside the tobacco cell (b). (From Jones CW et al Science 193:401)

fused protoplasts is large, the fused cells may not divide or may not divide continuously. Somatic hybrids between related species may, however, behave like allopolyploids and form fertile or sterile hybrids after regeneration. Fusion of animal cells with bacterial spheroplasts is shown in Figure P157. ▶cell fusion, ▶polyethylene glycol

Protoporphyria, Erythropoietic: An autosomal (human chromosome 18q21.3) dominant (or recessive) disease involving light-sensitive itching, inflammation of the skin. The porphyrin level of the blood may increase by over 16-fold, to 1 g/100 mL. The excess protoporphyrin is deposited in the liver, causing potentially serious damage. The basic defect probably involves a deficiency (10 to 25%) of the mitochondrially located ferrochelatase (FECH). ▶light-sensitivity defects, ▶mitochondrial disease in humans, ▶porphyria; Todd DJ 1994 Brit J Derm 131:751.

Protoporphyrin: The organic part of heme consisting of four pyrroles joined by methylene bridges. ▶heme

Protosilencer: On its own, it is incapable of silencing gene(s) or its silencing effect is minimal but it can reinforce and maintain the function of silencers. ▶silencers

Protosplice Site: Evolutionarily, the original splice site which is frequently AAG/CAG|GT where | is the insertion site. ▶splicing

Protostome: Organisms that develop the mouth from the blastopore such as annelids, molluscs, arthropods. ▶blastopore

Prototroph: A genotype that has wild type nutritional requirement. ▶autotroph, ▶auxotroph

Protozoa: Unicellular animals, mainly free-living (such as the *Paramecia*) some are, however, parasitic

Figure P157. Transformation of mammalian cells by fusion to bacterial spheroplasts. (Modified after Sandri-Goldin, RM et al 1983 *Methods Enzymol* 101:402)

(such as the *Giardias* which frequently contaminate drinking water sources), the *Trypanosomas* and *Leishmanias* which cause potentially lethal infections in animals and humans. ▶*Trypanosoma*, ▶*Leishmania*; for the genetic nomenclature of *Tetrahymena* and *Paramecia* see *Genetics* 149:459; micro- and macronuclear genes: <http://oxytricha.princeton.edu/dimorphism/database.htm>.

Provenance/Provenience: The origin of a genetic stock.
▶*accession*

Provirus: A DNA sequence in the eukaryotic chromosomal DNA that is a reverse transcriptase product of a retroviral RNA. ▶*retroviruses*, ▶*reverse transcription*, ▶*prophage*

Proximal: Situated in the vicinity of a reference point; e.g., a gene near the centromere is proximal, versus another that is in the direction of the telomere, and thus called distal. In conjugational transfer of bacteria

the marker that is transferred before another is the proximal. ▶*centromere*, ▶*telomere*, ▶*conjugation mapping*

Proximal Mutagen: A chemical that has been activated into a mutagenic substance; it may not have reached yet its most reactive state. ▶*promutagen*, ▶*activation of mutagens*, ▶*ultimate mutagen*, ▶*chemical mutagens*, ▶*activation of mutagens*

Proximity Ligation: A protein analysis technique using specific DNA sequences, which bind specific proteins. Sensitivity is much enhanced when polyclonal or monoclonal antibodies are used in connection with oligonucleotide extensions brought in the proximity of the target. ▶*antibody*; Gullberg M et al 2004 *Proc Natl Acad Sci USA* 101:8420.

PRP: An RNA-splicing factor component of the U snRNP complex. ▶*splicing*

PrP (protease resistant protein): ▶*prion*

Prp73: A mammalian chaperon binding to the first 20 residues (S peptide) of ribonuclease A and stimulates the uptake of polypeptides by lysosomes. ▶[ribonuclease A](#), ▶[Hsp70](#), ▶[lysosome](#)

Prp20p: The yeast homolog of RCC1. ▶[RCC](#)

PrPres (PrP^{*}): A partially protease resistant aggregate of PrP^C and PrP^{SC}. ▶[prion](#)

PrP-SEN: The general name of the protease-sensitive prion protein. ▶[prion](#)

PRR: Post-replication repair. ▶[DNA repair](#)

PRR: Positive regulatory region. ▶[negative regulation](#), ▶[Arabinose operon](#)

PRR: Pathogen recognition receptor.

PRTF: Pheromone receptor transcription factors, co-operating with GRM (general regulator mating factor) in the determination of mating type. ▶[pheromone](#), ▶[mating type determination in yeast](#), ▶*Schizosaccharomyces pombe*; Tan S, Richmond TJ 1990 Cell 62:367.

Przewalsky Horse: The Mongolian wild horse but can be found (~1200) only in captivity, although its reintroduction into the wild in Mongolia and China is underway. All existing individuals have descended from the 13 animals captured about a century ago. Its chromosome number is $2n = 66$ yet it makes viable hybrids with the domesticated species. ▶[horse](#)

PSA (prostate-specific antigen): A M_r 33,000 kallikrein type protease glycoprotein (APS) encoded at human chromosome 19q13. High levels of this protein in the serum may be an indication of prostatic carcinoma. The level of PSA varies a great deal and it is high after ejaculation and may provide false positive indication of cancer. It may serve as a target for cancer gene therapy. The six-transmembrane epithelial antigen of the prostate (STEAP, 7p22.3) is also elevated in prostate cancer. Hepsin (transmembrane serine protease) and pim-1 (serine/threonine kinase) levels are strongly correlated with prostate cancer as detected by tissue microarray analysis. The prostate-specific membrane antigen (PSMA) is highly expressed in prostate cancer cells and in other solid tumors. It is a glutamate carboxypeptidase and cuts methotrexate and the neuropeptide *N*-acetyl-L-aspartyl-L-glutamate; its crystal structure may facilitate drug development (Davis MI et al 2005 Proc Natl Acad Sci USA 102:5981). ▶[prostate cancer](#), ▶[cancer gene therapy](#), ▶[tissue microarray](#); Berry MJ 2001 N Engl J Med 344:1373; Dhanasekara S et al 2001 Nature [Lond] 412:822.

PSD-95: A family of membrane associated guanyl kinases; they also anchor K⁺ channels by their PDZ domains. ▶[ion channels](#), ▶[GTP](#)

PSE: Proximal sequence element. ▶[Hogness box](#)

PSE: Pale soft exudative meat is controlled in pigs by the *Halothane* gene.

Pseudoachondroplasia: A dominant human-chromosome 19p12-p13.1 gene mutation controlling the cartilage oligomeric matrix protein (COMP), and it is responsible for short stature (see Fig. P158). ▶[achondroplasia](#), ▶[multiple epiphyseal dysplasia](#), ▶[COMP](#); Hecht JT et al 1995 Nature Genet 10:325; Briggs MD, Chapman KL 2002 Hum Mut 19:465.

Figure P158. Left: Pseudoachondroplasia, Right: Normal extracellular cartilage matrix

Pseudoaldosteronism (Liddle syndrome): A human chromosome 4 hypertension associated with hypoaldosteronism, hypokalemia, reduced renin and angiotensin. ▶[aldosteronism](#), ▶[hypokalemia](#), ▶[renin](#), ▶[angiotensin](#)

Pseudoalleles: A cluster of not fully complementing genes, separable by recombination. Pseudoalleles, e.g., a^1 and a^2 when heterozygous in trans position $a^1 a^+ // a^+ a^2$ show mutant phenotype whereas in cis position $a^1 a^2 // a^+ a^+$ are complementary (wild type), except when dominant alleles are involved. Since these alleles are closely linked, in order to be able to prove that recombination takes place (rather than mutation), the pseudoalleles must be genetically marked by flanking genes within preferably less than 10 m.u. apart of the locus. ▶[complex locus](#), ▶[step allelomorphism](#), ▶[morphogenesis in Drosophila](#), ▶[cis-trans test](#), ▶[SSNC](#); Carlson EA 1959 Quart Rev Biol 34:33.

Pseudoaneuploid: The chromosome number appears aneuploid but it is not truly the case only, centromere fusion or misdivision of the centromeres have caused the changes in numbers. ▶[Robertsonian translocation](#), ▶[misdivision](#), ▶[B chromosomes](#)

Pseudoautosomal (PAR): Genes located in both telomeric regions of the X and Y chromosomes (~2.6 Mbp at the short arm [PAR1] and a similar PAR2 site in the long arm in the human genome) where recombination can take place and consequently, despite the sex-chromosomal location, sex-linkage is not obvious. A gene for schizophrenia was suggested to be pseudoautosomal. *SYBL1*, encoding a synaptobrevin-like protein is present in both X and Y chromosomal PAR regions and it displays lyonization in the X-chromosome and inactivation in the Y. The pseudoautosomal boundary is apparently spanned by one or another (depending on the species) 5'- or 3'-truncated gene. The short stature gene (*SHOX1/SHOXY*), the Leri-Weill dyschondrosteosis and a Hodgkin disease gene are all located in the PAR at Xpter-p22.32. The *SHOX2* gene is at 3q25-q26.

All human and chicken homologues of the snake Z-linked genes were located on autosomes, suggesting that the sex chromosomes of snakes, mammals, and birds were all derived from different autosomal pairs of the common ancestor (Matsubara K et al 2006 Proc Natl Acad Sci USA 103:18190). ▶ [auto-some](#), ▶ [sex determinations](#), ▶ [differential segment](#), ▶ [holandric genes](#), ▶ [syntagmin](#), ▶ [lyonization](#), ▶ [IL-9](#), ▶ [Hodgkin disease](#), ▶ [short syndrome](#); Ciccodicola A et al 2000 Hum Mol Genet 9:395; Cormier-Daire V et al 1999 Acta Paediatr 88 (Suppl):55.

Pseudobivalent: The chromosomes associated are not homologous. ▶ [synapsis](#), ▶ [illegitimate pairing](#)

P

Pseudoborder: DNA sequences in certain agrobacterial vectors or within the cloned foreign DNA and may cause deletions and rearrangements within the T-DNA inserts in the transgenic plants. ▶ [T-DNA](#), ▶ [transformation genetic](#)

Pseudocentromeric: ▶ [supernumerary marker chromosome](#)

Pseudocholinesterase Deficiency (CH1, BCHE): A dominant (human chromosome 3q26.1-q26.2) breathing difficulty (apnea) after treated with the muscle relaxant succinylmethonium (succinylcholine chloride), a drug used for intubation, endoscopy, cesarean section, etc., as an adjuvant to anesthesia. Several allelic forms respond differently to drugs. Individuals with a defective enzyme may be particularly sensitive to cholinesterase inhibitor insecticides (parathion). The frequency of the gene varies a great deal in different populations. In Eskimos, the frequency of the gene controlling the deficiency may be higher than 0.1; in other populations it may be less than 0.0002. The BCHE2 form was assigned to 2q33-35 and the same enzyme was suggested to 16p11-q23.

Pseudodiploidy: Retroviral particles because after infection only a single provirus is detected in the host. Normally retroviruses carry two RNA genomes associated by base pairing at several sites, particularly at the 5' end. It is assumed that the two copies are maintained for the purpose of assured survival and possible repair by recombination. They also contain tRNAs that prime replication. Other RNAs (5S, 7S and cellular mRNA fragments) may also be included.

▶ [retroviruses](#)

Pseudodominance: When a heterozygote loses the dominant allele, the recessive allele is uncovered (expressed) because of the lack of the dominant allele. Treating heterozygotes with mutagens (e.g., ionizing radiation) that cause deletions can readily induce pseudodominance. Before such experiments are conducted, it is advisable to place flanking genetic markers to the chromosome carrying the recessive markers to be able to rule out recombination and reversions. Segregation after somatic recombination may be a common cause of pseudo-dominance. Loss of heterozygosity is a frequent cause of oncogenic transformation. Pseudodominance-like phenomenon occurs in a population when the mating is between some cryptic heterozygotes. ▶ [deletion](#), ▶ [LOH](#), ▶ [segregation](#), ▶ [oncogenic transformation](#), ▶ [mitotic crossing over](#)

Pseudoextinction: The disappearance of a species by evolution into another form.

Pseudogamy: Apomictic or parthenogenetic reproduction. ▶ [apomixis](#), ▶ [parthenogenesis](#)

Pseudogene: Has substantial homology with (clustered) functional genes of eukaryotes but it is inactive because of numerous mutations that prevent its full expression and may no longer be available for transcription. Some pseudogenes are transcribed but the transcript is degraded by nonsense-mediated mRNA decay (Mitrovich QM, Anderson P 2005 Current Biol 15:963). Of the 201 pseudogenes identified by the 2007 ENCODE project, 20% were found to be transcribed (Zheng D et al 2007 Genome Res 17:839). Although pseudogenes may not have a protein product they may regulate the expression of their normal homolog either by stabilizing the normal transcript by blocking an RNase or by competitively inhibiting a transcriptional repressor (Hirotune S et al 2003 Nature [Lond] 423:91). The number of pseudogenes is variable in different species. The human genome may contain 20,000 pseudogenes. Organisms with small genomes (e.g., *Drosophila*) have very few and it appears that some organisms eliminated from their genome the DNA sequences that are no longer functional. Pseudogenes may make difficult the estimation of the number of

genes on the basis of incomplete sequences and lack of functional information. Pseudogenes originated either from duplication or in case of processed pseudogenes (without intron) by reverse transcription. Their nucleotide sequence is rather well conserved indicating functional significance. Paired-end diTAG (PET) analysis may permit their detection (Ruan Y et al 2007 Genome Res 17:828). ►C-value paradox, ►gene relic, ►processed pseudogene, ►duplications, ►mRNA surveillance, ►paired-end diTAG; Harrison PM et al 2001 Nucleic Acids Res 29:818; Avise JC 2001 Science 294:86; Echols N et al 2002 Nucleic Acids Res 30:2515; Balakirev ES, Ayala FJ 2003 Annu Rev Genet 37:123; human pseudogenes-gene conversion targets: <http://genome.uiowa.edu/pseudogenes/>.

Pseudohairpin: The overall structure is folded back yet there is not full complementarity along the strands (see Fig. P159).

Figure P159. Pseudohairpin

Pseudohemophilia: A bleeding disease, distinct from hemophilia; it is caused by some abnormalities of the platelets. ►hemophilia, ►platelet anomalies, ►hemostasis

Pseudohermaphroditism: ►hermaphrodite

Pseudohermaphroditism, Male: It is determined by a gene in human chromosome 17q12-q21. It is responsible for the deficiency of 17-ketosteroid reductase/17-β-hydroxysteroid dehydrogenase and consequently for feminization in prepubertal males and gynecomastia and virilization after puberty when usually the enzyme is expressed. The affected individuals may be surgically assisted to develop into sterile female phenotype (by removal of the hidden testes) or into male phenotype by reconfiguration of the external male genitalia. Infertility, however, cannot be corrected. Recessive mutations in the luteinizing hormone receptor gene (LHB, 19q13.32) may also be responsible. The condition may be due to deficiency of steroid 5-α-reductase (SRD5A2, 2p23). The SRDA1 isozyme encoded at 5p15 does not appear to be involved in this disorder. The afflicted XY individuals may have blind vagina and a rudimentary hypospadiac penis but no gynecomastia. They may produce viable sperm although they may sire offspring only by intrauterine insemination because of underdeveloped prostate and seminal vesicles. Several defects in steroid biosynthesis may cause male pseudohermaphroditism. The 17,20 desmolase deficiency is most likely X-chromosome linked. Lipoid adrenal hyperplasia

(8p11.2) responsible for complex defects in cortisol or aldosterone may cause even life-threatening conditions. Luteinizing hormone/choriogonadotropin receptor (LHCCGR, 2p21) may cause abnormalities of the Leydig cell differentiation in XY and possibly in XX individuals. Methemoglobinemia and deficiency of cytochrome b5 (18q23) may also cause pseudohermaphroditism. ►gynecomastia, ►polycystic ovarian cancer, ►hermaphroditism, ►infertility, ►testicular feminization, ►luteinization, ►Müllerian ducts, ►anti-Müllerian hormone, ►Reifenstein syndrome, ►hypospadias, ►Wilms tumor, ►adrenal hyperplasia, ►adrenal hypoplasia, ►androgen-insensitivity, ►methemoglobin, ►cytochromes

Pseudohitchhiking: Adaptive mutations near neutral loci may simulate genetic drift. ►hitchhiking

Pseudohomothallism: In the fungus (e.g., *Podospira anserina*) binucleate ascospores are formed and each spore contains both mating types and is thus self-fertile. ►homothallism, ►heterothallism

Pseudo-Hurler Syndrome: ►mucopolipidosis

Pseudohypha (in *Saccharomyces cerevisiae*): The formation occurs by deficiency of nutrient (N) and may cause polarized growth on the surface of the agar medium favoring delay in mitosis and precocious entry into meiosis. The pseudohyphal growth is symmetric and synchronous in comparison to the regular budding that is asymmetric and asynchronous. Cyclins 1 and 2 promote pseudohyphal growth whereas cyclin 3 is inhibitory in yeast. Alternative controls exist. Protein Ste12, the MAP kinase signal transduction pathways also regulate hyphal growth. Filamentous growth is a requisite for pathogenicity of *Ustilago maydis* and *Candida albicans*. ►cyclin, ►CDK, ►*Ustilago maydis*, ►candidiasis, ►MAP, ►Ste

Pseudohypoadosteronism (PHA; 1q31-q42, 17p11-q21, 12p13, 16p13-p12): hyperkalemic, hyperchloremic acidosis and hypertension. The genes at chromosomes 17 and 1 encode a threonine/serine kinase, WNK4, localized in the tight junctions. The disease in this protein is due to missense mutations. Mutations in WNK4 in mice cause higher blood pressure, hyperkalemia, hypercalciuria and marked hyperplasia of the distal convoluted tubule (DCT). WNT4 (chromosome 17) regulates the balance between NaCl reabsorption and K⁺ secretion (Laloti MD et al 2006 Nature Genet 38:1124) by altering the mass and function of the DCT through its effect on NCC (Na/Cl co-transporter). In chromosome 12 the cytoplasmic WNK1 is encoded and the defect is due to large intronic deletions that boost the expression of the protein. Both of these proteins are in the distal

nephron (a basic morphological and functional unit of the kidney) that is responsible for potassium and pH homeostasis. These two anomalies are dominant. The recessive PHA in chromosome 16 encodes subunits of an epithelial Na^+ ion channel. ▶aldosteronism, ▶Gordon syndrome, ▶hypoadosteronism, ▶hyperkalemic, ▶hypertension, ▶intron, ▶ion channels; Wilson FH et al 2001 Science 293:1107.

Pseudohypoparathyroidism: ▶Albright hereditary osteodystrophy

Pseudoknot: Formed when a stem-and-loop RNA structure is bound at the base of the loop by hydrogen bonds or by a ligand resulting in a two-stem two-loop stacking (see Fig. P160). The actual configurations of the pseudoknots may vary. Pseudo-half-knots form only a single loop. Such structures may modulate RNA functions and can be exploited also in designing highly selective drugs. Some insect RNA viruses, which use CAA (glutamine) rather than AUG (methionine) for translation initiation do not require an initiator tRNA but apparently rely on a pseudoknot formed between a 15–43 nucleotide upstream loop and the sequence immediately preceding the CAA codon. Pseudoknot structure is highly conserved in telomerases. Mutations that disrupt the pseudoknot helix abolished telomerase activity whereas intraloop hairpin base-pairing did not reduce telomerase activity (Chen J-L, Greider CW 2005 Proc Natl Acad Sci USA 102:8080). Pseudoknots initiate translational frame-shifting in overlapping genes. The Pseudoknot Local Motif Model and Dynamic Partner Sequence Stacking (PLMM_DPSS) algorithm, which predicts all PLM model pseudoknots within an RNA sequence in a neighboring-region-interference-free fashion. The PLM model is derived from the existing Pseudobase (collection of pseudoknots) entries and it is most sensitive. The innovative DPSS approach calculates the optimally lowest stacking energy between two partner sequences (Huang X, Ali H 2007 Nucleic Acids Res 35:656). ▶repeat inverted, ▶antisense RNA, ▶overlapping genes, ▶TFO, ▶telomerase, ▶frame-shifting ribosomal; Kim Y-G et al 1999 Proc Natl Acad Sci USA 96:14234; Xayaphoummine A et al 2003 Proc

Natl Acad Sci USA 100:15310; pseudoknot folding: <http://bibiserv.techfak.uni-bielefeld.de/pknotsrg/>.

Pseudolinkage: The linkage due to translocation between non-homologous chromosomes. ▶affinity

Pseudolysogen: Lyses the bacterial cells so slowly as if it would be lysogenic. ▶lysogeny

Pseudomonas: *Pseudomonas* bacteria include several species that degrade oil spills, polycyclic hydrocarbons, benzene and other pollutants. ▶oil spills, ▶biodegradation; Coates JD et al 2001 Nature [Lond] 411:1039.

***Pseudomonas aeruginosa*:** A 6.3 million-bp bacterium and an opportunistic human parasite. It is the most common cause of death in cystic fibrosis but it is involved in some pneumonias and other infections (urinary tract, burn victims, etc.). It grows also on soil and plant and animal tissues. This Gram-negative bacterium is highly resistant to antibiotics and disinfectants. Close to 10% of its genes is regulatory and the large number of its putative pump proteins explains its resistance to drugs. ▶cystic fibrosis; Stover CK 2000 Nature [Lond] 407:959; genome, annotations: <http://www.pseudomonas.com/>; <http://www.systomonas.de>.

***Pseudomonas* Exotoxin:** Kills by irreversible ribosylation of ADP and subsequent inactivation of translation elongation factor, EF-2. Its applied significance is the potential for cancer therapy. ▶toxins

***Pseudomonas syringae*:** A plant pathogenic relative of *P. aeruginosa*. The 6.5 megabase sequenced genome includes a circular chromosome plus two plasmids including 5763 open reading frames of which 298 are putative virulence genes. This bacterium may promote secondary infection by the same pathogen rather than display a hypersensitive response in the host by a jasmonic acid structural mimic (coronatine). It can increase susceptibility also to herbivorous insects without relying on coronatine (Cui J et al 2005 Proc Natl Acad Sci USA 102:1791). Related *Pseudomonas* subspecies, distinguished by host-specificity, display differences in genes of antibiotic resistance, DNA repair and ectoin ([4S]-2-methyl-1,4,5,6-tetrahydropyrimidine-4-carboxylacid), a natural protective agent against external harmful effects (Feil H et al 2005 Proc Natl Acad Sci USA 102: 11064). ▶ORF, ▶host–pathogen relation; Buell CR et al 2003 Proc Nat Acad Sci USA 100:10181.

***Pseudomonas tabaci*:** A bacteria causing “wildfire” disease (necrotic spots) on tobacco leaves (see Fig. P161). The symptoms may be mimicked by methionine sulfoximine, a methionine analog.

Figure P160. Pseudoknot

Figure P161. Wildfire disease spots (Courtesy of Dr. Peter. Carlson)

Pseudomosaic: May occur in a sample of amniocentesis caused by the conditions of culture rather than the genetic/chromosomal condition of the fetus.

Pseudo-Overdominance: Certain phenotype(s) may appear in excess of expectation in a population because of the close linkage of the responsible gene to advantageous alleles. Also QTL loci may appear overdominant if they are relatively closely linked and display heterosis because the QTL mapping techniques cannot determine the map positions with great accuracy, and the molecular function of the genes involved is not known. ▶overdominance, ▶fitness, ▶QTL, ▶interval mapping, ▶hitchhiking

Pseudopilus (Ψ -pilus): A bacterial appendage (~55 nm) that may extend beyond the cell surface into the periplasm and may be a conduit for macromolecular transport in bacteria. ▶pilus, ▶DNA uptake

Pseudoplasmodium: A migrating slug of cellular slime molds. ▶*Dictyostelium*

Pseudopodium: ▶amoeba

Pseudopregnant: Female (mice) mated with vasectomized males and then implanted with blastocyst stage embryos derived from other matings. ▶vasectomy, ▶allopheny

Pseudoqueen: In social insects (bees, ants, termites) one worker (XX) may become fertile pseudoqueen after the loss of the queen of the colony. This type of development is promoted by special feeding (royal treatment) of the originally worker caste insects. ▶honey bee

Pseudorecombinant: Reassortment of two viral genome components from different viruses, transmitted by the same insect vector.

Pseudoreplication: The samples are not independent replicates and the conclusion based on them may not be statistically reliable.

Pseudoreversion: An apparent back mutation caused by an extra-site suppressor mutation. ▶reversion

Pseudorheumatoid Dysplasia: A rare recessive cartilage defect due to mutation in the cysteine-rich secreted protein gene family (see Fig. P162). ▶arthritis, ▶rheumatic fever

Figure P162. Swollen joints of a finger in pseudorheumatoid dysplasia

Pseudosubstrate: A molecule with similarity to an enzyme substrate but it is actually an inhibitor, and special regulators are required for its removal so the enzyme is permitted to access its true substrate. ▶substrate, ▶intrasteric regulation

Pseudotemperate Phage: It has a lysogenic cycle yet does not have a stable prophage state, e.g., the PBS1 transducing phage of *Bacillus subtilis*. ▶lysogeny, ▶prophage

Pseudotransduction: The virus is not integrated into the chromosome and the passenger DNA can be expressed only from the cytoplasm when the appropriate promoter is present in the vector.

Pseudo-Trisomic: It is actually disomic but one of the chromosomes is represented by two telocentric chromosomes, each represent one and the other arm of the same chromosome, thus two telocentrics + one normal chromosome occurs. ▶trisomy, ▶telocentric chromosome

Pseudotype: The virus carrying foreign protein on his envelope and may expand the normal host range.

Pseudotyping: If two types of viruses invade the same cell, genetic material of one may slip into the capsid of the other and this type of packaging permits the introduction of the viral genome into a host, which otherwise would be incompatible with the virion. This phenomenon may be taken advantage of also during the construction of viral vectors and helper viruses. The ability of a virus to infect a certain type of cell depends on the interaction between the viral glycoprotein and the nature of the cell surface receptors. The vesicular stomatitis virus viral envelope glycoprotein (VSV-G) is highly fusogenic for a wide range of cell types and organisms. Thus, it can be employed for pseudotyped viral vectors to expand their effective host range. The hemagglutinating

paromyxovirus of Japan (HVJ) and other viruses can also be used similarly. ►[pseudovirus](#) [pseudovirion], ►[amphotropic](#), ►[ecotropic](#), ►[packaging cell lines](#), ►[retroviral vectors](#); Mazarakis ND et al 2001 Hum Mol Genet 10:2109; Peng KV et al 2001 Gene Ther 8:1456.

Pseudouridine (ψ): A pyrimidine nucleoside (5- β -ribofuranosyluracil) occurs in the T arm of tRNA by post-transcriptional modification of a uracil residue. Pseudouridine has been also found in ribosomal RNAs and snRNAs. The modification is mediated by the nucleolar ψ synthase with the assistance of other proteins. A requisite for the process is that a small nucleolar RNA (snoRNA) carrying a single stranded H box (ANANNA) and a ACA-3' Box would pair with the target RNA at about 12 or less region of complementarity. After the enzyme gained access to the U site, the N1—C1' bond in a uracil is severed and after a 180° rotation the C5 position becomes available for the formation of a new bond. Thus the N1 and N3 sites may become readily available for hydrogen pairing and pseudouridine can bind easier in inter- or intramolecular reactions. Pseudouridine deficiency is not lethal in yeast yet it adversely affects growth. The crystal structure and function of the H/ACA ribonucleoprotein, a member of pseudouridine synthases, has been determined (Li L, Ye K 2006 Nature [Lond] 443:302). ► ψ for formula, ►[tRNA](#), ►[snoRNA](#); Bortolin M-L et al 1999 EMBO J 18:457; Hoang C, Ferré-D'Amaré AR 2001 Cell 107:929.

Pseudovirion (pseudovirus): Contains non-viral DNA within the viral capsid and can thus be used to unload foreign DNA into a cell if a helper virus is provided. ►[virion](#), ►[capsid](#); Liu Y et al 2001 Appl Microbiol Biotechnol 56:150; Ou WC et al 2001 J Med Virol 64:366.

Pseudowild Type: Displays wild phenotype because a mutation at a site different from the mutant locus that it masks, but most commonly a duplicated segment, compensates for the original and still present recessive mutation. In *Neurospora* it occurs at much higher frequency than expected by back mutation. It may also be due to a suppressor mutation. (See Mitchell MB et al 1952 Proc Natl Acad Sci USA 38:569).

Pseudoxanthoma Elasticum (PXE, 16p13.1): Autosomal recessive or dominant disorders of an ABCG6 (multiple drug resistance) transporter causing by degenerative changes in the skin (peau d'orange = orange rind), veins, eyes, intestines, etc., resulting in heart disease and hypertension. The defect involves dysplasia of elastin fibers and it affects the skin, retina, arteries, teeth, etc. ►[coronary heart disease](#), ►[hypertension](#), ►[skin diseases](#), ►[ABC transporters](#);

Le Saux O et al 2001 Am J Hum Genet 69:749; problems of translation and advocacy of research models: Terry SF et al 2007 Nature Rev Genet 8:157.

Pseudo-Zellweger Syndrome: ►[peroxisomal 3-oxoacyl-coenzyme A thiolase deficiency](#), ►[Zellweger syndrome](#)

PSI (ψ): Pseudouridine, and also the packaging signal in retrovirions. ►[tRNA pseudouridine loop](#), ►[retrovirus](#), ►[retroviral vectors](#), pseudouridine formula on page at ► ψ

PSI⁺: A yeast prion, an extrachromosomal protein suppressing nonsense codons. It functions in collaboration with the nuclear genes *SUP35*. Overexpression of this gene induces the formation of PSI⁺ probably by a conformational change in the protein. Cells deleted in the amino-terminal region of Sup35 are resistant to PSI⁺. Expansion of imperfect oligopeptide repeats in Sup35 (PQGGYQQYN) and in PrP (PHGGWGQ) seems to be responsible for the abnormality. Overexpression of Hsp104 heat shock protein cures the cells from PSI⁺. ►[prion](#), ►[Hsp](#); Masison DC et al 2000 Curr Issues Mol Biol 2:51; Jensen MA et al 2001 Genetics 159:527.

Psi Vector: ►[E vector](#)

PSI-Blast: ►[Blast](#)

PsnDNA: 150–300 bp pachytene DNA sequences flanking 800–3000 bp internal chromosomal segments in eukaryotes, and the two short and the central DNA sequences are called PDNA (pachytene DNA). The PsnDNAs are supposed to be nicked by an endonuclease after homologous small nuclear RNA (snRNA) and a non-histone protein (PsnProtein) have opened the sequences to the action of the enzyme. These molecules appear only during late leptotene to pachytene and are assumed to be mediating recombination. ►[crossing over](#), ►[meiosis](#), ►[snRNA](#), ►[ZygDNA](#); Stern H, Hotta Y 1984 Symp Soc Exp Biol 38:161.

Psoralen Dye: Can combine with the DNA connecting nucleosomal core particles. After irradiation with near-ultraviolet light, cross-link between the two DNA strands occurs. Psoralen-conjugated triple helix forming oligonucleotides have been used to induce site-specific mutations in COS cells at very high frequency (see Fig. P163). Targeting psoralen cross-links with triple helix forming oligonucleotides can induce in base substitution and deletion mutations in mammalian cells. Deficiencies in non-homologous

Figure P163. Psoralen

end-joining and mismatch repair did not influence the mutation pattern. In contrast, the frequency of base substitutions depended on ERCC1 and DNA polymerase ζ but it was independent of nucleotide excision repair and transcription-coupled repair genes (Richards S et al 2005 *Nucleic Acids Res* 33:5382). Some celery stocks may contain higher than normal amounts of psoralen. ▶triple helix formation, ▶site-specific mutation, ▶COS cell, ▶DNMA repair, ▶DNA polymerases; Cimino GD et al 1985 *Annu Rev Biochem* 54:1151; Luo Z et al 1997 *Proc Natl Acad Sci USA* 97:9003; Oh DH et al 2001 *Proc Natl Acad Sci USA* 98:11271.

Psoriasis (PSOR): A scaly proliferation of keratinocytes, a type of autoimmune skin defect determined either by dominant gene(s) of reduced penetrance or polygenic inheritance involving relatively few genes. Its incidence is common in Caucasian populations (1–3%) but it is much less frequent in Orientals (Eskimos, American Indians and Japanese) and it was almost absent in Africa. Recurrence rate may vary (8–23% among first-degree relatives), depending on the type involved. If both parents are affected the recurrence among children may reach up to 75%. Concordance among monozygotic twins is 35% to 72% and only 12% to 23% in fraternal twins (Duffy DL et al 1993 *J Am Acad Dermatol* 29:428). The psoriasis haplotype appears to include HLA-BW 17, HLA-C and HLA-A 13 genes. Some observations indicate that bacterial superantigens may trigger psoriasis. Psoriasis-like skin disease and arthritis may be caused by epidermal deletion of Jun proteins in mice (Zenz R et al 2005 *Nature [Lond]* 437:369). Psoriasis susceptibility genes have been assigned to 16q, 10q, 19p13.3, 3q21, 1q21, 17q25, 4qter, 14q31-q32, 6p21 and 20p. Runx transcription factors may stimulate it. AP1/4/08 and AIRE may cause loss of self-tolerance (*Nature Genet* 17:399 [1997]). Linkage with other chromosomes is less certain. Psoriasis increases the risk of basal cell carcinoma. Microarray analysis revealed upregulation of transcription of at least 161 genes in psoriasis. Some the transcripts are modulated also in other skin diseases. ▶HLA, ▶keratosis, ▶ichthyosis, ▶skin diseases, ▶nevroid basal cell carcinoma, ▶Hirschsprung disease, ▶dermatitis atopic, ▶IL-20, ▶APEBEC, ▶AIRE, ▶Runx, ▶autoimmune disease, ▶Jun; Bhalerao J, Bowcock AM 1998 *Hum Mol Genet* 7:1537; Bowcock AM et al 2001 *Hum Mol Genet* 10:1793; Int Psoriasis Genet Consortium 2003 *Am J Hum Genet* 73:430; review: Schön MP et al 2005 *N Engl J Med* 352:1899; Bowcock AM 2005 *Annu Rev Hum Genet* 6:93; review: Lowes MA et al 2007 *Nature [Lond]* 445:866.

P{Switch}: ▶Gene-Switch, ▶hybrid dysgenesis

Psychiatric Disorder: ▶psychoses

Psychomimetic: Drugs affect the state of mind in a manner similar to psychoses. ▶psychoses, ▶psychotropic drugs, ▶ergot

Psychoses: A group of mental-nervous disorders with variable genetic and environmental components. ▶autism, ▶manic depression, ▶schizophrenia, ▶paranoia, ▶affective disorders, ▶attention deficit hyperactivity, ▶Tourette's syndrome, ▶IQ, ▶dyslexia, ▶panic disorder, ▶bipolar mood disorder

Psychopathology: The manifestation of a neuronal disease involved in mental and behavioral illness.

Psychotherapy: The treatment/support provided for transient or lasting emotional and behavioral disorders. It may involve verbal support or chemical medication. Genetic counselors need familiarity with the verbal support option. ▶counseling genetic

Psychotropic Drugs: These affect the state of mind. They are used as medicine in various types of psychoses and may be very beneficial (e.g., lithium, valium, etc.) if applied under medical monitoring. Possible adverse side effects vary by the chemical nature of the drug and may include heart disease, birth defects, addiction, etc. ▶psychoses, ▶psychomimetic

Psychrophiles: Organisms that grow under low temperatures. ▶antifreeze proteins

PTA Deficiency Disease: Controlled by incompletely dominant (4q35) genes. Plasma thromboplastic antecedent protein deficiency is involved that results in unexpected bleeding after tooth extraction or various surgeries. Nose bleeding (epistaxis) is common but uterine bleeding (menorrhagia) or blood in the urine (hematuria) is rare. The carrier frequency in Ashkenazy Jewish populations is about 8.1%. ▶antihemophilia factors, ▶pseudohemophilia

PTB (phosphotyrosine-binding domain): PTB is present in proteins involved in signaling. ▶SH2, ▶SH3, ▶WW, ▶SCK, ▶pleckstrin, ▶signal transduction

PTB (polypyrimidine tract binding protein, 58 kDa): Involved in regulation of eukaryotic mRNA metabolism, regulation of splicing, IRES-mediated translation initiation and mRNA stability. ▶splicing, ▶IRES, ▶translation; Oberstrass FC et al 2005 *Science* 309:2054.

PTC: ▶phenylthiocarbamide; also papillary thyroid carcinoma; a variant of the RET oncogene caused neoplasia. ▶RET

PtdInsP₂: ▶phosphoinositides

PTEN (phosphatase and tensin homolog; deleted in chromosome 10 [10ter-q11, 10q24-q26, 10q22-q23],

syn. MMAC1 [mutated in multiple advanced cancer]): A tumor suppressor involved in brain, prostate, breast, multiple hamartomas (Lhermitte-Duclos disease/Cowden syndrome), Bannayan-Zonona syndrome and other cancers. It inhibits cell migration and cell adhesion and dephosphorylates FAK, serine, threonine and tyrosine residues in proteins. The primary target of PTEN appears to be phosphatidylinositol-3,4,5 trisphosphate (PIP3) and acts as tumor suppressor by promoting apoptosis. PTEN and p53 mutually promote each other in tumor suppression (Chen Z et al 2005 Nature [Lond] 436:725). In vivo, PTEN may act as a lipid phosphatase and this function may be essential for tumor suppression. PTEN appears to guard centromere-kinetochore integrity and chromosomal stability (Shen WH et al 2007 Cell 128:157). The protein (tyrosine, serine/threonine) phosphatase activity may not be important for tumor suppression. Some cancer cells (glioma, prostate, breast cancer) may be reverted to normalcy by the addition of PTEN. The PTEN-Akt pathway probably governs stem cell activation by helping control nuclear localization of the Wnt pathway effector β -catenin. Akt phosphorylates β -catenin at Ser552, resulting in a nuclear-localized form in intestinal stem cells (ISC). Our observations show that intestinal polyposis is initiated by PTEN-deficient ISCs that undergo excessive proliferation driven by Akt activation and nuclear localization of β -catenin (He XC et al 2007 Nature Genet 39:189).

The catalytic domain identity motif is HCXXGXXRS/T. The two α -helix domains flanking the catalytic domain are encoded in its exon 5, and must be intact for proper function. The tensin-homology domain enables the recognition of the cell adhesion system (actin, integrin, FAK, Src). In mouse the *Pten*^{+/-} heterozygotes are subject to autoimmune disease and FAS-mediated apoptosis. The normal FAS function can be restored by the administration of phosphatidyl inositol 3 kinase. PTEN has an influence on cyclin D1 and signal transduction. Mutations in PTEN may be found in Proteus syndrome or Proteus-like syndrome. Experimental deletion of *Pten* (by using seven doses of polyinosine-polycytidine in *Mx-1 Cre* mice) initiated leukemia cancer stem cell as well as hematopoietic stem cell proliferation. Without *Pten*, the hematopoietic stem cells were depleted by time in a cell autonomous manner. In contrast, the leukemia stem cells became transplantable and progressed to leukemia within 4–6 weeks. Rapamycin, which targets TOR, however, depletes leukemia stem cells and rescues *Pten*-deficient hematopoietic stem cells. Thus the two types of stem cells can be distinguished (Yilmaz ÖH et al 2006 Nature [Lond] 441:475; Zhang J et al 2006 Nature [Lond] 441:518). ▶tumor suppressor, ▶tensin, ▶FAK, ▶multiple hamartomas syndrome, ▶Bannayan-Zonona syndrome,

▶polyposis juvenile, ▶AKT, ▶catenins, ▶Wingless, ▶phosphatidylinositol, ▶prostate cancer, ▶PIP2, ▶PIP3, ▶PIK, ▶TOR, ▶rapamycin, ▶hematopoiesis, ▶stem cell, ▶chemotaxis, ▶apoptosis, ▶wound healing, ▶Parkinson disease, ▶Proteus syndrome, ▶NEDD; Di Cristofano A, Pandolfi PP 2000 Cell 100:387; Wen S et al 2001 Proc Natl Acad Sci USA 98:4622; Maehama T et al 2001 Annu Rev Biochem 70:247; Waite KA, Eng C 2002 Am J Hum Genet 70:829; Zhou X-P et al 2003 Am J Hum Genet 73:404.

Pteridines: Purine derivatives, involved in coloring of insect eyes, wings, amphibian skin, etc. Pteridines may be light receptors. Reduction in tetrahydrobiopterin and related amines may be responsible for nervous disorders (see Fig. P164). ▶photoreceptors, ▶rhodopsin, ▶ommochromes, ▶GTP cyclohydrolase deficiency; Blau N et al 1998 J Inherit Metab Dis 21:433.

Figure P164. Pterine

Pterygium, Multiple, Syndrome (Escobar syndrome, 2q33-q34): The webbing of the neck and depressed areas (fossae) under the elbow, and other joints and hypogonadism in males, small labia and clitoris in females and other anomalies. ▶hypogonadism, ▶clitoris, ▶Popliteal pterygium

PTG (protein targeting glycogen): Forms complexes of phosphatases, kinases and glycogen synthase with glycogen. ▶glycogen, ▶kinase

PTGS: Post-transcriptional gene silencing presumably by degradation of the mRNA or inactivation of infectious (viral) RNA. Recent evidence indicates the presence of a 25-nucleotide long antisense RNA in the silenced cells. ▶RNAi, ▶RIGS, ▶methylation of DNA, ▶epigenesis, ▶post-transcriptional gene silencing, ▶RNA surveillance

Ptilinum: An inflatable head of the larva emerging from the puparium that cyclically is inflated/deflated to pry open the puparium by a wedging type of operation.

PTIP (PAX transactivation interacting domain protein): Contains tandem BRCA1 carboxy terminal domains (BRCT) and it is responsible for phosphorylation-dependent protein binding a condition required for DNA repair. The Met¹⁷⁷⁵ → Arg mutation in the BRCA1 (breast cancer) gene product fails to bind phosphopeptides and increases the susceptibility to

cancer. ►PAX, ►breast cancer; Manke IA et al 2003 Science 3002:636.

PTK: Protein-tyrosine kinase involved in regulation of signal transduction and in growth and differentiation of cells. ►protein kinases

Ptois: Drooping eyelid(s). ►epicanthus, ►blepharophimosis

PTP: ►tyrosine phosphatase, ►protein-tyrosine phosphatase non-receptor

PTPCR (PicoTiterPlate PCR): A DNA amplification procedure on an extremely small platform in pL quantities. Subsequently the products can be transferred to solid support and transcription, translation or sequencing can be carried out (Leamon JH et al 2004 Electrophoresis 25:1176). ►amplification, ►polymerase chain reaction, ►measurement units

PTPN (protein tyrosine phosphatase non-receptor type, PTPN22, 1p13): Associated with autoimmune diseases (diabetes I, rheumatoid arthritis, lupus, Graves thyroiditis, Addison disease, etc.). In case of a gain-of-function mutation the T cell produce lower amounts of interleukin-2 when stimulated the T cell receptors (TCR) and the phosphatase negatively regulates activation of T lymphocytes. (See Vang T et al 2005 Nature Genet 37:1317).

PTPRC: Protein tyrosine phosphatase receptor type C.

pu (particle units): Used for quantifying the number of potentially infectious virus particles per volume. It is a newer alternative for the *pfu* units but it is supposed to be employed for highly purified preparations. The particle count is determined from the absorbance at 260 nm according to the formula that 1 unit at $A_{260} = 1.25 \times 10^{12}$ particles/mL. Generally, it corresponds to 10–100 times of the *pfu* titer. ►*pfu*

PU.1 (PU1): A transcription factor in blood-forming cells regulating the differentiation of macrophages, B lymphocytes and monocytes; it belongs to the ETS family of oncogenes. Deletion of an upstream regulatory element (URE) leads to acute myeloid leukemia (Rosenbauer F et al 2006 Nat Genet 38:27). ►ETS, ►monocytes, ►macrophages, ►lymphocytes, ►leukemia, ►transcriptional priming; Dekoter RP, Singh H 2000 Science 288:1439; Lewis RT et al 2001 J Biol Chem 276:9550.

PubChem: Biological activities of small molecules database: <http://pubchem.ncbi.nlm.nih.gov/>.

Puberty: The time of sexual maturation, accompanied by the appearance of secondary sexual characteristics such as facial hair in males, enlargement of the breast in females, etc. Puberty is initiated by the secretion of gonadotropin releasing hormone by

the brain that activates the release of the pituitary hormones required for gonadal functions. It is facilitated by the KiSS-1 peptide and its receptor, GPR54 (Kaiser UB, Kuohung W 2005 Endocrine 26:277). ►gonadotropin, ►pituitary, ►gonads

Puberty Precocious: Autosomal dominant disorders occur in two forms: isosexual, when sexual maturation in both males and females takes place before age 10 and 8.5, respectively but may be even much earlier, especially in females. Another form is male-limited. Testosterone production seems to be independent from gonadotropin releasing hormone production. The disorder is associated with a defect in the luteinizing hormone receptor. ►luteinizing hormone-releasing factor, ►animal hormones, ►hormonal effects on sex expression, ►G-proteins

PubGene: A human gene-to-gene co-citation index involving 13,712 named human genes. (See Jenssen T-K et al 2001 Nature Genet 28:21).

Public Blood Systems: ►private blood groups

Public Opinion: In the underdeveloped world with inadequate educational systems, superstitions greatly affect people's view on all aspects of life and society. In the culturally and technically advanced nations the newspapers, television and Internet resources may influence public opinion to a great degree. Application of scientific principles is commonly decided by plebiscites or by legislative action. In a democratic society the citizens' view must necessarily be considered. The dilemma of how well informed is the general public or the legislative/governmental system regarding the implications of scientific principles is an important problem. In a survey in England the public indicated that automobiles are safer than trains. The actual statistics indicated, however, that the safety of trains is about 100 times better. People generally believe that atomic power plants expose the public to unnecessary health and genetic risks. The hazards burning fossil fuels or using wood fireplaces are much less frequently considered although they generate carcinogenic and mutagenic emissions. Very often even the scientists are unable to predict the future consequences of the scientific achievements they brought about as it was apparent by the consensus reached on recombinant DNA by the historical Asilomar Conference. The problems of using genetically modified organisms, cloning, stem cell applications cannot be resolved by political approaches. The problems created by technology and science can be resolved only by better scientific research. ►gene therapy, ►stem cells, ►GMO, ►recombinant DNA and biohazards, ►atomic radiations, ►informed consent, ►criticism on genetics

Publication Ethics: Subject to the same common sense rules as any other principle of ethics. The detailed guidelines in Human Reproduction 2001, vol 16:1783–1788 contain specific, valid points. Fabricated data in publications have serious effect on scientific research conducted in other laboratories unaware of the misconduct but faked reports are even more critical and dangerous when they influence clinical practice and may endanger life of patients (Unger K, Couzin J 2006 Science 312:38). ►ethics, ►misconduct scientific

PubMed Central: A digital archive of peer-reviewed journals containing >300,000 full text articles. Can be entered through Entrez. ►Entrez

PUBS: Percutaneous (through the skin) umbilical blood sampling, a method of prenatal biopsy for the identification of hereditary blood, cytological and other anomalies. ►amniocentesis, ►prenatal diagnosis

pUC Vectors: Small (*pUC12/13* 1680 bp, *pUC18/19* 2686 bp) plasmids containing the replicational origin (*ori*) and the *Amp^r* gene of pBR322, and they carry the *LacZ'* fragment of the bacterial β -galactosidase (see Fig. P165). The *Z'* indicates that within this region there is multiple cloning site (MCS) for recognition by 13 restriction enzymes. The orientation of the MCS is in reverse in pUC18 relative to pUC19. Genes inserted into *Lac* may be expressed under the control of the *Lac* promoter as a fusion protein. Most commonly, the insertion inactivates the *Lac* gene and white colonies are formed in Xgal medium rather than blue when the gene is active. The pUC vectors can be used with JM105 and NM522

E. coli strains. ►vectors, ►Xgal, ►Lac, ►filamentous phages; Messing J 1996 Mol Biotechnol 5:39.

Puccinia graminis: ►stem rust

PUF Proteins: They control mRNA stability by binding to the 3'-untranslated end. (Wickens M et al 2002 Trends Genet 18:150).

Puff: The swollen area of polytenic chromosomes active in transcription. Puffing is induced by expression of transcription factor genes regulated by steroid hormones (ecdysone).

Ecdysone formation comes in sequential pulses and thereby sequential activation of genes involved in metamorphosis of insects can be visualized at the level of the giant chromosomes. The puffs represent active transcription at particular genes, and the pattern of puffing shifts along the salivary gland chromosomes during development (see Fig. P166) and/or activation and the RNA extracted from the puffs reflect the differences in the base sequences of the genic DNA. Puffing has been described also in the rare polytenic chromosomes of some plant species, e.g., *Allium ursinum* or *Aconitum ranunculifolium*. These have been observed in specialized tissues of the chalaza or in the antipodal cells. ►giant chromosomes, ►ecdysone, ►PARP; Beermann W 1961 Verh Dtsch Zool Ges 1961:44; Mok EH et al 2001 Chromosoma 110:186.

Pufferfish, Japanese (*Fugu rubripes*, Tetraodontidae): A small vertebrate with about 365 Mbp DNA, i.e., only somewhat more than 1/10 of that of most mammals, and therefore it is suitable for structural and functional studies at the molecular level (see

Figure P165. pUC₁₉ (The diagram is the courtesy of CLONTECH Laboratories Inc., Palo Alto, CA.)

Figure P166. Selective activity of genes during development of the Dipteran fly *Rhynchosciara angela* is reflected in the puffing pattern of the salivary gland chromosomes. Lower case letters designate bands. Roman numerals indicate regions of the chromosomes. (After Breuer M E, Pavan C 1954. By permission from Kühn A 1971 Lectures on Developmental Physiology, Springer-Verlag, New York)

Figure P167. *Takifugu rubripes* (courtesy of Wikipedia; author Chris 73)

Fig. P167). More than 95% of the genome has been sequenced by 2002. About one-third of the genome is genic and repetitive sequences occupy less than one-sixth. The species, *Spheroides nephelus* is also used for studies of control of gene expression. *Tetraodon nigroviridis* ($n = 21$) DNA (27,918 genes) sequences have been used for the determination of human gene number. About 14,500 human ecores are conserved also in this pufferfish species ►[ecores](#); Crolius HR et al 2000 Genome Res 10:939; Aparicio S et al 2002 Science 297:1301; Jaillon O et al 2004 Nature [Lond] 431:946.

Pull-Down Assay: Expected to reveal interacting proteins. One of the proteins is attached to agarose beads and so immobilized. Then the test protein is added and the mixture is incubated to allow time for forming some links. Subsequently the mix is centrifuged. If there is a binding between them both proteins are found in the pellet and interaction is assumed. ►[immunoprecipitation](#), ►[genetic networks](#); Brymora A et al 2001 Anal Biochem 295:119.

Pullulanase: A secreted *Klebsiella* enzyme (~117 kDa) which cleaves starch into dextrin. It occurs also in the endosperm of cereals and other plant tissues and it is regulated by thioredoxin. ►[thioredoxin](#); Schindler I et al 2001 Biochim Biophys Acta 1548:175.

Pulmonary Adenoma: Lung cancer controlled by QTL. Dense SNP map of mouse identified the pulmonary susceptibility locus (*Pas1*) including within a 0.5 Mb region *Kras2* (Kirsten rat sarcoma oncogene 2) and *Casc1/Las1* susceptibility genes in chromosome 6. The *Glu102* allele of *Casc1* preferentially promotes susceptibility to tumorigenesis by chemicals (Liu P et al 2006 Nat Genet 38:888). Change from in the balance of expression of *Kras2* and *Pas1* entails susceptibility to resistance (To MD et al 2006 Nature

Table P3. Pulse-chase method. Autoradiographic analysis of the replication of the DNA in chromosomes by the pulse-chase procedure. (Drawn after Taylor JH et al 1957 Proc Natl Acad USA 43:122)

Genet 38:926). LKB1 hemizygosity or homozygous loss substantially accelerated pulmonary adenoma (Hongbin J et al 2007 Nature [Lond] 448:807). ▶QTL, ▶RAS, ▶small cell lung carcinoma, ▶non-small-cell lung carcinoma, ▶LKB

Pulmonary Emphysema: The increase in size of the air space of the lung by dilation of the alveoli (small sac-like structures) or by destruction of their walls. Smoking may be a cause.

Pulmonary Hypertension (PPH, FPPH): Characterized by shortness of breath, hypoxemia and arterial hypertension caused by the proliferation of endothelial smooth muscles and vascular remodeling. It is a 2q33 dominant disorder with reduced penetrance. Various drugs (such as the banned anti-obesity drug fen-phen) may trigger it. The basic defect is in gene BMPR2 (bone morphogenetic protein receptor II). Haplo-insufficiency may cause it. The consequence is inappropriate regulation by the serine/threonine kinases of the phosphorylated Smad proteins leading to inadequate maintenance of blood vessel integrity. ▶bone morphogenetic protein, ▶Smad, ▶hypertension, ▶haplo-insufficient, ▶bone morphogenetic protein, ▶Smad; Machado RD et al 2001 Am J Hum Genet 68:92.

Pulmonary Surfactant Proteins: ▶respiratory distress

Pulmonary Stenosis: ▶stenosis

Pulse-Chase Analysis: Expose cells, for a period of time, to a radioactive compound such as ³H-thymidine (pulse) and examine the labeling of chromosomes in some cells. The culture is then transferred to non-radioactive thymidine and allowed to complete a

division (chased to another stage) and study again the distribution of the label and determine its fate in the cells. The experiment permitted the first time the valid conclusion that DNA replication is semi-conservative. ▶radioactive tracer, ▶radioactive label, see Table P3.

Pulsed Field Gel Electrophoresis (PFGE): A procedure combining static electricity and alternating electric fields with gel electrophoresis for the separation of DNA of entire chromosomes of lower eukaryotes, such as of yeast and *Tetrahymena* or large DNA fragments cloned in YAC vectors of any genome cut by rare-cutting restriction enzymes. ▶CHEF, ▶FIGE, ▶OFAGE, ▶YAC, ▶PHOGE, ▶TAFE, ▶RGE; Mulvey MR et al 2001 J Clin Microbiol 39:3481.

Puma Cat (*Felis concolor*, *Puma concolor*): 2n = 38. (see Fig. P168).

Figure P168. Puma

PUMA (p53 upregulated modulator of apoptosis): ►p53, ►apoptosis, ►BAX, ►SLUG

PUMA2: The evolutionary analysis of metabolism, <http://compbio.mcs.anl.gov/puma2/>.

Pump: The various transmembrane proteins mediating active transport of ions and molecules through biological membranes. ►sodium pump

Punctuated Equilibrium: ►punctuated evolution

Punctuated Evolution: A theory that evolution would follow alternating periods of rapid changes and relatively stable intervals (punctuations). Natural selection of beneficial mutations appears after some intervals and spread over the population. At the DNA level about 22% of the substitutional changes represent punctuated evolution. Punctuational changes are more common in plants and fungi than in animals (Pagel M et al 2006 Science 314:119). ►speciation, ►beneficial mutation, ►neutral mutation, ►hopeful monster, ►shifting balance theory, ►gradualism; Gould SJ, Eldredge N 1993 Nature [Lond] 366:223; Elena SF et al 1996 Science 272:1797; Voigt C et al 2000 Adv Protein Chem 55:79.

Punctuation Codons (UAA, UGA, UAG): Terminate translation of the mRNA.

Punnett Square: Permits simple prediction of the expected pheno- and genotypic proportions. It is a checkerboard where on top and at the left column the male and female gametic output is represented and in the body of the table the genotypes are found (see Figure P169). If, e.g., the heterozygote has the genetic constitution of *Aa*, *Bb*, the gametes and genotypes will be AB, Ab aB and ab. In case of linkage and recombination the actual frequency of each type of gamete must be used to obtain the correct genotypic proportions in the body of the checkerboard. ►modified Mendelian ratios, ►Mendelian segregation

| Male gametes | | AB | Ab | aB | ab |
|----------------|----|----------|----------|----------|----------|
| Female gametes | AB | AB AB | AB Ab | AB aB | AB ab |
| | Ab | Ab AB | Ab Ab | Ab aB | Ab ab |
| | aB | aB AB | aB Ab | aB aB | aB ab |
| | ab | ab AB | ab Ab | ab aB | ab ab |

Figure P169. Punnett square

Pupa: A stage in insect development between the larval stage and the emergence of the adult (imago) (see Fig. P170). ►*Drosophila*, ►juvenile hormone

Figure P170. *Drosophila* pupa

Puparium: The case in which the *Drosophila* (and other insect) pupa develops for about four days after hatching of the egg, and in another four days the imago emerges. ►*Drosophila*

Pure Culture: Involves only a single organism. ►axenic culture

Pure Line: Genetically homogeneous (homozygous), and its progeny is expected to be identical with the parental line unless mutation occurs. (See Johannsen W 1909 Elemente der exakten Erblchkeitslehre, Fischer, Jena, Germany).

Pure-Breeding: Homozygous for the genes considered.

Purine: A nitrogenous base composed of a fused pyrimidine and imidazole ring; the principal purines in the cells are adenine, guanine, xanthine, hypoxanthine (but theobromine, caffeine and uric acid are also purines).

5',8-Purine Cyclodeoxynucleosides: Formed in two diastereoisomers by exposure of DNA to reactive oxygen species. The cyclopurines may cross-link the C-8 adenine or guanine and the 5' position of 2-deoxyribose (see Fig. P171). These diastereoisomers may block DNA replication and are cytotoxic.

Figure P171. 5',8-cyclo-2'-deoxyadenosine phosphate

Commonly excision repair may not correct the damage although the xeroderma pigmentosum A protein may cut at both flanks and excises them. These types of damaged nucleosides may accumulate by time and result in progressive neurodegeneration in xeroderma pigmentosum patients. ▶[cyclobutane](#), ▶[excision repair](#), ▶[xeroderma pigmentosum](#); Kuraoka I et al 2000 Proc Natl Acad USA 97:3837.

Purine Repressor (PurR): A member of the *Lac* repressor family of proteins regulating 10 operons involved in the biosynthesis of purine and affecting to some extent 4 genes controlling de novo pyrimidine synthesis and salvage. Its ca. 60 amino acids, the NH₂ domain binds to DNA and its ca. 280 residue COOH domain binds effectors and it functions in oligomerization. ▶[Lac repressor](#), ▶[salvage pathway](#); Moraitis MI et al 2001 Biochemistry 40:8109.

Purity of the Gametes: One of the most important discoveries of Mendel. At anaphase I of meiosis of diploids the bivalent chromosomes segregate and at anaphase II, the chromatids separate. Therefore, in the gametes of diploids only a single allelic form of the parents is present with rare exceptions, e.g., nondisjunction and polyploids. ▶[meiosis](#), ▶[nondisjunction](#), ▶[gene conversion](#), ▶[Mendelian laws](#)

Purkinje Cells: Large pear-shaped cells in the cerebellum, these are connected to multi-branched nerve cells traversing the cerebellar cortex. In the heart they are tightly appositioned cells transmitting impulses. ▶[cerebellum](#), ▶[motor proteins](#)

P

Puromycin: An antibiotic, it inhibits protein synthesis by binding to the large subunit of ribosomes; its structure resembles the 3'-end of a charged tRNA. Therefore it can attach to the A site of the ribosome and forms a peptide bond but it cannot move to the P site and thus causes premature peptide chain termination. ▶[antibiotics](#), ▶[signaling to translation](#), (see Fig. P172) formula

Figure P172. Puromycin

PUS: ▶[pyogenic](#)

Pushme-Pullyou (pushmi-pullyu) Selection: A positive-negative selection system to isolate engineered chromosomes in somatic cell hybrids, which have retained the segment positively selected for, and lost the regions selected against. (See Higgins AW et al 1999 Chromosoma 108:256; Trimarchi JM, Lees JA 2002 Nature Rev Mol Cell Biol 3:11).

PV16/18E6: A human papilloma virus oncoprotein. (▶[oncoprotein](#)) Burkitt lymphoma and murine lymphocytomas and may have activating role for MYC that is in the same chromosome. ▶[MYC](#), ▶[oncogenes](#), ▶[Burkitt lymphoma](#)

πVX: A microplasmid (902 bp) containing a polylinker and an amber suppressor for tyrosine tRNA. It can be used for cloning eukaryotic genes. ▶[recombinational probe](#)

PWM (position weight matrix): Used for identification of and search for functional nucleotide sequences, which are highly degenerate, e.g., the TATA boxes in the promoters. The PWM reflects the frequency of the four nucleotides (A, T, G, C) in an aligned set of different sequences sharing common function. After it had been determined in well-characterized core promoter regions, the PWM can be used to scan for TATA boxes in anonymous nucleotide sequences. The similarities between PWM and specific sequences and the matching value (within an accepted range) is determined and called a signal. Bucher (J Mol Biol 212:563) used a PWM for TATA box: GTATAAAGGCGGGG, and when the best fit was designated as 0, the majority of "unknown" TATA boxes scored within 0 to -8.16. Some of these might be, however, false positives. ▶[TATA box](#), ▶[core promoter](#), ▶[anonymous DNA segment](#), ▶[position-specific scoring matrix](#); Audic S, Claverie J-M 1998 Trends Genet 14:10.

PX (phox): A 125-amino acid module present in a variety of proteins involved in binding phosphoinositides.

P2X₁: A receptor for ATP in the in ligand-gated membrane cation channels. P2X is a component of the contractile mechanism of the vas deferens muscles, which propel the sperm into the ejaculate during copulation. Its defect entails ~90% sterility although without apparent harm to the male or the female mice. It has also several other signaling functions. ▶[vas deferens](#), ▶[ion channels](#), ▶[congenital aplasia of the vas deferens](#); Khakh BS, North RA 2006 Nature [Lond] 442:527.

PX DNA: A four-stranded molecule where the parallel helices are held together by reciprocal recombination at every site of juxtaposition. Its topoisomer is JX₂ and it also contains adjacent helices but there is no reciprocal exchange at the contact points. (See Yan H et al 2002 Nature [Lond] 415:62).

Pxr: ►SXR

Pycnidium: A hollow spherical or pear-shaped fruiting structure of fungi producing the pycnidiospores, which are released through the top opening, the ostiole. ►stem rust

Pycnodysostosis: A rare autosomal recessive (1q21) human malady characterized by defects in ossification (bone development) resulting in short stature, deformed skull with large fontanelles (soft, incompletely ossified spots of the skull common in fetuses and infants) and general fragility of the bones. The primary defects appears to be in cathepsin K, a major bone protease although interleukin-6 receptor has also been implicated. (see Fig. P173) ►Toulouse-Lautrec, ►cleidocranial dysostosis, ►cathepsins

Figure P173. The famous French artist Henri Toulouse-Lautrec (1864–1901) might have suffered from this malady and his self-portrait reveals some of the characteristics of the malformations. The exact nature of his condition cannot be diagnosed but it is known that his parents were close relatives. (By permission of the St. Martin Press, New York)

Pycnosis (pyknosis): A physiological effect of ionizing radiation on chromosomes expressed as clumping or stickiness. It is dose-dependent and the late prophase stage irradiation is most effective in causing it. Anaphase proceeds but the chromosomes have difficulties in separation, display chromatin bridges and may break up into fragments. ►bridge, ►karyorrhexis, ►heteropycnosis, ►acinus

Pygmy: The Central African human tribe of about 100,000 has an average height of 142 cm. In comparison, the average height of Swiss and Californian is 167–169 and 170–172 cm, respectively. The Pygmies do not respond to exogenous somatotropin but the concentration of serum somatomedins in the adolescent Pygmies is about a third below that in non-Pygmies of comparable

age. Although the shortness of Pygmies appears recessive, intermarriages indicate polygenic determination of height. ►dwarfism, ►stature in humans, ►nanism, ►somatomedin, ►somatotropin

PYK2: Protein tyrosine kinase links Src with G_i and G_q-coupled receptors with Grb2 and Sos proteins in the MAP kinase pathway of signal transduction. Lyso-phosphatidic acid (LPA) and bradykinin stimulate its phosphorylation by Src. Over-expressing mutants of Pyk or the protein tyrosine kinase Csk reduces the stimulation by LPA, bradykinin or over-expressed Grb2 and Sos. ►CAM, ►MAP, ►Src, ►G_i, ►G_q, ►lysophosphatidic acid, ►kininogen, ►Csk, ►Grb2, ►Sos, ►signal transduction; Felsch JS et al 1998 Proc Natl Acad Sci USA 95:5051; Sorokin A et al 2001 J Biol Chem 276:21521.

Pyknons: Short RNA motifs shared by genic and non-genic transcript regions of the human genome and are presumably mediating post-transcriptional gene silencing and RNA interference. Pyknons are most frequent in the 3'-nontranslated areas of genes (Rigoutsos I et al 2006 Proc Natl Acad Sci USA 103:6605).

Pyknosis: ►pycnosis

Pyloric Stenosis: A smaller than normal opening of the pylorus, the lower gate of the stomach that separates it from the small intestine (duodenum). It does not appear to have independent genetic control but it is part of some syndromes. It affects males five times as frequently as females; the overall incidence for both sexes is about 3/1000 birth. About 20% of the sons of affected females display this anomaly but only about 4% of the sons if the father has the malady. It may be caused by a deficiency of neuronal nitric acid synthase. ►sex-influenced, ►nitric oxide, ►imprinting

PYO: Personal years of observations; a term used in medical and clinical genetics

Pyocin: A bacteriotoxic protein produced by some strains *Pseudomonas aeruginosa* bacteria. ►bacteriocins

Pyogenic: Producing pus (DNA and protein-rich) excretum upon inflammation containing leukocytes in a yellowish fluid. It is produced abundantly by the body also after *Streptococcus* and *Staphylococcus* and other bacterial infections. ►IRAK, ►leukocyte, ►Streptococcus, ►Staphylococcus

Pyramidal Cells: Excitatory neurons in cerebral cortex. ►brain, ►neuron

Pyramiding: To build up on a larger base; to accumulate in plant protection introduction of more than one gene

and different transgenes into a plant variety conveying resistance to the same agent, in order to slow down or prevent development of resistance in the pathogen or pest.

Pyrene: A fluorochrome, frequently used as a bimolecular excimer (see Fig. P174). Pyrene incorporation into the sugar position of DNA by one carbon linker results in very weak monomer fluorescing because of quenching. Similar was the observation with RNA or RNA–DNA hybridization. Pyrene-modified RNA displayed drastically increased fluorescence however when paired with complementary RNA and is a useful tool for monitoring RNA hybridization (Nakamura M et al 2005 Nucleic Acids Res 33:5887). ▶FRET, ▶excimer

Figure P174. Pyrene

Pyrenoid: A dense, refringent protein structure in the chloroplast of algae and liverworts associated with starch deposition. ▶chloroplast

Pyrethrin (pyrethroids, permethrin): Insecticides are natural products of *Pyrethrum* (*Chrysanthemum cinerariaefolium*) plants (Compositae). They affect the voltage-gated Na⁺ ion channels and humans may have severe allergic reactions to pyrethrins. ▶ion channels, ▶insecticide resistance

Pyrethrum (*Chrysanthemum* spp): A plant source of the natural insecticide, pyrethrin, with basic chromosome number $x = 9$ (see Fig. P175). Some species are diploid or tetraploids or hexaploids. ▶pyrethrin

Figure P175. Pyrethrum

Pyridine Nucleotide: A coenzyme containing a nicotinamide derivative, NAD, NADP.

Pyridoxine (pyridoxal): Vitamin B₆ is part of the pyridoxal phosphate coenzyme, instrumental in transamination reactions (see Fig. P176). In *E. coli* bacteria vitamin B₆ is synthesized through deoxyxylulose 5-phosphate and phosphohydroxy-L-threonine. In plants (*Arabidopsis*) the synthetic pathway differs in as much as it is biosynthesized from ribose 5-phosphate or ribulose 5-phosphate and from dihydroxyacetone phosphate or glyceraldehyde 3-phosphate in the cytosol rather than in the chloroplasts (Tambasco-Studart M et al 2005 Proc Natl Acad Sci USA 102:13687).

Figure P176. Pyridoxine

An apparently autosomal recessive disorder in humans involving seizures is caused by pyridoxin deficiency because of a deficit in glutamic acid decarboxylase (GAD) activity and consequently insufficiency of GABA, required for normal function of neurotransmitters. Administration of pyridoxin caused cessation of the seizures. The GAD gene was located in the long arm of human chromosome 2. An autosomal dominant regulatory pyridoxine kinase function has also been identified in humans. ▶epilepsy

Pyridoxine Dependency: It may manifest as autosomal recessive seizures with perinatal onset (around birth).

Pyrimidine: A heterocyclic nitrogenous base such as cytosine, thymine, uracil in nucleic acids but also the sedative and hypnotic analogs of uracil, barbiturate and derivatives (see Fig. P177). Pyrimidine biosynthesis may follow either a de novo or a salvage pathway. Some of the pyrimidine moieties, e.g., of thiamin are biosynthesized through a route different from that of nucleic acid pyrimidines. ▶J base, ▶thiouracil, ▶pseudouracil, ▶de novo synthesis, ▶salvage pathway, ▶formulas; Fox BA, Bzik DJ 2002 Nature [Lond] 415:926.

Pyrimidine Dimer: Cross-linked adjacent pyrimidines (thymidine or cytidine) in DNA causing a distortion in the strand involved and thus interfering with proper functions (see Fig. P178). It is induced by short-wavelength UV irradiation. The thymidine dimers may be split by visible light-inducible enzymatic repair (light repair) or by excision repair (dark repair). ▶cyclobutane ring, ▶physical mutagens, ▶genetic repair, ▶DNA repair, ▶photolyase, ▶CPD, ▶glycosylases, ▶pyrimidine-pyrimidinone photoproduct,

Figure P177. The major cellular pyrimidines

Figure P178. Cross-linked neighboring thymines in the DNA

Figure P179. Thymine–Cytosine photoproduct

► [photoreactivation](#); Otoshi E et al 2000 *Cancer Res* 60:1729.

Pyrimidine Dimer N-Glycosylase: A DNA repair enzyme that creates an apyrimidinic site. Then the phosphodiester bond is severed and a 3'-OH group is formed on the terminal deoxyribose. Exonuclease 3'→5' activity of the DNA polymerase splits off the new 3'-OH end of the apyrimidinic site. After this, the replacement-replication—ligation process repairs the former thymine dimer defect. ► [glycosylase](#), ► [DNA repair](#), ► [pyrimidine dimer](#); Piersen CE et al 1995 *J Biol Chem* 270:23475.

Pyrimidine 5'-Nucleotidase Deficiency (P5N): May cause hereditary hemolytic anemia as the pyrimidines inhibit the hexose monophosphate shunt in young erythrocytes. There are two isozymes of which P5N1 is most commonly the cause of the anemia. ► [pentose phosphate pathway](#), ► [anemia](#); Marinaki AM et al 2001 *Blood* 97:3327.

Pyrimidine-Pyrimidinone Photoproduct: A pyrimidine dimer involving a 6—4 linkage between thymine and cytosine (see Fig. P179). ► [cyclobutane](#), ► [Dewar product](#), ► [cis-syn dimer](#), ► [translesion pathway](#), ► [photolyase](#); Vreeswijk MP et al 1994 *J Biol Chem* 269:31858.

Pyrimidone: Hydroxypyrimidine (see Fig. P180).

Figure P180. 4(6)-hydroxypyrimidine (left); 2-hydroxypyrimidine (right)

Pyrimidopurines: A malondialdehyde-DNA adduct derived from deoxyguanosine. ► [adduct](#)

Pyronin: A histochemical red stain used for the identification of RNA.

Pyrosequencing: Used for the analysis of the nucleotide sequence of less than 200 base long DNA strands for the detection of mutational alteration(s). Pyrosequencing has been applied to the analysis of the genome of Neanderthals. It uses the enzymes DNA polymerase, sulfurylase, firefly luciferase and apyrase. The incorporation of the nucleotides (which are not labeled) in the growing end is monitored by light flashes in a single tube. Electrophoresis is not used. Nucleotide triphosphates added to the reaction in sequence. Visible light is generated and detected when pyrophosphate is released during incorporation

from the nucleotide triphosphates with the cooperative effects of the sulfurylase and the luciferase. This is a very fast procedure and may be automated.

Another fast and convenient method of sequencing by synthesis involves four chemically cleavable fluorescent nucleotide analogues as reversible terminators. Each of the nucleotide analogues contains a 3'-*O*-allyl group and a unique fluorophore with a distinct fluorescence emission at the base through a cleavable allyl linker. These nucleotide analogues are good substrates for DNA polymerase in a solution-phase DNA extension reaction and that the fluorophore and the 3'-*O*-allyl group can be removed with high efficiency in aqueous solution. By this procedure 20 continuous bases of a homopolymeric DNA template immobilized on a chip were accurately sequenced. Such a method can be extended eventually to longer sequences (Ju J et al 2006 Proc Natl Acad Sci USA 103:19635).

►DNA sequencing, ►sulfurylase, ►luciferase, ►apyrase, ►Neanderthal; Ronaghi M 2001 Genome Res 11:3; Marziali A, Akeson M 2001 Annu Rev Biomed Engr 3:195; Fakhrai-Rad H et al 2002 Hum Mut 19:479; Goldberg SMD et al 2006 Proc Natl Acad Sci USA 103:11240; Margulies M et al 2005 Nature [Lond] 437:376; note corrigendum Nature [Lond] 441:120.

Pyrrole: A saturated five-membered heterocyclic ring such as found in protoporphyrin. Pyrrole-imidazole polyamides may bind to specific DNA of the transcription factor TFIIIA and regulate the transcription of the 5S RNA. *N*-methylimidazole (Im)—*N*-methylpyrrole (Py) may target G=C and Py—Im the C=G base pairs, respectively. The Py—Py combination is specific for T=A and A=T. ►porphyrin, ►porphyria, ►heme

Pyrrolizidine Alkaloids (petasitenine, senkirkine): Occur in several plant species (*Tussilago*, *Heliotropium*, etc.) and some of which are used as food or medicinal plants but they are mutagenic/carcinogenic. They occur also in some moths and convey protection against predators. ►Echinacea; Ober D, Hartmann T 1999 Proc Natl Acad Sci USA 96:14777.

PZD: ►micromanipulation of the oocyte
Historical vignette

“...alle essentiellen Merkmale...epigenetisch sind, und da die Determinierung ihrer Spezifität durch den Kern erhalten.”

“... all characters are epigenetic and their specificity depends on the cell nucleus.”

Pyrrolysine: The 22nd amino acid encoded in Archaea and Eubacteria by the stop codon UAG. Pyrrolysine is charged to tRNA^{CUA} (encoded by *pylT*) by PylS aminoacyl-tRNA synthetase and thus can be incorporated into *E. coli* proteins (Blight SK et al 2004 Nature [Lond] 431:333). ►amino acids, ►genetic code, ►aminoacyl tRNA synthetase, ►unnatural amino acids, ►selenocysteine; Hao B et al 2002 Science 296:1462; Srinivasan G et al 2002 Science 296:1459; pyrrolysyl-tRNA synthetase crystal structure: Kavran JM et al 2007 Proc Natl Acad Sci USA 104:11268.

Pyruvate Dehydrogenase Complex: Contains three enzymes, pyruvate dehydrogenase, dihydrolipoyl transacetylase and dihydrolipoyl dehydrogenase and the function of the complex requires the coenzymes: thiamin pyrophosphate (TPP), flavin adenine dinucleotide (FAD), coenzyme A (CoA), nicotinamide adenine dinucleotide (NAD), and lipoate. The result of the reactions is oxidative decarboxylation whereby CO₂ and acetyl CoA are formed. ►oxidative decarboxylation; Zhou ZH et al 2001 J Biol Chem 276:21704.

Pyruvate Kinase Deficiency: A recessive (human chromosome 1q21-q22, PK1) hemolytic anemia actually caused by two enzymes that are the products either of differential processing of the same transcript or chromosomal rearrangement. In the presence of some tumor promoters hepatic pyruvate kinase activity decreases. ►anemia, ►hemolytic anemia, ►glycolysis

Pyruvic Acid: A ketoacid (CH₃COCOOH) formed from glycogen, starch and glucose under aerobic conditions (under anaerobiosis is reduced to lactate and NAD⁺ is formed). Hyperpolarization technology permits imaging of pyruvate metabolic path in real time without invasive procedures (Golman K et al 2006 Proc Natl Acad Sci USA 103:11270). ►Emden-Meyerhof pathway, ►pentose phosphate shunt

PyV: Polyoma virus.

PYY₃₋₃₆: A neuropeptide Y (NPY)-like, but it is a gastrointestinal hormone that inhibits food uptake. ►obesity, ►leptin, ►neuropeptide Y; Batterham RL et al 2002 Nature [Lond] 418:650.

Q

q: Long arm of chromosomes. ►p

Q Banding: Chromosome staining with quinacrine that reveals cross bands. Due to the availability of newer microtechniques, this procedure is no longer generally used. ►chromosome banding, ►quinacrine mustard; Caspersson TG et al 1971 *Hereditas* 67:89.

Q2 Domain: ►CREB

Q-β: An RNA bacteriophage of a molecular weight of about 1.5×10^6 Da. The Qβ replicase is an RNA-dependent RNA polymerase that synthesizes the single-stranded RNA genome of the phage without an endogenous primer. The replicase can use both the + and the - strand as a template and therefore it amplifies the genome rapidly. It is a heterotetramer consisting of one viral encoded and three host polypeptides. ►replicase, ►plus strand; Munishkin AV et al 1991 *J Mol Biol* 221:463.

Q-Q-TOF: Has uses to quadrupoles and time of flight analysis for proteins and proteome.

qORF: An open reading frame with questionable information on its transcription. ►ORF, ►transcription

QSTAR Pulsar: A quadrupole time-of-flight mass spectrometer. ►quadrupole, ►MALDI, ►proteomics; Steen H et al 2001 *J Mass Spectrom* 36:782.

QTDt: Quantitative transmission disequilibrium test (Abecasis GR et al 2000 *Eur J Hum Genet* 8:545).

QTL (quantitative trait loci): Control the expression of complex traits such as weight, height, cognitive ability, and many diseases, etc. Their expression is usually not strict and even in the absence of the critical genes a quantitative trait may appear under the influence of extrinsic factors yet their expression is more likely when the appropriate alleles are present. Their physical presence may be traced in restriction fragments separated by electrophoresis because the DNA is independent of extrinsic factors. Their cosegregation is identified, and can be used for improving quantitative traits for plant breeding purposes, and for genetically defining behavioral traits and other polygenic characters. QTLs can be genetically mapped by several procedures, and most commonly using the principles of maximum likelihood for statistical analysis. In a backcross generation the phenotype (ϕ_i) and genotype (g_i) relations are

expressed as: $\phi_i = \mu + bg_i + \epsilon_i$ where g_i corresponds to the homozygous and heterozygous dominants of the QTL and its value may vary between 1 and 0. The mean of ϵ_i (a random variable) = 0 and its variance is σ^2 . The values of μ , b and σ^2 are unknown. The genotypic value of Qq and other contributors to the quantitative trait is μ and b is the effect of a substitution of another allele at the quantitative trait loci. The statistical procedures shown below were adapted from Arús P, Moreno-González J 1993, p 314 In: Hayward MD et al (Eds.) *Plant Breeding*, Chapman & Hall, London, New York.

The likelihood function $Lg_i(\mu, b, \sigma^2)$

$$= \frac{1}{\sqrt{2\pi\sigma^2}} e^{-\frac{(\phi_i - \mu - bg_i)^2}{2\sigma^2}}$$

and the likelihood that all individuals will be in the flanking parental marker classes (k) $M_1M_1M_2M_2$, $M_1M_1M_2m_2$, $M_1m_1M_2M_2$, and $M_1m_1M_2m_2$ will be $L_k(\mu, b, \sigma^2) = \prod_i [P_i(1)L_i(1) + P_i(0)L_i(0)]$ where $P_i(1)$, and $P_i(0)$ are the probabilities that QQ and Qq quantitative genes will be in the recombinant classes, respective the flanking markers concerned. The maximum likelihood estimates for incomplete data can also be determined (Dempster AP et al 1977 *J R Stat Soc* 39:1). The likelihood for all observations is: $L(\mu, b, \sigma^2) = \prod_k L_k(\mu, b, \sigma^2)$. For the determination of the LOD score, to ascertain that the information obtained is real rather than a false, spurious conclusion would be drawn the following equation has to be resolved:

$$LOD = \frac{\log L(\mu, b, \sigma^2)}{L(\mu_0, b_0, \sigma_0^2)}$$

One must keep in mind that the estimates are as good as the data collected. Large populations and genes with greater quantitative effects improve the chances to find linkage. For estimating linkage information from multiple marker data, computer assistance is required; various programs are available. For mapping QTL in humans generally sib pairs are used. Statistical analysis indicates that choosing extreme discordant pairs makes the analysis more efficient. Just because of this selection, QTL estimates may be loaded with errors of under and overestimation. Expectation-maximization-likelihood-ratio test may permit assessing the effects of missing data (Niu T et al 2005 *Genetics* 169:1021). Least squares, Bayesian and non-parametric methods are also available. Allison DB et al (2002 *Am J Hum Genet* 70:575) are discussing methods useful for eliminating errors. Although most commonly single quantitative traits are analyzed at a time, the simultaneous study of multiple traits may be desirable. Quantitative traits

generally are not expressed in isolation and we may have to face epistasis of multi-traits. The abundance of mRNA transcripts can be considered as expression QTL (eQTL). The differences in eQTL may represent different sets of genes and can be mapped (Schadt EE et al 2003 Nature [Lond] 422:297). Microarray analysis can reveal large number of genes that influence phenotypic variation (Morley M et al 2004 Nature [Lond] 430:743). It is highly desirable that QTL would be amenable to isolation and cloning. (see Frary A et al 2000 Science 289:85) to better understand their function. A transition mutation (A→G) in intron 3 of an IGF2 (insulin-like growth factor) locus, despite the fact that it is not translated, may increase muscle growth by about three-fold. It is expressed only in the paternal gene copy and it indicates that regulatory genes may have major phenotypic effect (Van Laere A-S et al 2003 Nature [Lond] 425:832). In yeast, sporulation efficiency was resolved to single-nucleotide changes at the non-coding regulatory region (*RME1*) and to two nonsense mutations (*TAO3* and *MKT1*). The control of sporulation may be heterogeneous in the different strains (Deutschbauer AM, Davis RW 2005 Nature Genet 37:1333).

In introgression lines of tomato a *Solanum penellii* chromosome segment, containing the flower- and fruit-specific invertase locus, *LIN5* increased sugar yield of the common tomato (*Solanum lycopersicon*). A single amino acid substitution near the catalytic site of the enzyme exerted a critical effect, depending in extent on the genetic milieu of the recombinants (Fridman E et al 2004 Science 305:1786). In yeast crosses, the median variance of heritable QTL appeared 27% and no QTLs were detected for 40% of highly heritable transcripts. Modeling of QTLs indicated that only 3% of the highly heritable traits could be attributed to a single locus, 17 to 18% were apparently determined by one or two loci and half seemed to be under the control of more than five loci. Interaction among the gene products was indicated in 16% of the highly heritable traits (Brem RB, Kruglyak L 2005 Proc Natl Acad Sci USA 102:1572). In most complex traits several gene loci interact to a variable extent. In *two-locus mapping* two-stage procedure was proposed. For each transcript and marker a Wilcoxon test was used for the segregants at a locus. On the basis of the Wilcoxon test the quantitative trait with the most significant rank was named as the primary QTL. Besides the primary locus secondary loci were identified. Then non-parametric empirical Bayes' estimate determined the posterior probability that the primary QTL was a true positive and then the posterior probability of the true positive nature of the secondary QTL was

determined. The product of these two probabilities is the joint probabilities for the two estimates. An interaction test for each locus pair used the model

$$t = ax + by + cxy + d$$

where $t = \ln$ of the ratio of expression between the strain of interest and the reference sample; a , b , c and d are parameters specific for a given sample of a transcript, x is the inheritance at the first locus and y is inheritance at the second locus. An F-test determined that $c + 0$ and compared the goodness-of-fit of this model with a pure additive model. The P value of the interaction was evaluated by the Q-VALUE program available free through the Internet <http://faculty.washington.edu/~jstorey/qvalue/> (Brem RB et al 2005 Nature [Lond] 436:701). This two-stage test detected many interactions missed by single-locus tests. A robust bootstrap procedure identified 843 QTLs in mouse with an average 95% confidence interval of 2.8 Mb (Valdar W et al 2006 Nature Genet 38:879; <http://gscan.well.ox.ac.uk>). Multivariate version of the Bayes methodology for joint mapping of QTLs, using the Markov chain–Monte Carlo (MCMC) algorithm is also useful (Liu J et al 2007 Am J Hum Genet 81:304). ►LOD score, ►mapping genetic, ►linkage, ►gene block, ►RFLP, ►liability, ►ASP analysis, ►interval mapping, ►complex inheritance, ►infinitesimal model, ►BLUP, ►bootstrap, ►co-suppression, ►introgression, ►least squares, ►Bayes' theorem, ►non-parametric tests, ►Wilcoxon rank correlation test, ►goodness of fit, ►F-distribution, ►SNIPs, ►Hase-man-Elston regression, ►genetic genomics, ►rice; see also Darvasi A 1998 Nature Genet 18:19; Kao C-H 2000 Genetics 156:855; Mackay TFC 2001 Nature Rev Genet 2:11; Flint J, Mott R 2001 Nature Rev Genet 2:437; Mackay TFC 2001 Annu Rev Genet 35:303; Dekkers JCM, Hospital F 2002 Nature Rev Genet 3:22; Korstanje R, Paigen B 2002 Nature Genet 31:235; Feingold E 2002 Am J Hum Genet 71:217; Hoh J, Ott J 2003 Nature Rev Genet 4:701, review on sibling pairs: Cuenko KT et al 2003 Am J Hum Genet 73:863; functional QTL map for developmental traits: Wu R, Lin M 2006 Nature Rev Genet 7:229; QTL mapping, molecular bases in animals: Georges M 2007 Annu Rev Genomics Hum Genet 8 131; QTL comparisons: <http://pmrc.med.mssm.edu:9090/QTL/jsp/qtlhome.jsp>; miRNA QTL target sites: <http://compbio.utmem.edu/miRSNP/>; domesticated (agricultural) animal QTL: <http://www.animalgenome.org/QTLdb/>.

QTN: The nucleotide sequences for quantitative traits.

Quadrant: Consists of four parts, e.g., a tetrad.

Quadratic Check: Used for testing two genes presumed to be required for phytopathogenic infection in the manner shown in Fig. Q1. Resistance in the plants is usually a dominant trait. ►Flor's model

| Plant \ Pathogen | Pathogen | |
|---------------------|-------------------|--------------------|
| | Low pathogenicity | High pathogenicity |
| Plant reaction low | No infection | Infection |
| Plant reaction high | Infection | Infection |

Figure Q1. Quadratic check

Quadriplegia: ►tetraplegia

Quadriradial Chromosome: May be produced by cross-linking mutagens (see Fig. Q2).

Figure Q2. Quadriradial

Quadrivalent: Partially or completely identical four chromosomes in a polyploid that display pairing although of the four, at any particular position, only two can be synapsed. During meiosis they show quadrivalent association of four chromosomes. ►synapsis, ►meiosis, ►bivalent

Quadroma (hybrid hybridoma): The fusion product of two hybridomas. ►hybridoma; Lindhofer H et al 1995 J Immunol 155:219.

Quadruplets: Fourfold twins, and in the absence of the use of fertility increasing treatment, their expected frequency is about 1 in $(89)^3$ whereas the expectation for triplets and quintuplets is about $(89)^2$ and $(89)^4$, respectively. ►twinning

Quadruplex: A tetraploid or tetrasomic with four doses of the dominant alleles at a locus. ►autopolyploid, ►G quartet

Quadruplex DNA: Has four parallel and antiparallel strands in vitro, and blocks replication. In some instances G-quadruplex DNA may boost c-Myc gene proliferating activity (Siddiqui-Jain A et al 2002 Proc Natl Acad Sci USA 99:11593). ►Myc, ►tetraplex;

Schaffitzel C et al 2001 Proc Natl Acad Sci USA 98:8572; G-quadruplex search tool: <http://bioinformatics.ramapo.edu/QGRS/index.php>; <http://miracle.igib.res.in/quadfinder/>.

Quadruplicate Genes: Four genes conveying identical or similar phenotype but segregating independently in F_2 and displaying a dominant recessive proportion of 255:1.

Quadrupole: Used in specific mass spectrometers for the tracking of ion density in proteomic analysis. The quadrupole is made up of four rods, which permit the filtering of the mass that traverses them with the mediation of an oscillating electric field to obtain the mass spectrum. The amplitude of the electric field is scanned and recorded. Triple quadrupole devices usually analyze peptides. The unit mass resolution is excellent with an accuracy of 0.1 to 1 Da. ►mass spectrum, ►proteomics, ►MALDI, ►Q-Q-TOF; Hager JW 2002 Rapid Commun Mass Spectrom 16:512.

Quality of Life: A subjective judgment of the functional ability of a patient.

Quality Protein Maize: ►high-lysine corn

Quantitative Gene Numbers: They are difficult to determine because environmental effects obscure the impact of genes with minor effects. Several statistical procedures have been worked out for approximation. The simplest one is as follows:

$$N = \frac{R^2}{8(s_1^2 - s_2^2)}$$

where N = gene number, R is the difference between the parental means, s_1^2 = variance of the F_1 , s_2^2 = variance of the F_2 generations. The most common view is that quantitative traits are determined by large number of genes and each of them contributes only little to the observed phenotype. The association between bristle numbers (a quantitative trait) and the *scabrous* locus of *Drosophila* indicated, however that approximately 32% of the genetic variation in abdominal and 21% of the sternopleural bristle number was associated with DNA sequence polymorphism at this single locus. ►gene number, ►quantitative trait, ►QTL; Mather K, Jinks JL 1977 Introduction to Biometrical Genetics, Cornell University Press, Ithaca, New York; Jones CD 2001 J Hered 92[3]:274.

Quantitative Genetics: Studies genetic mechanisms involved with the expression of quantitative traits and its techniques involve those of population genetics and biometry. ►quantitative trait, ►QTL,

►population genetics, ►biometry, ►selection, ►heritability, ►statistics

Quantitative Trait: Shows continuous variation of expression and can be characterized by measurement or by counting in contrast to qualitative traits, which can be identified satisfactorily by simple description such as black or white. ►gene titration, ►dichotomous trait

Quantitative Trait Loci: ►QTL

Quantized: Using synchronous cultures and time-lapse video tape microscopy showed that the generation time in mammalian cells occurs with intervals of 3–4 h between bursts in division. The length of the cycles is dependent on the prevailing temperature, shorter at higher and longer at lower. This indicates that the cells have an oscillatory clock. ►oscillator; Klevecz RR 1976 Proc Natl Acad Sci USA 73:4012.

Quantum: The unit to quantify energy. ►photon

Quantum Computer: Fundamentally different from the standard binary computers where the information *bits* are either 0 or 1, in the quantum computer the *qubit* can be 0 and 1 and simultaneously both. This concept is different from the existing computers based on physics and it obeys the laws of quantum mechanics. At present there are difficulties in actually building the machines. A new approach to the problem is one-way four-qubit quantum state tomography (Walther P et al 2005 Nature [Lond] 434:169). The quantum computer may not be of general usefulness but may be especially useful to study electronic state of atoms or ions, their structures and reactivity. Quantum computers have the property of *entanglement*, i.e., the qubits can be interdependent. The entangled state may become, unfortunately, quickly unstable (*decoherence*) and one qubit can affect others too. The quantum computers are also much more error prone than the classical ones. There are still both theoretical and engineering problems to solve yet some progress is underway. (See Steane A 1998 Rep Progr Physics; Kim J et al 2004 J Magn Res 166:35; Stix G 2005 Sci Am 292(1):78; Keyes RW 2005 Computer 38(1):65; Ball P 2006 Nature [Lond] 440:398).

Quantum Dot (qdot): Built of semiconductor, luminescent nanometer-size crystals (e.g., of zinc sulfide-capped cadmium selenide). They may bind fluorochromes, organic and macromolecules and thus permit their tracing as stable, very bright, narrow-band emissions can be tuned from ultraviolet to infrared, water-soluble and non-invasive labels. This technology may increase the contrast in MRI, PET, computed tomography, etc. The fluorescence lifetime of the qdots is long and permits the separation from autofluorescence found in cells. The surface

molecules can be protected from oxidation or other chemical reactions and this shell conveys to qdots photostability of several orders larger compared to other dyes. The dots are available in a wide range of well-separable colors all of which can be excited by a single wavelength. Confocal microscopy and other devices can track single qdots up to a few hours. The qdots can be tagged by various ligands such as DNA oligonucleotides, aptamers or antibodies. Besides animal and whole cell labeling, special cytoplasmic and nuclear targets, cell lineages, signal transduction pathways, membrane proteins, microtubules, actin, nuclear antigens, chromosomes and pathogens can be monitored. The qdots can be equipped with membrane-crossing and cell internalization or enzymatic functions. Generally qdots are innocuous yet they may adversely effect embryo development at higher concentrations. Quantum dot technology permits relatively fast identification of 10 bacteria/mL samples if amplification is allowed. This procedure facilitates biodefense and identification of other infections. Specific phages are biotinylated in vivo and attached to streptavidin-coated qdots. After infection in 20–45 min 10–1000 phages are released and can be readily detected (Edgar R et al 2006 Proc Natl Acad Sci USA 103:4841). ►nanocrystal semiconductor, ►nanotechnology, ►non-isotopic labeling, ►aptamer, ►semiconductor, ►luminescence, ►confocal microscopy, ►MRI, ►tomography, ►bio-tin, ►streptavidin, ►pathogen identification, ►bio-terrorism; Han M et al 2001 Nature Biotechnol 19:631; Jaiswal JK et al 2003 Nature Biotechnol 21:47; Michalet X et al 2005 Science 307:538.

Quantum Speciation: A rapid formation of a new species by selection and genetic drift. ►selection, ►genetic drift

Quarantine: A state of isolation and observation without any external contact, especially from infection for a period of time in case of a contagious disease.

Quarter-Power Scaling: Biological scaling can be expressed by the formula $Y = Y_0 M^b$ where Y is a variable (e.g., life span or metabolic rate), Y_0 is a normalization constant and b = scaling exponent, M = body mass. Y_0 varies with the trait and type of an organism, b is practically constant 1/4 or multiples of it. E.g. blood circulation time and life span are $M^{1/4}$, whole organism metabolic rate is $M^{3/4}$, diameter of tree trunks and aortas $M^{3/8}$, etc. ►synaptic scaling; West GB et al 1999 Science 284:1677.

Quartet: A structure consisting of four elements. ►G quartet

Quartile: One-fourth or 25% of the data or population.

Quasi: In various combinations it indicates almost, resembling or about of the notion that the following word specifies, e.g., quasi-species means that its difference from other form(s) may not qualify it for the status of a separate species with certainty.

Quasidominant: Recessive inheritance is misclassified as dominant because the mating took place between a heterozygote and a homozygous recessive individual.

Quasi Linkage: ► [affinity](#)

Quasi-Monoclonal Antibody: Produced by mice heterozygous for the V(D)J IM-immunoglobulin heavy chain (Ig) and the other allele being non-functional. Functional κ chain is also missing. When the heavy chain, specific for the hapten 4-hydroxy-3-nitrophenyl acetyl could join any λ chain, the antibody was monospecific but somatic mutation and secondary rearrangements changed the specificity of 20% of the B cell antigen receptors. Such a system can thus be used to study antibody diversity. ► [antibody](#)

Quasi-Species: A small degree of genetic (nucleic acid) variation does not qualify it clearly for separate

species status. In RNA viruses due to high mutation rate (low repair) this state seem to exist and play role in their pathogenesis (Vignuzzi M et al 2006 Nature [Lond] 439:344).

Quaternary Structure: The aggregate of multiple polypeptide subunits into a protein or by cross-linking DNA strands into a joint structure. ► [cross-linking](#), ► [protein structure](#); <http://www.mercity.com/>; <http://pqs.ebi.ac.uk>.

Queen: The reproductive female in cast insect colonies such as exist in bees, ants. ► [pseudoqueen](#)

Queen Victoria: ► [hemophilias](#), ► [Romanovs](#), see Fig. Q3.

Quelling: A gene or chromatin repeat-associated post transcriptional silencing of genes without methylation, but involving RNAi (siRNA). It occurs when into plants or fungi foreign DNA is introduced by transformation. ► [co-suppression](#), ► [MSUD](#), ► [transvection](#), ► [sense suppression](#), ► [silencer](#), ► [RNAi](#); Maine EM 2000 Genome Biol 1(3): Reviews 1018.

Quenched Autoligation Probe (QUAL): QUAL probes use a pair of modified oligonucleotides. An electrophilic probe with internal fluorophore and

Figure Q3. Queen Victoria's family was the most famous to be affected by hemophilia, shown here, at a reunion on April 23, 1894. (1) Kaiser Wilhelm II, grandson, (2) Queen Victoria, (3) daughter Victoria, (4) granddaughter Tsarina Alexandra, (5) granddaughter Irene, (6) granddaughter Alice, (7) son and future king of England Edward VII, (8) daughter Beatrice, (9) son Arthur, (10) granddaughter Marie, (11) granddaughter Elizabeth. For most likely genetic constitutions regarding hemophilia see under hemophilia. (Courtesy of the Humanities Research Center, Gernsheim Collection, University of Texas, Austin, Texas)

a DABOSYL quencher is attached to the 5' terminus by a sulfonate ester linkage, and a nucleophilic probe containing a 3'-phosphorothioate group is employed. In the presence of a target, the two probes bind side-by-side and nucleophilic displacement of the quencher by the phosphorothioate leads to probe ligation and unquenching of the fluorophore. The reaction can be monitored by the gradual increase of fluorescence over minutes or hours. The probe can tell apart 16S RNAs even in very closely related bacteria. ►DABOCYL acid, ►phosphorothioate, ►fluorophore, ►bacteria, ►pathogen identification; Silverman AP, Kool ET 2005 Nucleic Acids Res 33:4978.

Quenching: The suppression of fluorescence, transfer of electrons or suppression of an activator by blocking the binding site of the activator or binding it to another protein which prevents its binding to the activator binding site in the DNA.

Quetelet Index: Essentially the same as body mass index, $(\text{weight})/(\text{height})^2$. L.A.J. Quételet, an astronomer, a pioneer of biometry has already shown in 1835 that human stature follows the normal distribution. Old textbooks of genetics referred to the principle of normal distribution of quantitative traits as Quetelet's Law. According to the Quetelet-Galton Law when a quantitative trait did not follow the normal distribution the role of heredity in the expression of the trait was questioned and the variation was attributed to environmental causes. ►body mass index

Q

Queunine: A rare modified purine. It is a derivative of guanine and it occurs in tRNA. Mammals cannot synthesize it and they obtain it from the intestinal microflora. Cancer cells have less of queunine in the tRNA. ►colicines, ►deazanucleotides

Quick-Stop: The temperature-sensitive DNA replication mutant *dna* of *E. coli* stops DNA replication immediately when the temperature rises to 42°C from the permissive 37°C. ►temperature-sensitive mutation; Rangarajan S et al 1999 Proc Natl Acad Sci USA 96:9224.

Quiescent Zone: A small region at the root tip where no cell division takes place in contrast to the neighboring cells, which are meristematically active (see Fig. Q4). In Arabidopsis roots, a *Retino-Blastoma-Related* gene is the main regulator of the meristematic (stem cell) state (Wildwater M et al 2005 Cell 123:1337). ►root, ►meristem, ►retinoblastoma

Figure Q4. Quiescent zone

Quinacrine Mustard (ICR 100): A light-sensitive, fluorescent compound used for chromosome staining (see Fig. Q5). Quinacrine (atabrine) staining permitted the first time the visualization of banding in the human chromosomes. It caused particularly bright fluorescence of the long arm of the human Y chromosome and facilitated the recognition of the XYY karyotype (see Fig. Q6). ICR 100 is strongly mutagenic; it is also a highly toxic antihelminthic drug. ►Q banding, ►acridine dyes

Figure Q5. ICR-stained Y chromosome

Figure Q6. Quinacrine mustard

Quintuplex: ►quadruplex

Quormone: Quorum-sensing signaling molecules, acylated homoserine lactones.

Quorum Factors: Signaling molecules in autoinduction. ►autoinduction

Quorum Quenching: *N*-acyl-L-homoserine lactone hydrolase disrupts signals to quorum-sensing (Liu D et al 2005 Proc Natl Acad Sci USA 102:11882).

Quorum-Sensing: A system of cell density-dependent expression of specific gene sets. In the luminescent bacteria *Vibrio fischeri* and *V. harveyi* the quorum-sensing signal is acylated homoserine lactone (AHL). AHL triggers biofilm production in the infectious *Pseudomonas aeruginosa* and that protects the bacteria from antibiotics. AHL production is quite

widespread among bacteria, including bacteria living on plant hosts. *P. aeruginosa*—in response to AHL—can produce, e.g., phenazine (mutagen involved also in electron transport), an antibiotic that keeps away other (Gram positive) bacteria and thus may protect its host, e.g., wheat. Besides AHL, other quorum-sensing signals have been detected in various bacteria and also in fungi. The toxic *Enterococcus faecalis* when it detects target cells, releases high level of cytolysin (Coburn PS et al 2004 Science 306:2270). In several species of bacteria quorum-sensing is dependent of an autoinducer (AI-2) product of the LuxS enzyme (4,5-dihydroxy-2,3-pentanedione, Xavier KB, Bassler BL 2005 Nature [Lond] 437:750). AI-2 signal transduction requires the integral membrane receptor LuxPQ, which has a periplasmic component LuxP and a histidine sensor kinase

subunit, LuxQ. Light-induced conformation change in LuxPQ seems to regulate quorum sensing (see Fig. Q7) (Neiditch MB et al 2006 Cell 126:1095). ►autoinduction, ►biofilm, ►multicellular, ►cytolysin, ►quorum quenching, ►luciferase; Miller MB Bassler BL 2001 Annu Rev Microbiol 55:165; Fuqua C et al 2001 Annu Rev Genet 35:439; Mok KC et al 2003 EMBO J 22:870; Miller ST et al 2004 Mol Cell 15:677; Neiditch MB et al 2005 Mol Cell 18:507.

Figure Q7. Cartoon of conformational changes in the four lux subunits leading to quorum sensing

q.v. (quod vide): see it.

Historical vignettes

The majority of geneticists know that Carl Correns was one of the three rediscoverers of the Mendelian principles in 1900. Actually he named them as Mendel's Rules. In the same year in a footnote he also noted that the allelic frequencies comply with the $p^2 + 2pq + q^2$ binomial (nine years before Hardy and Weinberg), and reported linkage in *Matthiola*.. He was also one of the discoverers of cytoplasmic inheritance. In 1902 (Botanische Zeitung 60:64–82) he suggested a mechanism for crossing over nine years before Morgan's paper appeared in J. Exp. Zool. (11:365). “We assume that in the same chromosome the two Anlagen of each pair of traits lie next to each other (A next to a and B next to b, etc.) and that the pairs of Anlagen themselves are behind each other. The picture is shown in Fig. 1.

A, B, C, D, E, etc. are the Anlagen of parent I; a, b, c, d, e, etc. are those of parent II.

Through the usual cell- and nuclear divisions the same type of products are obtained as the chromosomes split longitudinally...”

When one pair contains antagonistic Anlagen, while the rest of the pairs are formed of two identical types of Anlagen, or the Anlagen are ‘conjugated’ as they are in *Matthiola* hybrids, which I have described, then further assumptions are necessary... Then AbCdE/aBcDe and aBcDe/AbCdE yield both AbCdE and aBcDe; ABcdE/abCDe and abCDe/ABcdE both ABcdE and abCDe, etc.”

Peter Starlinger (discoverer of insertion mutations in bacteria with Heinz Saedler in 1972 [Biochimie 54:177] made the remark below in 2005 in Annu. Rev. Plant Biol. 56:1.

“It was only then that we realized the relation of these element to McClintock’s transposable elements, in spite of the fact that I had known McClintock’s work since my student days, and in spite of a series of seminars that we had held on this topic in the institute in Cologne. Sometimes we are blind!”

R

R (r, Röntgen, Roentgen): This is a unit of ionizing radiation (1 electrostatic unit of charge in 1 cm³ dry air at 0 °C and 760 mm pressure; about 93 ergs/living cells). ▶Rad, ▶Rem, ▶rep, ▶Gy, ▶Sv, ▶cR, ▶measurement units

R: This is a free software environment for statistical computing and graphics. (See <http://www.r-project.org/>).

ρ (population recombination parameter): This is inversely proportional to linkage disequilibrium in a population (Hudson RR 2001 Genetics 150:1805). The size of ρ under conditions of selection is generally lower than expected under condition of neutral equilibrium; conversely linkage disequilibrium increases under domestication (Wright SI et al 2005 Science 308:1310). ▶linkage disequilibrium

ρ (rho): ▶buoyant density, ▶petite colony mutants, ▶transcription termination in prokaryotes

R1: Refer to methylation sites in the cytoplasmic region of *E. coli* chemotaxis transducer proteins.

R1, R2: These are ubiquitous retroposons in arthropod ribosomal RNA. ▶retroposon; Pérez-González CE, Eickbush TH 2002 Genetics 162:799.

R2: ▶hybrid dysgenesis I–R

rl: ▶rapid lysis mutants of bacteriophages

R Bands: These are heat-denaturation resistant chromosomal bands and half of them have telomeric sites. The bright field R bands usually show the reverse Giemsa pattern of the bands (see Fig. R1). ▶isochores, ▶C banding, ▶G banding, ▶chromosome banding; Dutrillaux B, Lejeune J 1974 Adv Hum Genet 5:119.

Figure R1. R-banded human chromosome

R Bodies: These refractive bodies are temperate bacteriophages within the κ particles of paramecia. ▶symbionts hereditary, ▶*Paramecium*

R End: ▶packaging of λ DNA

R Factors: Denote resistance factors in bacterial plasmids that may make the host bacteria insensitive

to antibiotics and to normally bacteriotoxic drugs. They are common among gram negative bacteria and are readily transmitted to other strains because the plasmids are generally endowed with transfer factors. These plasmids usually do not integrate into the bacterial host genome but can recombine with each other and generate new plasmids with multiple resistance factors. Because of the presence of multiple resistance factors, only simultaneous administration of multiple antibiotics may stop the multiplication of the bacteria. ▶plasmid, ▶plasmid mobilization, ▶plasmid conjugative, ▶antibiotics; Watanabe T 1963 Bacteriol Rev 27:87; Falkow S 1975 Infectious multiple drug resistance, London; Patterson JE 2000 Semin Respir Infect 15[4]:299.

R Group (a radix): Abbreviation of an alkyl group or any other chemical substitutions.

R Locus of Maize: Along with the B locus this is involved in the activation of several genes of the anthocyanin biosynthetic pathway. These genes are separable by recombination and give rise to the phenotypes represented in Figure R2. P stands for plant color and S for seed color. In this figure the embryo represents the plant. The R locus includes a large number of different alleles. A detailed structure of the locus is described by May & Dellaporta (1998 Plant J 13:247), and Walker (1998 Genetics 148:1973). Additional references are also provided. ▶tissue specificity, ▶paramutation

Figure R2. Resolution of the R locus of maize

R Loop: Refers to the DNA strand displaced by RNA in a double-stranded DNA-RNA heteroduplex; also the genomic DNA intron forms a R loop when the gene is hybridized with cDNA or mRNA. At the beginning of the replication of the mtDNA a R loop is formed which is synthesized on the light strand of the mtDNA. This R loop is processed into primers for the heavy chain replication. ▶DNA replication mitochondrial, ▶primer; White RL, Hogness DS 1977 Cell 10:177.

R Plasmids: These carry resistance factors (genes for antibiotic resistance and other agents).

R Point (restriction point): Before the S phase, cells in the G1 phase pause and may or may not continue the cell cycle. Cancer cells bypass the restriction point and continue uncontrolled divisions. Cultured cells may require serum or amino acids to pass from G1 to S. ► [cell cycle](#); Ekholm SV et al 2001 *Mol Cell Biol* 21:3256.

Rabbit Reticulocyte In Vitro Translation: Mammalian mRNA (extracted from cells or transcribed in vitro) can be translated into protein under cell-free conditions using lysates of immature red blood cells of anemic rabbits. Anemia is induced in animals by subcutaneous injections of neutralized 1.2% acetylphenylhydrazine solutions (HEPES buffer) for five days. After the larger white blood cells are removed by centrifugation, the red blood cells are lysed at 0 °C by sterile double-distilled water. Then the endogenous mRNA is destroyed by micrococcal nuclease in the presence of Ca²⁺. Without calcium the nuclease does not work. The reaction is stopped by EGTA

(ethylene glycol tetraacetic acid, which chelates calcium). Hemin [C₃₄ H₃₂ ClFeN₄O₄], dissolved in KOH, is needed for suppressing an inhibitor of eukaryotic translation-initiation factor eIF-2. The translation mixture must contain spermidine or RNasin ribonuclease inhibitors, creatine phosphate (an energy donor), dithiothreitol (a reducing agent to prevent the formation of sulfoxides from the S-labeled amino acids), all normal amino acids (except the one which will carry the radioactive label), buffer, radioactive amino acid (e.g., [³⁵S]methionine), reticulocyte lysate, tRNAs, KCl and magnesium acetate (to enhance translation) and polyadenylate-tailed mRNA (to be translated into protein). It should be ensured that all solutions are made of RNase-free material and the vessels are free of RNase. Incubation is at 30 °C for 30 to 60 min. Before precipitating (by 10% trichloroacetic acid) the synthesized protein, the ³⁵S-methionine-tRNA is destroyed either by 0.3 N NaOH or, in case SDS-polyacrylamide gels are used for subsequent analysis, by pancreatic ribonuclease. Immunoprecipitation may also be used for the analysis of the translation product. The amount of protein synthesized can be measured by scintillation counting. Rabbit reticulocyte lysates are also available commercially. Numerous variations of the procedure are available in laboratory manuals. Alternatively, wheat germ extract may be used for in vitro translation. ► [wheat germ translation system](#), ► [eIF-2](#), ► [translation repressor proteins](#), ► [polyA mRNA](#), ► [SDS polyacrylamide gels](#), ► [immunoprecipitation](#), ► [scintillation counters](#); Olliver L, Boyd CD 1998 *Methods Mol Biol* 86:221; Lorsch JR, Herschlag 1999 *EMBO J* 18:6705.

Rabies: Encephalomyelitis caused by infection of a non-segmented negative-strand RNA virus. The (–) strand genome is condensed as a nucleoprotein into a nucleocapsid and serves as a template for the RNA-dependent RNA polymerase. Replication produces a full length (+) viral RNA copy, which serves as template for the (–) RNAS genomic copy and is then encapsidated in the virion. Switching from transcription to replication is regulated by the amount of nucleoprotein in the cytoplasm. The 11 oligomers are built from 99-nucleotide RNA segments (see Fig. R3). In some insects the nucleoprotein rings may have 9, 10, 11, 12 or 13 copies (Albertini AAV et al 2006 *Science* 313:360). The onset of the disease is characterized by inflammation and hyperactivity eventually leading to death. A wide range of wild (raccoons, foxes, mice) and domestic animals (dogs, cats) are susceptible to infection through saliva in their bites. Humans have relatively greater resistance, there is about 15% lethality without treatment. For prevention attenuated virus or genetic immunization (immunoglobulin G) may be used. ► [replicase](#),

Rabl Orientation: In the late 1800s K. Rabl provided evidence for the continuity of the chromosomes inasmuch as in the very early prophase the chromosomes emerge from the premeiotic interphase in the same configuration as they entered the anaphase and telophase, i.e., the centromeres target the nuclear envelope at special locations and face the centrioles in close proximity. ►co-orientation; Marshall WF et al 1996 Mol Biol Cell 7:825.

Rabson-Mendenhall Syndrome (19p13.2): This is a dominant insulin-receptor defect (degradation) resulting in insulin-resistant diabetes. The condition is characterized by hypertrophy of the pineal gland, dental and skin anomalies (acanthosis nigricans) and early lethality. ►pineal gland, ►brain, ►diabetes, ►insulin-receptor protein

RAC (same as Akt or PKB): A serine/threonine kinase member of the RAS protein family and transmits signals from the cell surface membrane to the cytoskeleton. Human RAC1 (homolog of CED10) mediates the removal of dead cells destroyed by apoptosis. When activated it inhibits transferrin-receptor mediated endocytosis and along with RHO regulates the formation of clathrin-coated vesicles and actin polymerization. It has an important role in RAS-mediated oncogenic transformation. RAC

activates NADPH oxidase and thus free radical production as a defense against infections. Rac2 guanosine triphosphatase is selectively expressed in T_H1 lymphocytes (mediating cellular immunity) and in cooperation with NF-κB it induces IFN-γ promoter. Rac mediates the progression of the cell cycle. The prokaryotic RacA protein fastens the chromosomes to the opposite poles for cell division (Ben Yehuda S et al 2005 Mol Cell 17:773). ►serine/threonine kinase, ►RAS, ►RHO, ►PAK, ►Pac, ►p35, ►clathrin, ►signal transduction, ►cell membrane, ►cytoskeleton, ►PKB, ►endocytosis, ►apoptosis, ►transferrin, ►ROS, ►oxidative burst, ►IFN-γ, ►NF-κB, ►T cell, ►dendritic cell; Mettouchi A et al 2001 Mol Cell 8:115; Hakeda-Suzuki S et al 2002 Nature [Lond] 416:438.

RAC: Recombinant DNA Advisory Committee of the National Institute of Health (USA) oversees the application of recombinant DNA technology. (See <http://www4.od.nih.gov/oba/rac/aboutrdagt.htm>).

Raccoon (*Procyon lotor*): 2n = 38. This is primarily a North American, omnivorous, furry mammal with an average weight of about 10 kg (see Fig. R4).

Figure R4. Raccoon

R

Race: A group within a species, distinguished by several characteristics, such as allelic frequencies and morphology. For instance, it has been suggested that a combination of isosorbide dinitrate and hydralazine (BiDiI) is particularly effective for the treatment of heart failure among American blacks (Taylor A et al 2004 New Engl J Med 351:2049). For many people, talking about race is discriminatory and, therefore, they deny the racial basis of diseases. Certainly many social, environmental and economic factors contribute to the development of a particular disease but if ethnicity also plays a role, it must not be ignored because of “political correctness” as long as genetic factors common in a particular lineage can help in identifying and curing the disease. ►evolutionary distance, ►human races, ►racism, ►ethnicity

RACE: Refers to rapid amplification of cDNA ends by PCR. ►[polymerase chain reaction](#); Schafer BC 1995 Anal Biochem 227:255.

RACEfrags: Denotes rapid amplification of cDNA fragments.

Racemate: This is a Mixture of D and L optical stereoisomers (enantiomorphs) which subsequently becomes optically inactive. All naturally synthesized amino acids are in the L form but degradation generates the D enantiomorph. The degree of racemization of aspartic acid is faster than that of other amino acids. It has been recently used to determine the authenticity of ancient samples of DNA because the degradation of DNA and the racemization of amino acids, particularly Asp, indicate whether the spurious DNA is really ancient or just a contaminant in the archeological sample. In case the D/L Asp ratio exceeds 0.08 the ancient DNA cannot be retrieved. Degradation also depends on a number of factors, most notably the temperature to which the specimen had been historically exposed. The best preservation has been observed in insects enclosed in amber (although there is some controversy about these samples). In specimens where the D/L Asp ratio is about 0.05, up to 340 bp long DNA sequences can be detected using PCR technology. ►[enantiomorph](#), ►[radiocarbon dating](#), ►[evolutionary clock](#)

Raceme: Refers to inflorescence with an elongated main stem and flowers on near equal-size pedicels (see Fig. R5).

Figure R5. Raceme

Rachis: Refers to the axis of a spike (grass ear) and fern leaf (frond).

Racial Distance: ►[evolutionary distance](#)

Racism: The assumption of superiority of any particular ethnic group or groups and the consequent inferiority of some others. It advocates hatred and social discrimination on the basis of differences. The origin of racism can be traced back to prehistoric times where it served the purpose of exploitation of conquered or minority groups. Some forms of racism may be found in nearly all societies; even the Bible, arguably, is not exempt from racist ideas, and it has been frequently used as a justification by bigots. In the nineteenth century the rise of the eugenics

movement gave false scientific encouragement to racism, providing biological and ideological support for colonialism and social exploitation. Racist ideas were used to justify slavery. Racism culminated in the Third Reich of Hitler's Germany resulting not just in discrimination and suppression, but also in mass physical elimination of "Non-Aryan" people in an attempt to establish Rassenhygiene (race hygiene). Racism cannot be justified on the basis of any scientific evidence and it is morally unacceptable to enlightened societies. Human racial differences are based on a limited number of genes and all racial groups share the vast majority of genes. Actually, the world's most successful societies excelled because of their multiracial and multicultural composition. There is ample biological evidence supporting the superiority of hybrids of mammalian and plant species. ►[human races](#), ►[evolutionary distance](#), ►[hybrid vigor](#), ►[eugenics](#), ►[miscegenation](#), ►[human intelligence](#), ►[admixture in populations](#)

RACK: Denotes the receptor for activated C kinase. ►[C kinase](#)

RAD2: A yeast gene involved in cutting DNA; its human homolog is XPG. ►[DNA repair](#)

RAD3: A yeast DNA helicase and a component of transcription factor TFIIF; its human equivalent is XPD. In yeast *RAD3* regulates telomere integrity. A defect in a Rad3 like protein may be responsible for ataxia telangiectasia. ►[DNA repair](#), ►[ataxia telangiectasia](#), ►[telomeres](#)

Rad4: ►[RAD23](#)

Rad5: This is a member of the SWI/SNF family of ATPases and it also has the characteristic of ubiquitin ligases. ►[SWI/SNF](#), ►[ubiquitin](#)

Rad6: A protein with Ubc2 functions involved in both proteolysis and genetic repair in yeast. ►[ubiquitin](#), ►[Ubc2](#), ►[DNA repair](#)

RAD10: A yeast homolog of human gene ERCC1, which is involved in nucleotide excision repair. ►[nucleotide excision repair](#), ►[mismatch repair](#)

RAD14: This is a yeast gene, its protein product binds to damaged DNA. The human homolog is XPA. ►DNA repair

Rad18: A yeast protein involved in genetic repair in association with Rad6. ►Rad6

RAD21: This controls double-strand break repair caused by ionizing radiation.

RAD23: This is involved in nucleotide exchange repair. It interacts with the 26S proteasome by binding to the RAD4 repair protein. ►DNA repair, ►proteasome, ►xeroderma pigmentosum

Rad24: This is a 14-3-3 protein regulating nuclear export-import. ►Chk1, ►protein 14-3-3

RAD25 (ERCC): A helicase subunit of the general transcription factor TFIIH which is credited with promoter clearance for the onset of transcription following ATP hydrolysis and after the open promoter complex is formed. It is also a DNA repair enzyme encoded by the xeroderma pigmentosum gene F. ►transcription factors, ►open promoter complex, ►regulation of gene activity, ►helicase, ►DNA repair, ►promoter clearance, ►xeroderma pigmentosum, ►progeria

RAD27/FEN1 (Rthp/Fen-1): This 45 kDa 5'→3' exonuclease/endonuclease removes the RNA primer from Okazaki fragments with the cooperation of other proteins such RNA-DNA junction endonuclease, PCNA and DNA helicase. The FEN-1/DNase IV protein of eukaryotes performs the same functions as carried out by prokaryotic DNA polymerases beyond polymerization. The eukaryotic cells rely for this function on the PCNA-associated FEN-1. FEN-1 can cut also branched DNA molecules. ►Okazaki fragment, ►DNA replication in eukaryotes, ►flap nuclease, ►PCNA; Lieber MR 1997 Bioassays 19:233; Debrauwère H et al 2001 Proc Natl Acad Sci USA 98:8263.

RAD28: This is the yeast homolog of the gene of the Cockayne syndrome. ►Cockayne syndrome

RAD30: This encodes DNA polymerase η and it homologous to *E. coli*'s DinB, UmuC and *S. cerevisiae* Rev1.

RAD50, RAD51, RAD52, RAD53, RAD54, RAD55, Rad56, RAD57: These yeast genes are involved in radiation sensitivity, DNA double-strand break, repair and recombination. Rad51 and Rad52 proteins are vital for eukaryotic recombination. Overexpression of

RAD51 and RAD52 reduces double-strand break-induced homologous recombination in mammalian cells (Kim PM et al 2001 Nucleic Acids Res 29:4352). Replication protein A interacts with Rad proteins. The human breast cancer gene forms a complex with hRad50-p95-hMre11 proteins. Rad 53 along with chromatin assembly factor Asf1 mediates the deposition of acetylated histones H3 and H4 on to the newly replicated DNA. ►DNA repair, ►replication, ►replication fork, ►replication protein A, ►radiation-sensitivity, ►recombination mechanisms eukaryotes, ►non-homologous end-joining, ►chromatin assembly; Masson J-Y et al 2001 Proc Natl Acad Sci USA 98:8440; Davis AP, Symington LS 2001 Genetics 159:515.

RAD51: A gene of budding yeast regulates double-strand breaks and genetic recombination depending on ATP. RAD51 protein bears resemblance to the human protein (15q151) with similar functions. The human Rad51 protein (hRAD51) forms a helical filament on single-stranded DNA and regulates homologous recombination by controlling ATP activity through its ATPase function stimulated by Ca^{2+} . Ca^{2+} preserves the hRad51-ATP-ssDNA complex by slowing down ATP hydrolysis. Mg^{2+} promotes ATP hydrolysis and converts the complex into a recombination inactive form ((Bugreev DV, Mazin AV 2004 Proc Nature Acad Sci USA 101:9988). Disruption of *RAD51* in mice has embryonic lethal effects. *RAD51* is homologous with the bacterial gene *RecA* and bacteriophage T4 gene *Uvsx* mediating strand exchange in genetic recombination. In the recombination function RAD52 and its various yeast homologs (RAD55, RAD57 and other proteins) assist RAD1. The RPA (replication protein A, its homologs are the SSB [single strand binding protein] in bacteria and the p32 protein in phage) prepares the broken ends of the DNA to find the proper sequences in the homologous chromosomes that may be suitable for joining. In the plant *Arabidopsis* the homologous locus has almost the same role in recombination as in other eukaryotes but it has no adverse effect on vegetative growth. The *rad51-1* mutation, however, causes male and female sterility (Li W et al 2004 Proc Natl Acad Sci USA 101: 10596). ►DNA repair, ►SRS2, ►RecA1, ►Dmc1, ►recombination mechanisms in eukaryotes, ►RAD54; Fasullo M et al 2001 Genetics 158:959; Yu X et al 2001 Proc Natl Acad Sci USA 98:8419.

RAD53: A yeast kinase gene encoding pRAD53 signal transducer and S phase checkpoint controller; it is also known as SAD1, MEC2 and SPK1. Rad53 is activated by a conserved protein, Mrc1 (mediator of replication checkpoint) in response to DNA damage.

►MEC1, ►DNA replication; Alcasabas AA et al 2001 Nature Cell Biol 3:958.

RAD54: It has been proposed that this has a helicase function but it appears that this protein is DNA-dependent ATPase. It interacts with RAD1 scaffold and promotes homologous DNA pairing at the expense of ATP hydrolysis. Rdh54/Tid1 of yeast—similar to Rad54—also mediates the DNA exchange. ►helicase, ►ATPase, ►RAD1; Solinger JA, Heyer W-D 2001 Proc Natl Acad Sci USA 98: 8447; Ristic D et al 2001 Proc Natl Acad Sci USA 98:8454; Kim PM et al 2002 Nucleic Acids Res 30:2727.

Radiation, Acute: The irradiation is delivered in a single dose at a high rate, in contrast to *chronic radiation* in which the same dose is administered over a prolonged period of time. ►radiation effects, ►physical mutagens

Radiation, Adaptive: ►radiation evolutionary

Radiation, Background: It includes all radioactive (ionizing) radiation in the environment arising from inadequately shielded X-ray machines, cosmic radiation, fallout, laboratory isotope pollution, and radioactive rocks or radon gas that increases the dose delivered by medical treatment or other intended sources.

Radiation, Brain Damage: Actively dividing cells are most likely to suffer from ionizing radiation. The epidemiological data collected from the population of Hiroshima and Nagasaki indicated that the greatest susceptibility was during the first 8–15 weeks of the human fetus.

R

Radiation Cancer: Many of the different cancers are associated with chromosomal rearrangement(s), and ionizing radiation causes chromosomal breakage and rearrangements. Proximity of the X-ray-induced breakage sites favors rearrangements. Ultraviolet radiation may be responsible for the induction of skin cancer, especially if the body's genetic repair mechanism is weakened. According to estimates, 10 mSv may be responsible for 1 cancer death per 10,000 people. In the USA the permissible legal dose limit for the public is 0.25 mSv/year but it should be reduced to 0.20 mSv/year. Ionizing radiation is used to treat cancer. ►Sievert, ►DNA repair, ►ultraviolet radiation, ►xeroderma pigmentosum, ►excision repair, ►physical mutagens, ►radiation hazard assessment, ►radiation safety hazards

Radiation Chimera: An antigenically different bone marrow transplant is harbored in the body after

extensive radiation treatment destroys or substantially reduces the immune reaction of the recipient. Also, mutant sector(s) caused by radiation-induced mutations or deletions (see Fig. R6).

Figure R6. Chimeric Dahlia flower, the consequence of radiation exposure. (Photograph of Dr. Arnold Sparrow. Courtesy of the Brookhaven National Laboratory, Upton, New York)

Radiation Chronic: ►radiation acute

Radiation Density: This is generally measured by LET (linear energy transfer) values, i.e., the average amount of energy released per unit length of the tract. In case the density is low the genetic damage is expected to be discrete. High LET radiation causes extensive damage along a very short path (see Fig. R7). ►physical mutagens, ►radiation effects

Figure R7. Radiation density. The pattern of ionization density along the track of hard and soft X-rays and α -particles. (After Gray LH from Wagner RP, Mitchell HK 1964 Genetics and Metabolism. Wiley, New York)

Radiation Doubling Dose: ▶doubling dose

Radiation Effects: Ionizing radiation may cause gross chromosome breakage (deletions, duplications, inversions, reciprocal translocations, isochromatid breaks, transpositions, change in chromosome numbers if applied to the spindle apparatus) or minute changes including destruction of a single base in the nucleic acids or very short deletions involving only a few base pairs or oxidation of bases. The damage is often clustered. These effects depend on the quality of the ionizing radiation and the status of the biological material involved. The physical effect of radiation is frequently characterized by LET (linear energy transfer in keV/nm path), indicating the amount of energy released per unit tract as ionization and excitation in the biological target (▶radiation density). Also, if the dose is delivered at a low rate, most of the damage may be repaired by the metabolic system of the cells. In prophase the chromatid breaks may remain open only for a few minutes but at the interphase they may remain open substantially longer. The frequency of chromosome breakage is considerably increased in the presence of abundant oxygen, whereas anoxia has the opposite effect. Actively metabolizing cells are more susceptible to radiation damage than dormant ones (germinating seeds versus dry ones). Chromosomal aberrations requiring two breaks (e.g., inversions, translocations) occur by second order kinetics whereas the induction rate of point mutations shows first order kinetics. Ultraviolet radiation causes excitation rather than ionization in the genetic molecules. The most prevalent damage is the formation of pyrimidine dimers although chromosome or chromatid breaks may also occur. Radiation-induced malignant growth appears to be mediated by protein tyrosine phosphorylation followed by activation of the RAF oncogene. Suppressing cell proliferation due to interferon regulatory factor (IRF) that arrests the cell cycle may prevent the accumulation of radiation-induced mutations. Independently from IRF, p53 may have a similar effect. Also, ionizing radiation may induce the transcription of p21, a cell cycle inhibitor, by a p53 and IRF dependent mechanism. The adverse effect of radiation therapy may be circumvented by the application of pifithrin (small molecule inhibitor of p53). The potential pathway of events after exposure to radiation is as follows: (i) initial hit, (ii) excitation/ionization, (iii) radical formation and other chemical reactions, (iv) DNA/chromosome damage, (v) DNA repair or mutation, (vi) cell death, (vii) modifying physiological events, and (viii) teratogenesis/carcinogenesis/mutation fixation. For years radiation damage was attributed to damage within the cell exposed, but recent evidence (Azzam EI et al 2001

Proc Natl Acad Sci USA 98:473) has indicated that the damage is also communicated to the neighboring cells through gap junctions with the mediation of connexin 43. As a consequence in the neighboring cells the stress-inducible protein p21^{Waf1} and genetic changes become detectable. The effect of radiation on a wide array of genes (Goss Tusher V et al 2001 Proc Natl Acad Sci USA 98:5116) can be assessed by microarray hybridization. ▶ionizing radiation hazards, ▶doubling dose, ▶hormesis, ▶radiation measurement, ▶UV, ▶ultraviolet light, ▶DNA repair, ▶RAF, ▶signal transduction, ▶p21, ▶p53, ▶interferon, ▶radiation hazard assessment, ▶X-ray caused chromosome breakage, ▶kinetics, ▶target theory, ▶mental retardation, ▶Kudson's two-mutation theory, ▶Armitage-Doll model; Hollaender A (Ed.) 1954–55 Radiation Biology, McGraw-Hill, New York, see also General References.

Radiation, Evolutionary: The spread of taxonomic categories as a consequence of adaptation and speciation mediated by forces of selection, mutation, migration and random drift.

Radiation Hazard Assessment: For the exposure of the whole human body to X or γ radiation, the minimal biologically detectable dose in mSv (milliSievert) is: no symptoms 0.01–0.05, chromosomal defects detectable by cytological analysis 50–250, physiological symptoms at acute exposure 500–700, vomiting in 10% of cases 750–1250, disability and hematological changes 1,500–2,000, median human lethal dose 3,000 but at doses above 4,500 the mortality is expected to be over 50%. Prolonged exposure below 1,000 Sv may cause leukemia and death. Single exposure of the spermatogonia to 0.5 Sv may block sperm formation. In mice, the LD₅₀/cGy for primary spermatocytes was 200, meiosis (leptotene-diplotene) 500, diplotene 800, diakinesis 900, secondary spermatocytes 1,000, spermatids 1,500 and spermatozoa 50,000 (mouse data from Alpen, 1998). In mice, 1 Gy may kill the fertilized zygote but the same dose may have no such effect 5–8 days after conception, indicating the potentials of cell replacement. In humans, the most common response of the fetus is mental retardation following intrauterine exposure to 1–5 Gy. Carcinogenesis is well demonstrated by radiation exposure but the course of the initial effect may be greatly influenced by a variety of innate and environmental factors. The risk of very low doses of radiation is very difficult to quantify. Generally, extrapolation is used from higher doses and therefore the risk may be under- or overestimated (Brenner DJ et al 2003 Proc Natl Acad Sci USA 100:13761).

A single exposure of women to 3–4 Sv and 10–20 Sv over a longer time (2 weeks) may result in permanent sterility. A fetus in a pregnant woman should not be exposed to any radiation but in the case of an emergency it should not exceed a total of 0.005 Sv and any person under 18 years of age should not receive an accumulated dose over 0.05 Sv/year. A single 0.1 Sv dose may cause cancer in 0.01 fraction of the exposed individuals. For *occupational exposure*, the maximal limit in mSv for the whole body is 50, for lens of the eye 150, and for other specific organs or tissues 500. In the case of cumulative exposure the maximal limit should be below 10 mSv \times age in years. For public, educational and training exposure, the recommended maximal limit in mSv/year is 1 for the whole body, and 5.0 for the eye, skin and extremities. In the spring of 1996 the European Union (EU) lowered the permissible dose limits following which members of the public can be exposed to a maximum of 1 mSv every year (the earlier limit was 5 mSv). However, recent analysis has revealed no harmless dose even at low exposure. The limit of exposure for the personnel of radiation industry is now 100 mSv over five consecutive years and an average limit of 20 mSv/year (previous limit was 50 mSv). These guidelines must be implemented within four years by EU member states.

The exposure by routine *medical* X-ray examination is not supposed to be higher than 0.04 to 10 mSv, by fluoroscopy or X-ray movie not more than 25 mSv, and by dental examination involving the entire jaws not above 30 mSv. Nuclear medicine using radioactive tracers or positron emission tomography also involves some exposure (~ 0.012 Sv). The replacement of ^{131}I by ^{123}I is desirable for thyroid analyses. Smoking tobacco may increase the degree of exposure to ^{210}Pb and ^{210}Po . By comparison, in a normally operated nuclear power plant the exposure may range from 3 to 30 mSv/year. Those living in a granite building may be exposed to 5 mSv/year and a transcontinental flight may involve an exposure of 0.03 mSv. The terrestrial radiation (^{40}K , ^{87}Rb , U, Th series, Rn) may also be a source to reckon with. Radiation from a color television/video display set may be 0.001 mSv/year to the viewer if he/she remains very close to the set, however modern units are safer (2–3 μSv /year). Inspection of luggage at the airports may add 0.002 mrem, and smoke detectors 0.008 mrem to personal exposure. A plutonium-powered cardiac pacemaker may increase the radiation exposure of the wearer by 100 mrem. It should be borne in mind that there may be no threshold below which ionizing radiation would have no effect. It has been assumed until recently that radiation damage is caused by direct hits. There is, however, a significant

bystander effect to the cells in the vicinity of the hit cells. Within 1 mm distance α radiation increases the number of micronuclei (broken chromosomes) by a factor of 1.7 and apoptosis increases 2.8-fold. The bystander effect is apparently mediated through gap-junction signals (Belyakov OV et al 2005 Proc Natl Acad Sci USA 102:14203).

The worldwide average exposure from natural sources amounts to ~ 2.4 mSv, mostly from α particles of radon gas and cosmic rays (muons) and terrestrial γ rays. Moreover, 100 h of air travel adds ~ 0.5 mSv and medical X-rays contribute ~ 0.4 mSv annually. The 1945 atmospheric explosion and the following weapon tests constitute a fallout of 0.005 mSv.

The current approximate incidence of mutation in live-born human offspring and the estimated increase per rem per generation in parenthesis are as follows: autosomal dominant 0.0025 – 0.0075 (0.000005 – 0.00002), recessive 0.0025, X-linked 0.0004 (0.000001), translocations 0.0006 (0.0025) and trisomy 0.0008 (0.000001). Approximately 5 Gy (500 rem) is considered the human lethal dose, the bacterium *Deinococcus radiodurans* can recover from doses as high as 30,000 Gy.

The very efficient recombinational repair in this prokaryote can explain this high radiation resistance. The chromosomes are just as well broken into pieces as other DNAs but its genetic material exists in pairs and within 12 to 24 h repair by recombination at the Holliday junctures restores their integrity. Even small doses, such as delivered by therapeutic X-radiation, may increase by about one-third the number of broken chromosomes and radiation by isotope treatment has a similar effect, depending on the dose and the duration of the exposure. Eventually, the broken chromosomes, or at least some of them, may be eliminated from the body. Radiation sensitivity is generally positively correlated with the size of the genetic material although in polyploids the damage may not be readily detectable because of the redundancy of the genes. There is no universal consensus on the hazards involved in exposure to very low levels of ionizing radiation. ►atomic radiation, ►isotopes, ►radiation effects, ►radiation measurement, ►radiation sensitivity, ►radiation protection, ►doubling dose, ►hormesis, ►radiation threshold, ►mental retardation, ►DNA repair, ►Holliday model of recombination, ►X-ray chromosome breakage, ►Sv, ►Gy, ►BERT, ►hemical, ►rem, ►BERT, ►bystander effect; personal exposure: www.umich.edu/~radinfo; Dowd SB, Tilson ER 1999 Practical Radiation Protection and Applied Radiobiology, Saunders, Philadelphia; the book includes more than 100 Internet information addresses; Sankaranarayanan K 1999 Mutation Res

Radiation Hybrid (RH): Human chromosomes are broken into several fragments with 8000 rad dose of X-rays. The irradiated cells are quickly fused (with the aid of polyethylene glycol) to somatic cell hybrids with Chinese hamster cells and thus translocations and insertions into the hamster chromosomes are generated. The greater the distance between two human DNA markers, the higher the chances of a breakage. To estimate the frequency of breakage, information is obtained about “recombination” in a manner analogous to classical genetic recombinational mapping. The recombination frequency in radiation hybrids varies between 0 and 1 (no recombination or the markers are always independent, respectively). In meiotic recombination the maximal value is 0.5 for independent segregation. The formula given here and the recombination frequencies (expressed in centiRays [cR]) give an estimate of the frequency of breakage. At 65 Gy the estimated 1 cR \approx 30 kb, at 90 Gy 1 cR \approx 55 kb. $\theta = [(A^+B^-) + (A^-B^+)]/[T(R_A + R_B - 2R_AR_B)]$ where (A^+B^-) are the hybrid clones retaining A but not B and (A^-B^+) retain B but not A, T = the total number of hybrids and R_A, R_B denote the recombinant fractions. The linkage analysis can be extended to more than two points. The fragments retained can be analyzed by PCR procedures and they are expected to carry with them neighboring sequences and thus provide information on the physical linkage for sequences of about 10 megabase. The recombination process is dose-dependent. In one study 50 Gy permitted the retention of an intact chromosome arm in 10% of the cases whereas 40% had fragments of 3–30 Mb and 50% 2–3 Mb. Using 250 Gy less than 6% of the hybrids involved larger than 3 Mb pieces. If the fragments generated are intended for positional cloning, usually higher doses are used. The retention of fragments varies; centromeric pieces are more likely to be retained. The fragmented DNA can be further analyzed by probing with Southern blots, polymerase chain reaction, using sequence tagged sites (STS), FISH, etc. The fragments are unstable unless they are fused with rodent chromosomes. The radiation hybrids may retain up to a dozen or more fragments. An added special advantage is that genes without allelic variation can also be mapped. The radiation hybrid mapping method has been applied to plants as well. Single maize chromosome additions to oat lines permitted the resolution of 0.5 to 1.0

megabase sequences using 30 to 50 krad γ -rays. The hexaploid oat background assured the survival of the (diploid) maize chromosome fragments. Radiation hybrid transcript maps are available for mouse, rat, human, dog, cat and zebrafish and are useful tools for evolutionary analyses. ▶ [somatic cell hybrid](#), ▶ [mapping genetic](#), ▶ [physical mapping](#), ▶ [framework map](#), ▶ [Rhalloc](#), ▶ [Rhdb](#), ▶ [recombination](#), ▶ [Gy](#), ▶ [centiRay](#), ▶ [STS](#), ▶ [FISH](#), ▶ [Southern blot](#), ▶ [probe](#), ▶ [positional cloning](#), ▶ θ [theta], ▶ [WGRH](#), ▶ [PRINS](#), ▶ [IRS-PCR](#), ▶ [RHKO](#), ▶ [Rhalloc](#), ▶ [addition lines](#); a radiation hybrid map of the mouse genome: <http://www.ncbi.nlm.nih.gov/genemap>; <http://www.ebi.ac.uk/RHdb>; Van Etten WJ et al 1999 Nature Genet 22:384; Riera-Lizarazu O et al 2000 Genetics 156:327; Olivier M et al 2001 Science 291:1298; Hudson TJ et al 2001 Nature Genet 29:201; Avner P et al 2001 Nature Genet 29:194.

Radiation vs Nuclear Size: The harmful biological and genetic effects of ionizing radiation depend on the size of the cell nuclei, at the same dose. Larger nuclei present a larger target and suffer more damage than smaller ones. Haploid nuclei are more sensitive because the genes are normally present in a single dose. Polyploids are relatively less sensitive because of the multiple copies of the chromosomes. ▶ [radiation effects](#), ▶ [ionizing radiation](#), ▶ [physical mutagens](#), see Fig. R8.

Radiation Particulate: ►physical mutagens

Radiation Physiological Factors: The effect of radiation may be influenced by the species, age, developmental conditions, type of tissue and cells, metabolic state, genetic back-ground, repair mechanisms, temperature and the chemical environment (presence of oxygen and other enhancing or protective compounds). Actively dividing cells, imbibed seeds are far more sensitive to radiation damage than quiescent tissue or dry material. During pregnancy radiation exposure should be avoided especially during the early stages of gestation when cell division is most rapid. Also, developing children are at a higher radiation risk than adults. Any condition with the possibility of diminished genetic repair increases the chances of chromosomal aberration and gene mutation. ►physical mutagens, ►target theory, ►radiation hazard assessment, ►radiation brain damage, ►radiation vs nuclear size, ►radiation-sensitivity

Radiation Protection: This can be achieved by using isotopes, ventilation should be provided by exhaustion via seamless ducts through the buildings

and the particulate material should be trapped in appropriate filters or washed (scrubbed) before environmental discharge.

The source of radiation should be shielded. The transmission of the shielding material depends on the peak voltage of the X-ray or on the energy of the emitting isotope and the thickness of the shield (attenuating material is characterized by half-value [HVL] or tenth-value layers [TVL]) (see Table R1).

Table R1. Data on shielding effectiveness of commonly used radiation insulating material

| kV X-ray | Lead in millimeters | | Concrete in centimeters | |
|----------------------|---------------------|------|-------------------------|-------|
| | HVL | TVL | HVL | TVL |
| 50 | 0.05 | 0.16 | 0.43 | 0.15 |
| 100 | 0.24 | 0.8 | 1.5 | 5.0 |
| 200 | 0.48 | 1.6 | 2.5 | 8.25 |
| 500 | 3.6 | 11.9 | 3.5 | 11.5 |
| 1,000 | 7.9 | 26.0 | 4.38 | 14.5 |
| 4,000 | 16.5 | 54.8 | 9.00 | 30.00 |
| 10,000 | 16.5 | 55.0 | 11.5 | 38.25 |
| ⁶⁰ Cobalt | 6.5 | 21.6 | 4.75 | 15.50 |

Cracks, seams, conduits, filters, ducts, etc. should be regularly checked for possible leaks. Protective clothing (aprons, gloves, etc.) affords very limited protection. Radioactive waste should be disposed of in accordance with the government and local standards, whichever is higher. Caution signs should be used to identify radiation areas. “Radiation Area” is defined by the Occupational Safety and Health Standards of the USA as an area where a major portion of the body could receive in any hour a dose in excess of 5 millirem, or in any 5 consecutive days a dose in excess of 100 millirem. “High Radiation Area” means any area, accessible to personnel, in which radiation is present at such levels that a major portion of the body could receive in any one hour a dose in excess of 100 millirem. For non-ionizing electromagnetic radiation within the range of 10 MHz (megahertz, 10⁷ cycles/sec) to 100 Ghz (gigahertz, 10¹¹ cycles/sec) the energy density should not exceed 1 mW (milliwatt)/cm²/0.1 h. [Such radiations are within the realm of radio, microwave and radar range.] Emergency plans must be prepared for spillage, cleanup and fire. Before working with any hazardous material all personnel should be given proper training for safe storage, handling and

emergencies involved. ▶ isotopes, ▶ atomic radiation, ▶ ionizing radiation, ▶ radiation effects, ▶ radiation hazard assessment, ▶ radiation measurement, ▶ electromagnetic radiation, ▶ sulfhydryl

Radiation Resistant DNA Synthesis: Normally, the ataxia telangiectasia gene/protein (ATM) is a target of the damaging effects of ionizing radiation. ATM activated by radiation results in the activation of the cell cycle (G1→S) checkpoint kinase Chk2. The activation of Chk2 results in the phosphorylation of phosphatase Cdc25A at residue Ser¹²⁵. Cdc25A prevents dephosphorylation of Cdk2 and this leads to a transient stoppage of DNA synthesis at the S phase. If Chk2 cannot bind or phosphorylate Cdc25A, radiation resistant DNA synthesis proceeds. Thus, Chk2 acts as a tumor suppressor in ataxia telangiectasia. ▶ Chk2, ▶ Cdc25, ▶ cell cycle, ▶ ataxia telangiectasia; Falck J et al 2001 Nature [Lond] 410:842.

Radiation Response: Deletions (single chromosomal breaks) and mutations occur with 1st order kinetics, whereas the majority of chromosomal rearrangements (inversions, translocations) are proportional to the square of the dose and thus follow 2nd or 3rd order kinetics. The irradiated cell may communicate with the neighboring cells via IL-8 and these neighbors may also suffer oxidative stress as a bystander effect. ▶ IL8, ▶ physical mutagens, ▶ radiation effects, ▶ kinetics, ▶ chromosomal aberrations, ▶ radiation vs nuclear size, ▶ oxygen effect, ▶ radiation-sensitivity; Rothkamm K, Löbrich M 2003 Proc Natl Acad Sci USA 100:5057.

Radiation Safety: ▶ radiation protection, ▶ radiation hazard assessment, ▶ atomic radiation, ▶ cosmic radiation

Radiation Safety Standards: ▶ radiation hazard assessment, ▶ radiation protection

Radiation-Sensitivity: This characteristic of the DNA depends on many diverse factors such as the degree of coiling, the status of the nuclear matrix, hydration, copper ions, OH scavengers and thiols. The microbial flora seems to be protective against intestinal radiation effects (Crawford PA, Gordon JI 2005 Proc Natl Acad Sci USA 102:13254). In budding yeast a genome-wide screen of 3670 non-essential genes revealed 107 new loci that influence sensitivity to γ -rays. Further, 50% of these yeast genes display homology to human genes. ▶ DNA repair, ▶ chromosome breakage, ▶ aging, ▶ microcephaly [Nijmegen breakage syndrome], ▶ nevoid basal cell carcinoma, ▶ ataxia telangiectasia, ▶ xeroderma pigmentosum, ▶ radiation hazard assessment, ▶ radiation protection, ▶ radiation response, ▶ radiation vs

nuclear size, ▶ *Deinococcus radiodurans*, ▶ radiation physiological factors; Bennett CB et al 2001 Nature Genet 29:426.

Radiation Sickness: This occurs when the whole human body or parts of it is exposed to ionizing radiation. The symptoms and hazards are dependent on the dose. ▶ radiation hazard assessment

Radiation Therapy: Ionizing, electromagnetic radiation has anti-mitotic and destructive effects on live tissues and it is used to suppress cancerous growth. The therapeutic effects of radiation in cancer therapy may not have a direct impact on the genetic material of the cancer cells. The effective target may be the surrounding (endothelial) cells that provide angiogenesis to satisfy the cancer cells' increased requirement for blood (Paris F et al 2001 Science 293:293). Radiotherapy has been used to treat lymph nodes to suppress Hodgkin's disease, radioactive isotopes can be injected for localized radiation. Similar effects are expected by the use of magic bullets. Blood withdrawn from the body has been irradiated by UV light and returned to the system. The level of radio-curability varies for tumors of different tissues from 2000–3000 rad for reproductive and nerve tissues, to 5000–6000 rad for lymphatic node and breast cancers, to 8000 rad for melanomas and thyroid cancer. The proper function of the radiation source must be regularly monitored to ensure the safety of patients and operators. It has been assumed that very high doses of radiation may not be as dangerous because they destroy the irradiated cells whereas a lower level of radiation involves higher cancer risks. However, recent observations have indicated that in radiotherapy after the initial killing specific areas in breast and lung cancer are repopulated by new cells, which have a high chance to develop second-cancer growth (Sachs RK, Brenner DJ 2005 Proc Natl Acad Sci USA 102:13040). ▶ radiation effects, ▶ magic bullet, ▶ Hodgkin's disease, ▶ lymph node, ▶ radiation hazard assessment; Bharat B et al (Eds.) 1998 Advances in Radiation Therapy, Kluwer, Boston, Massachusetts.

Radiation Threshold: The minimal harmful radiation dose is very difficult to determine because the visible physiological signs may not truly reflect the long-range mutagenic and carcinogenic effects. The maximal permissible doses for medical, diagnostic or occupational radiation exposures reflect only conventional limits that have been revised many times as the sensitivity of physical and biological detection methods as well as the instrumentation of delivery have improved. It is conceivable that no low threshold exists. ▶ radiation response, ▶ cosmic

radiation, ►mutation frequency-undetected mutations, ►radiation safety standards, ►radiation hazard assessment

Radical: Refers to an atom or a group with an unpaired electron, a free radical.

Radical Amino Acid Substitution: This occurs when nucleotide substitution alters the physicochemical property (e.g., charge, polarity, volume) of the mutant protein. By conservative substitution the physical/chemical characteristics are not altered. The proportions of radical/conservative ratios are positively correlated with the non-synonymous/synonymous replacements. Also, transversions are more likely to cause radical changes. ►synonymous codons; Zhang J 2000 *J Mol Evol* 50:56; Dagan T et al 2000 *Mol Biol Evol* 19:1022.

Radical Scavenger: This may combine with free radicals and reduce the potential harm caused by the highly reactive molecules.

Radicle: The seed or primary root of a plant embryo. It also refers to the smallest branches of blood vessels and nerve cells.

Radin Blood Group (Rd): This is encoded in the short arm of human chromosome 1; its frequency is low.

Radioactive Decay: ►isotopes

Radioactive Isotope: ►isotopes, ►radioactive tracer, ►radioactive label

Radioactive Label: Compounds (nucleotides, amino acids) containing radioactive isotopes are incorporated into molecules to detect their synthesis, fate or location (radioactive tracers) in the cells. For detection purposes, scintillation counters or autoradiography is used most frequently. Geiger counters may also qualitatively detect their presence. For cytological analysis, isotopes that have a short path of radiation and display distinct, sharp marks on the film are used, e.g., tritium (^3H). For molecular biology, most commonly ^{32}P (in DNA, RNA) or ^{14}C and ^{35}S (in proteins) or ^{125}I in immunoglobulins are used. Radioactive labeling for genetic vectors or transgenes is not practical because at each subsequent division the label is diluted to about half. Labeling with integrated genetic markers is more useful because these are replicated along with the genetic material. ►Southern blotting, ►Northern blotting, ►Western blotting, ►nick translation, ►non-radioactive labels, ►isotopes, ►radioactive tracer

Radioactive Tracer: A radioactively labeled compound that permits tracing the biosynthetic transformations of the supplied chemical by determining when the

radioactivity appears in certain metabolites after the supply. It also reveals what part of a later metabolite has acquired the label from the supplied substance. The availability of $^{14}\text{CO}_2$ permits tracing the path of photosynthesis, and through the use of various isotopes, the metabolism of pharmaceuticals and the role of hormones, etc., can be determined. ►radioactive label, ►radioimmunoassay

Radioactivity: Refers to the emission of radiation (electromagnetic or particulate) by the disintegration of atomic nuclei.

Radioactivity Dating: ►evolutionary clock

Radioactivity Measurement: ►radiation measurements

Radioautography: Same as autoradiography.

Radiocarbon Dating: The age of ancient samples of less than 50,000 years (late Pleistocene to Holocene) is generally estimated by this method in archeology and evolution. Natural radiocarbon is the product of the interaction of cosmic radiation with nitrogen 14 (N^{14}) in the earth's atmosphere. This unstable nitrogen is converted to carbon 14 (C^{14}), which is oxidized to $^{14}\text{CO}_2$ and enters plants through photosynthesis and from them to animals. C^{14} is very rare, only $\sim 1 \times 10^{-10}$ fraction of all naturally occurring carbon. Plants absorb this unstable C in proportion to the total C in the environment. When the plant dies, metabolism ceases and in its tissues the proportion of C^{14} decays according to the age of the relic. After every 5568 years the amount of C^{14} isotope is reduced by half. The reduction is measured in terms of the emission of 160 keV β -rays (electrons) by the sample. The wood found in the tomb of the pharaoh in the pyramid Djoser in 1949 contained 50% C^{14} indicating that its age was about 5568 years. The validity of this estimate required that the atmosphere contained the same amounts of C^{14} during that period as it did at the time of the analysis. The half-life figure of 5568 was later corrected to 5730 ± 40 (Cambridge half-life). Today improved methods are available such as the accelerator mass spectrometry or liquid scintillation, which provide greater accuracy yet even the most advanced methods struggle with some uncertainties. Nevertheless, the radiocarbon dating principle developed by Willard F. Libby in 1949 earned a much-deserved Nobel Prize in 1960.

Carbon dating is also used for determining human age. The carbon dating method may yield erroneous results if the samples are contaminated by more recent carbon. For example, 1% of such contamination in a 40,000 year old specimen may falsely reduce the age by 7,000 years. Another source of bias is that the C^{14} to C^{12} proportions varied in the earth's atmosphere because the magnetic field varied during

the ages and also sunspots affected the amount of cosmic radiation reaching the upper atmosphere. Newer techniques using higher molecular weight of animal and human bone gelatins substantially improved the accuracy level by eliminating contamination by C^{12} . The other source of error was considerably reduced by more accurate determination of C^{14} in deep sea strata during the last 50,000 years. The new calibrations indicate that human dispersal in Europe was thousands of years faster than originally estimated. Also, in Southern France humans appeared around 36,000 BP rather than 31,000 to 32,000 BP. As the methods of calibration improve, changes even in the newer estimates are likely (Mellers P 2006 Nature [Lond] 439:931).

After 1955 (the beginning of the atmospheric nuclear weapons tests) the C^{14} level in the air increased and it was fixed from carbon dioxide by photosynthetic plants and ingested by herbivores through the diet. C^{14} has accumulated in the teeth during the formation of new enamel up to the age of 12. Tooth enamel contains $\sim 0.4\%$ C. In spite of the fact that after the test ban treaties in 1963 the atmospheric C^{14} is decreasing yet the level is sufficient for the determination of its presence in the teeth in proportion to that in the atmosphere at the age of tooth development. Although individual variations in the age of tooth formation and diet affect the incorporated amounts, it is a very sensitive indicator of age (Spalding KL 2005 Nature [Lond] 437:333). [▶isotopes](#), [▶half-life](#), [▶evolutionary clock](#), [▶argon dating](#), [▶out-of-Africa hypothesis](#), [▶Eve foremother](#), [▶Lascaux cave](#); Libby WF 1955 Radiocarbon dating, University Chicago Press; Guilderson TP et al 2005 Science 307:362.

Radioimmunoassay (RIA): The most commonly used isotope for radioimmunoassays, $^{125}\text{I}^+$ is generated by oxidation of Na^{135}I by chloramine-T (*N*-chlorobenzene sulfonamide). This labels tyrosine and histidine residues of the immunoglobulin without affecting the binding of the epitope and provides an extremely sensitive method for identifying minute quantities (1 pg) of antigen in an experiment. ^{35}S -methionine or ^{14}C can radiolabel target proteins. In the *Competition*

RIA an unlabeled target protein competes with a labeled antigen for binding sites on the antibody. The amounts of bound and unbound radioactivity are then quantified. In the *Immobilized Antigen RIA* an unlabeled antigen is attached to a solid support and exposed to a radiolabeled antibody (see Fig. R9). The amount of radioactivity bound then measures the amount of specific antigen present in the sample. In the *Immobilized Antibody RIA* a single antibody is bound to a solid support and exposed to a labeled antigen. Again, the amount of bound radioactivity indicates the amount of antigen present. In the *Double-Antibody RIA* one antibody is bound to a solid support and exposed to an unlabeled antigen. After washing, the target antibody is quantitated by a second radiolabeled antibody (instead of the radiolabel, biotinylation can also be used). This assay is very specific because it involves a step of purification. Radioisotope: [▶isotopes](#)

Radioisotope Dating: [▶fossil records](#)

Radiomimetic: These agents, primarily alkylating mutagens, may break single or both chromatids (isochromatids). Although it cannot be ruled out that the two chromatids break at the same place simultaneously, it is believed that isochromatid breaks are due to replicational events involving initially single chromatid breaks. They mimic the effects of ionizing radiation. [▶alkylating agents](#), [▶nitrogen mustards](#), [▶sulfur mustards](#), [▶epoxides](#), [▶ionizing radiation](#); Dustin AP 1947 Nature [Lond] 159:794.

Radiomorphoses: Morphological alterations in plants caused by ionizing irradiation during the life of the irradiated individuals. These effects may not be genetic.

Radionuclide: A nuclide that may disintegrate upon irradiation by corpuscular or electromagnetic radiation. [▶nuclides](#)

Figure R9. Radioimmuno assay

Radioprotectors: These protect against the harmful effect of ionizing radiation, e.g., sulfhydryl compounds, antioxidants, cysteine, cysteamine, amifostin and melatonin. (See separate entries; Maisin JR 1989 Adv Space Res 9[10]:205).

Radiotherapy: ►radiation therapy

Radioulnar Synostosis with Amegakaryocytic

Thrombocytopenia: Refers to dominant (7p15) bone fusion due to mutation in HOXA11 gene associated with abnormal easy bleeding. ►thrombocytopenia; Thompson AA, Nguyen LT 2000 Nature Genet 26:397.

Radish (*Raphanus sativus*): A cruciferous vegetable crop; $2n = 2x = 18$. The hybrid of *R. sativus* and *R. raphanistrum* appears to have an unusually superior fitness to both parental species and over a few generations drive to extinction the parental forms within a territory (Hegde SG et al 2006 Evolution 60:1187). ►Raphanobrassica, ►Brassica oleracea, ►mustards, ►fitness

Radix (root): A multiplier of successive integral powers of a sequence of digits, e.g., if the radix is 4, then 213.5 means 2 times 4 to the second power plus, 1 times 4 to the first power plus 3 times 4 to the zero power plus 5 times 4 to the minus 1 power.

Radon (Rn): ^{219}Rn (An) is a member of the actinium series, ^{220}Rn (Tn) is a member of the thorium emanation group and ^{222}Rn is derivative of uranium, a heavy (generally accumulates in basements), colorless radioactive noble gas which is formed by uranium (radium emanation) contaminated rocks. It may pose health hazards in buildings at some locations and with poor ventilation. In the USA, an estimated 200 mrem of radon is the average annual exposure/person. ►radiation hazards, ►cosmic radiation, ►rem, ►WL; Field RW, Becker K 2001 Radiat Prot Dosimetry 95:75.

RAF1: ►raf

raf: v-oncogene (cytoplasmic product is protein-serine/threonine kinase). The cellular homolog RAF1 is closely related to ARAF oncogenes. The v-raf is homologous to the Moloney murine leukemia virus oncogene. The avian MYC oncogene is the equivalent of the murine RAF. RAF1 has been assigned to human chromosome 3 and a pseudogene RAF2 is in chromosome 4. Human renal, stomach and laryngeal carcinoma cells reveal RAF1 sequences. Raf may be recruited to the cytoplasmic membrane by a carboxy-terminal anchor (RafCAAX) and its activation then

becomes independent from Raf which is associated with the plasma membrane cytoskeletal elements and not with the lipid bilayer. RAF-1 phosphorylates MEK-1 kinase involved in the signal transduction process of extracellular signal regulated kinases. RAF induces NF- κ B through MEKK1. Raf-1 is regulated by RKIP (Raf kinase inhibiting protein). Phosphorylation at the appropriate sites activates/inactivates RAF. The activation of Raf by basic fibroblast growth factor results in phosphorylation of serine 338 and 339 and activation by VGF phosphorylates tyrosine 340 and 341. Both pathways protect against apoptosis (Alavi A et al 2003 Science 301:94). ►ARA, ►MYC, ►Moloney, ►signal transduction, ►RAS, ►BRAF, ►v-oncogene, ►PAK, ►MAP kinase NF- κ B, ►MEKK, ►FGF, ►VGF, ►apoptosis; Chong H et al 2001 EMBO J 20:3716.

RAFT: The association of sphingolipids and cholesterol (~50 nm in diameter) and it mediates membrane traffic and cell signaling in mammals. Lipid rafts incorporate glycosylphosphatidyl inositol-anchored proteins, doubly acylated peripheral membrane proteins, cholesterol-linked proteins and transmembrane proteins. Host membrane-derived lipids surround enveloped viruses (e.g., HIV) that are acquired during budding in the replication process. The composition of these lipids is different from that of the host membrane. These lipid-enclosed structures indicate the existence of rafts within living cells (Brügger B et al 2006 Proc Natl Acad Sci USA 103:2641). Each raft does not carry more than 10 to 30 proteins. ►caveolae, ►endocytosis, ►sphingolipids, ►cholesterols, ►TOR, ►protein transport, ►liposome, ►SFK, ►HIV; Langlet C et al 2000 Curr Opin Immunol 12:250; Brown DA, London E 2000 J Biol Chem 275:17221; Simons K, Toomre D 2001 Nature Rev Mol Cell Biol 2:216.

RAFTK: ►CAM

RAG1, RAG2 (recombination activating gene): These are closely linked (11p13) and encode the proteins of lymphocyte-specific recombination of the V(D)J sequences of immunoglobulin genes. The functional part of RAG1 is the core sequence whereas other tracts can be deleted without affecting recombination. Mutation in RAG results in the inability to form functional antigen receptors on B and T cells and antibodies. The recombinational cleavage takes place between the *coding sequence* of the immunoglobulin genes and the so-called *recombinational signal sequence* (RSS) nucleotides. Recombination usually occurs between the original coding sequences or it may take place by the rejoining of one coding end, the signal sequence, which originally belonged to the other coding end (hybrid joint) or the same coding

and signal sequence end can be reunited (open-and-shut joint). Besides RAGs, the joining reaction requires the double-strand repair protein XRCC4, a DNA-dependent protein kinase and the Ku protein(s). For recombination, an accessory protein HMG1 or HMG2 is also required. Nucleotides may be added or deleted in each type of joining. RAG1 and RAG2 are actually transposons but after the joining of the V(D)J ends, normally following the formation of the antibody genes, RAGs are inactivated. RAG proteins seem homologous to the *Tc1* transposon of *Caenorhabditis*. The V(D)J recombinase shows a sequence similarity to retroviral integrase superfamily (Zhu L et al 2004 Nature [Lond] 432:995). RAG1 and RAG2 genes are coordinately regulated by cell-type specific elements upstream of RAG2. The 5' promoter upstream sequences in RAG2 regulate B and T cells differently. For T cells there are four T cell receptors (TCR) and for the B cell to recombine there are three immunoglobulin loci. ▶antibody, ▶immunoglobulins, ▶junctional diversification, ▶NHEJ, ▶combinatorial diversification, ▶RSS, ▶V(J)D recombinase, ▶XRCC4, ▶Ku, ▶DNA-PK, ▶TCR, ▶hybrid dysgenesis, ▶reticulosis familial histiocytic, ▶integrase; Schultz HY et al 2001 Molecular Cell 7:65; Qiu J-X et al 2001 Molecular Cell 7:77; Raghavan SC et al 2001 J Biol Chem 276:29126; Jones JM, Gellert M 2001 Proc Natl Acad Sci USA 98:12926.

RAGE (receptor for advanced glycation endproduct): A member of the immunoglobulin protein family on the cell surface. It interacts with multiple ligands and mediates homeostasis, development, inflammation, tumor proliferation, development and manifestation of some diseases (diabetes, Alzheimer's disease). RAGE is also a receptor for amphoterin. In cooperation with p21^{Ras}, MAP, NF-κB, CDC42, SAP/JNK, p44/p42 may alter cellular programming. By blocking the major factor complex of RAGE—amphoterin may prevent invasiveness of cancer and metastasis. (See individual entries of mentioned terms).

RAGE: Refers to random activation of gene expression.

Ragweed: A largely annual species of the genus *Ambrosia elatior* (Compositae) which is widespread in North America and Central Europe and causes pollen allergy (hay fever) of the nose and eye, skin irritations and even asthma without hay fever. The susceptibility is genetically controlled by a locus, *I_r*, within the HLA complex. The antigen E contained in the ragweed pollen elicits the IgE antibody. ▶HLA, ▶allergy, ▶atopy (See Fig. R10).

Figure R10. Ragweed (*A. artemisiifolia*)

RAIDD: An adaptor protein that joins the ICE/CED-3 apoptosis effector molecules. ▶apoptosis, ▶ICE

RALA: A RAS-like protein encoded in human chromosome 7. ▶RAS oncogene

RALB: A RAS-like protein encoded in human chromosome 13. ▶RAS oncogene

Raloxifene: A lipid-like molecule that enters the cell nucleus and can bind to the special raloxifene-response element in the DNA and activate the tumor growth factor-β3 gene (see Fig. R11). 17-epiestriol, an intermediate in the secretion of estrogen, activates Raloxifene. Raloxifene, an anti-estrogenic compound, is used in chemotherapy of breast cancer. Its advantage over the related compound tamoxifen is that it does not pose an appreciable risk for uterine cancer. ▶hormone-response elements, ▶estrogen receptor, ▶tamoxifen, ▶breast cancer, ▶estradiol; Greenberger LM et al 2001 Clin Cancer Res 7:3166.

Figure R11. Raloxifene

RAM: ▶random-access memory in the computer, also rabbit-antimouse immunoglobulin

ram: Refers to ribosomal ambiguity mutation causing high rate of translational error. ►ambiguity in translation

Raman Spectroscopy: Similar to infrared spectroscopy, it uses 10,000 to 1,000 nm spectral regimes to detect different rotational and vibrational states of molecules. If two atoms are far apart, their interaction is negligible. If they are very close they may show repulsion. It is useful to obtain information on the physical state of nucleic acids. The technique can be applied for the detection of a variety of breast cancers. Although the signals are weaker than in other optical methods, they are very specific (Haka AS et al 2005 Proc Natl Acad Sci USA 102:12371). ►FT-IR; Thomas GJ Jr 1999 Annu Rev Biophys Biomol Struct 28:1.

Ramet: This is a clonal descendant of a plant capable of independent reproduction. ►genet

Ramie (*Boehmeria nivea*): A subtropical-tropical, monoecious fiber plant; $2n = 2x = 14$.

Rammer: Refers to the annotation of ribosomal genes (Lagesen K et al 2007 Nucleic Acids Res 35:3100).

RAMP (ribosomally encoded antimicrobial peptide): Refers to the natural defense molecules of animals, plants and fungi. ►antimicrobial peptides, ►defensin

Ramus (plural rami, Latin word): Denotes a branch; it is used in various word combinations.

RAN (RAS-like nuclear G protein, TC4): A guanosine triphosphatase (GTPase) which is required for import and export through nuclear pores and activation of the mitotic spindle. It acts as a switch of GTP→GDP in DNA synthesis and cell cycle progression. The proper balance between RanGTP and RanGDP determines the nucleo-cytoplasmic traffic. Cytoplasmic RanGTP may inhibit transport to the nucleus. The binding protein RanBP enhances the activity of RanGTP-activating protein RanGAP. RanBP1 is a nucleus-localized transporter binding well to RanGTP and weakly to RanGDP. RanBP2 is localized primarily in the cytoplasmic fibers of the nuclear pore complex. RAN also monitors the integrity of tRNAs before they are exported to the cytoplasm. RAN processes the 7S RNA into 5.8 ribosomal RNA of eukaryotes. ►GTPase, ►RAS, ►importin, ►export adaptor, ►signal transduction, ►cell cycle, ►RNA transport, ►RCC, ►GAP, ►nuclear pore, ►nuclear localization signal, ►Pat1, ►meiosis, ►TPX, ►SUMO; Nachury MV et al 2001 Cell 104:95; Carazo-Salas RE et al. 2001 Nature Cell Biol 3:228; Seewald M J et al 2002 Nature [Lond] 415:662.

Rana (genus of frogs): Both the American leopard frog (*Rana pipiens*) and the European frog *R. temporaria* have $2n = 26$ chromosomes. Frogs are generally more aquatic than toads. ►frog, ►Bufo, ►Xenopus, ►toad

Random Access Memory (RAM): This storage of information can be referred to at any order as long the computer is switched on.

Random Amplified Polymorphic DNA: ►RAPD

Random Chromosome Segregation: The gene under study is (absolutely) or very closely linked to the centromere in polyploids. ►maximal equational segregation

Random Fixation: ►random genetic drift, ►founder principle

Random Genetic Drift: A change in gene frequency by chance. Such random changes are most likely to occur when the effective size of the population is reduced to relatively few individuals. Since random drift may occur repeatedly, large changes may eventually result in the genetic constitution of the population. Such changes are likely when a few individuals migrate to a new (isolated) habitat. ►effective population size, ►founder principle; Whitlock MC 2000 Evolution Int J Org Evolution 54:1855.

Random Mating: Each individual in the population has an equal chance to mate with any other of the opposite sex (panmixis). Random mating is assumed in the majority of principles of theoretical population genetics. The rules are based on the Hardy-Weinberg theorem and on that basis the genetic structure of the population can be predicted as long as the allelic frequencies do not change or the change is negligible. Allelic frequencies may be altered primarily by selection, migration and, if the size of the population is very small, by random genetic drift. In the short run mutation does not affect allelic frequencies because of its rarity and the chances of survival of the majority of new mutations are low.

In a population involving two different allelic pairs the frequency of the mating genotypes and the genotypic proportion of their progenies derived from the binomial distribution by expanding $(p + q)^4$ (see Table R2). ►Hardy-Weinberg theorem, ►mating systems, ►Pascal triangle

Random Oligonucleotide Primers Used For Synthesis of Radioactive Probes: Heterogeneous oligonucleotides can anneal to different and many positions along a nucleic acid chain. They can also serve as primers for the initiation of DNA synthesis. If the precursors are one type of radioactive [α - 32 P]-deoxyribonucleotide (dNTP), and cold dNTPs, highly radioactive

Table R2. Random mating. $MATES \rightarrow (A1A1) \times (A1A1), (A1A1) \times (A1A2), (A1A2) \times (A1A2), (A1A2) \times (A2A2), (A2A2) \times (A2A2), (A1A1) \times (A2A2)$

probes can be obtained. Single-stranded DNA templates can be copied with the aid of Klenow fragment of DNA polymerase I or in the case of RNA template reverse transcriptase can be used. The primers are usually short (6 to 12 base) and can be generated either by DNase digestion of commercially available DNA (from calf thymus or salmon sperm) or by an automatic DNA synthesizer. ►[probe](#), ►[nick translation](#)

Random Sample: This type of sample is withdrawn from a collection without any selection.

Random Variables: These may occur unpredictably in a sample because of unknown factors but their breadth can be described by statistical probability. ►[significance level](#), ►[inference statistical](#)

Random Walk: This is a physical theory of material distribution within media such as cell migration within connective tissues, Markov processes in DNA, diffusion in gases, liquids and solids, population changes as a result of birth and death, and evolutionary changes such as the emergence and extinction of species. (Berg HC 1993 Random walks in biology, Princeton University Press, Princeton, New Jersey; Cornette JL, Lieberman BS 2004 Proc Natl Acad Sci USA 101:187).

Range Constraints: The number of repetitive units of a microsatellite has limitations because of viability or adaptability. ►[microsatellite](#)

RANK (receptor activator of NF- κ B): ►[TRANCE](#)

RANTES (regulated on activation normally T-cell expressed and secreted): This is a chemoattractant of cytokines for monocytes and T cells. The chemokine receptors appear to be seven membrane proteins, coupled to G proteins. RANTES is also involved in a transient increase of cytosolic Ca^{2+} as well as Ca^{2+} release. The opening of the calcium channel increases the expression of interleukin-2 receptor, cytokine release and T cell proliferation. In

addition to inducing chemotaxis, RANTES can act as an antigen-independent activator of T cells in vitro. RANTES and MIP-1 chemokines along with the receptor CC CKR5 and fusin are believed to suppress replication of HIV. ►[MIP-1a](#), ►[fusin](#), ►[chemotaxis](#), ►[cytokine](#), ►[CC CKR5](#), ►[HIV](#), ►[acquired immunodeficiency](#), ►[T cell](#); Alam R et al 1993 J Immunol 150:3442; Casola A et al 2001 J Biol Chem 276:19715; structure of glycosaminoglycan interaction domain: Shaw JP et al 2004 Structure 12:2081.

RAP: ►[RNAIII/rnaii](#)

RAP: RAP30 and RAP74 are subunits of the general transcription factor TFIIF, which binds RNA polymerase II and recruits TFIID and TFIIB transcription factors to pol II (Conaway JW et al 2000 Trends Biochem Sci 25:375).

RAP1A (1p13.3), **RAP1B** (12q14), **RAP2** (13q34): These are RAS related eukaryotic proteins but unlike RAS they are localized on intracellular membranes. The guanine exchange factor of RAP1, Epac (exchange protein activated by cAMP) is activated by cAMP and it bears homologies to the regulatory subunit of PKA. Rap1A is a suppressor protein of Ras-induced transformation. It has identical amino acid sequences with the effector region of Ras p21. Along with SIR3, RAP1 is a transcriptional repressor of telomeric heterochromatin. RAP74 is a subunit of transcription factor TFIID and RAP74 is involved in binding to the serum response element. RAP1 (repressor/activator protein) of yeast binds to upstream activator sequences (UAS) alone as well as in association with other proteins; it also activates many genes besides silencing the mating type and the telomerase functions. Rap1 activates about 37% of RNA polymerase II initiations in yeast. Rap1 is also a negative regulator of TCR-mediated transcription of interleukin-2 (IL-2) gene. RAP1 may enhance meiotic recombination and opening up of the nucleosomal chromatin. RAP1 may stimulate the formation of boundary elements. The nerve growth factor (NGF) may signal to ERK (environmental regulated kinases) either through RAS or RAP. ►[RAS oncogene](#), ►[silencer](#), ►[serum response element](#), ►[transcription factors](#), ►[mating type determination](#), ►[telomerase](#), ►[TRF1](#), ►[TCR](#), ►[IL-2](#), ►[nucleosome](#), ►[PKA](#), ►[cAMP](#), ►[ORC](#), ►[HML and HMR](#), ►[boundary element](#), ►[adherens junction](#), ►[nucleoporin](#); Rousseau-Merck MF et al 1990 53:2; Morse RH 2000 Trends Genet 16:51; IdrissiF-Z et al 2001 J Biol Chem 276:26090.

Rapamycin (sirolimus): This immunosuppressor may block the cell cycle through the G1 phase by controlling mitogen-activated signal transduction. It regulates the prokaryotic ribosomal protein S6

and the elongation initiation protein eIF-4E (see Fig. R12). ▶FK506, ▶TOR, ▶cell cycle, ▶signal transduction, ▶S6 kinase, ▶eIF-4E, ▶immunosuppressant, ▶immunophilins, ▶non-ribosomal peptide; Cardenas ME et al 1998 Trends Biotechnol 16:427; Rohde, J. et al. 2001 J Biol Chem 276:9583.

Figure R12. Rapamycin

RAPD (pronounce rapid): These markers are generated by random amplified polymorphic DNA sequences using (on average) 10 base pair primers and the PCR technique for the physical mapping of chromosomes on the basis of DNA polymorphism in the absence of “visible” genes. The map so generated may be integrated into RFLP and classical genetic maps. ▶polymerase chain reaction, ▶physical mapping, ▶sequence-tagged site, ▶integrated map; Reiter RS et al 1992 Proc Natl Acad Sci USA 89:1477.

R

Rape (*Brassica napus*): This is an oil seed crop ($2n = 38$, AC genomes). The new varieties are low in the toxic erucic acid and glucosinolates. ▶canola, ▶erucic acid

Raphanobrassica: This is a man-made amphidiploid ($2n = 36$) of radish (*Raphanus sativus*, $n = 9$, R genome) and cabbage (*Brassica oleracea*, $n = 9$, C genome). ▶*Brassica oleracea*, ▶radish, ▶amphidiploid

Raphe: Refers to a ridge on the seeds where the stalk of the ovule was attached; it also refers to the seam of animal tissues.

Raphids: These are needle-like crystals within plant cells (often of oxaloacetic acid).

Raphilin: This is a peripheral membrane protein. It may bind RAB proteins in a GTP-dependent manner and may be phosphorylated by various kinases and may bind Ca^{2+} and phospholipids. ▶RAB

Rapid Lysis Mutants: *r* mutants of bacteriophage rapidly lyse the infected bacteria and, therefore, the size of the plaques is much larger than the ones made by wild type phage (see Fig. R13). ▶lysis, ▶plaque lift, ▶lysis inhibition

Figure R13 Rapid lysis mutants

Rapp-Hodgkin Syndrome: An anhidrotic ectodermal dysplasia with cleft lip and cleft palate. The latter symptoms do not always co-occur (mixed clefting). ▶ectodermal dysplasia, ▶anhidrosis, ▶cleft palate; Neilson DE et al 2002 Am J Med Genet 108:281.

Rapsyn (43 kDa): A peripheral membrane protein co-localized with the acetylcholine receptors at the neuromuscular synapsis. Mutations in rapsyn may lead to myasthenia. ▶acetylcholine, ▶myasthenia; Ohno K et al 2002 Am J Hum Genet 70:875.

RAR: Refers to repair and recombination.

RAR, RARE (retinoic acid receptor [element]): RAR and RXR- α , - β , - γ retinoid-X receptors are transducers of ligand-activated morphogenetic and homeostasis signals. RAR and RXR can form homodimers but are usually found as heterodimers. These then bind to the cognate hormone response elements and increase the efficiency of transcription. Docosahexaenoic acid ($\text{CH}_3[\text{CH}_2\text{CH}=\text{CH}]_6[\text{CH}_2]_2\text{CO}_2\text{H}$) is an activator of RXR. RAR- α ligands can accomplish the binding of the RXR-RAR- α dimers to DNA causing RXR activation and initiating the transcriptional activity of RAR- α . The RXR-RAR complex may also repress transcription. It is encoded in human chromosome 17q12. RAR may play a role in the development of promyelocytic leukemia (PML) when it associates with histone-deacetylase and other co-factors (see Fig. R14). In PML-RAR α patients pharmacological doses of retinoic acid lead to cancer remission because of the near normal differentiation of the hematopoietic (red blood-forming) cells but in

Figure R14. The action of RAR in promyelocytic anemia (Redrawn after Grignani, F. *et al.* 1998 Nature (Lond) 39:815)

promyelotic leukemia Zinc finger (PLZF) patients this treatment is quite ineffective. Retinoic acid may downregulate telomerase activity. The retinoid system also plays a role in differentiation, motor innervation of the limbs, skeletal development and in the development of the spinal cord. *RAR1* genes in plants play a defense role. ▶hormone response elements, ▶retinoic acid, ▶leukemia, ▶PPAR, ▶histone deacetylase, ▶Zinc finger, ▶innervation, ▶Sin3; Zhong S *et al* 1999 Nature Genet 23:287; Pendino F *et al* 2001 Proc Natl Acad Sci USA 98:6662.

RARE (RecA-assisted restriction endonuclease): At the site of a restriction enzyme recognition in or near a locus a triplex structure, with an oligonucleotide, is generated with the assistance of enzyme RecA. The genome is enzymatically methylated and RecA is removed. Only the site now unprotected will be cut by the restriction endonuclease. This procedure reduces the actual cleavage sites in the DNA. ▶recA, ▶restriction enzyme, ▶DNA methylation Ferrin LJ 2001 Mol Biotechnol 18[3]:233.

Rare-Cutter: This is a restriction enzyme with a longer DNA sequence (>8 nucleotides) recognition site. Therefore it cleaves DNA much less frequently (because of the greater specificity for sites) than enzymes which recognize only 4 bases in a sequence. ▶restriction enzyme

Rare-Mating: Cells of non-mating yeast strains are mixed with cells that are expected to mate under favorable conditions. Low frequency of mating may take place and the progeny may be isolated by efficient selection. Rare-mating is presumed to be the result of mitotic recombination or non-disjunction of chromosome III in the non-mating strain. When normal mating fails, protoplast fusion may generate hybrids. The latter procedure, however, produces complex progeny. ▶mating type determination, ▶protoplast fusion; Spencer JF, Spencer DM 1996 Methods Mol Biol 53:39.

RAS (p21^{ras}, 11p15.5): This is a protooncogene originally found in rat sarcoma virus; it codes for a monomeric GTP-binding protein in which point mutation mainly in codons 12, 13, 59 or 61 may lead

to oncogenic transformation. Alterations in site 12 in humans and in site 61 in rodents are common in tumors. RAS proteins have an important role in transmembrane signaling. Ras may have an alternate location at the Golgi membrane, depending on de/reacylation (Rocks O *et al* 2005 Science 307:1746). Protein Spred is an inhibitor of the RAS-MAP signaling pathway. The role of RAS may vary according to the cell type, from stimulation of adenylate cyclase to mating factor signal transduction and from proliferation to differentiation. The RAS protein becomes active only after prenylation by the 15-carbon farnesyl pyrophosphate. The prenylation is a thioether formation with an amino acid, resulting in the association of the protein with a membrane. RAS is not only one of the most important turnstile in signal transduction, but also one of the most common activated oncogenes. The activation involves changing of the bound GDP into GTP. GAPs (GTPase activating proteins) inactivate RAS by hydrolysis of GTP. In contrast GNRPs (guanine nucleotide releasing proteins) mediate the replacement of bound GDP by GTP and the activation of RAS. Receptor tyrosine kinases activate RAS either by inactivating GAP or activating GNP. The guanine-nucleotide exchange reaction is mediated by the SOS (son of sevenless) protein which has a GEF (guanidine exchange factor) domain. RAS is localized to the cell membrane. After ligand binding, SOS attaches to the adaptor protein Grb2 containing an SH3 domain and through the SH2 domain of Grb2 the complex binds to the phosphotyrosine residues of the signal receptor. The complex moving close to RAS makes possible that with the assistance of Cdc25, Sdc25 and GEF/GRF, respectively, the guanidine nucleotide is released. The RAS family is represented in various human chromosomes: NRAS in 1p21, HRAS in 11p15, KRAS in 6p12-p11 and RRAS in 19. Kras2 in mice has a tumor-inhibitory feature (Zhang Z *et al* 2001 Nature Genet 29:25). On the basis of homology three groups may be classified in mammals: (i) RAS, RAL, RRAS, (ii) RHO, and (iii) RAB. In *Drosophila* there are *Ras1* in 3–49, *Ras2* in 3–15 and *Ras3* in 3–1.4 (the latter has a higher homology to *Rap1* and it is now known as *Rap1*). In yeast, RAS homologs (*RAS1* and *RAS2*) are very closely related to the human protooncogenes

and can be replaced by them. RAS protein is also necessary for the completion of mitosis, in association with other factors. Probably, all eukaryotes carry RAS homologs. The p21 protein is also a mobile RAS protein. The RAS oncogene is generally active in tumorigenesis in the presence of the MYC or the E1A “immortalizing” oncogene products. MYC in cooperation with RAS mediates the progression of the cell cycle from G1 to the S phase through induction of the accumulation of active cyclin-dependent kinase and transcription factor E2F. The presence of RAS is necessary for tumor maintenance. The RAS promoter is high in GC and lacks a TATA box. The various RAS genes (human, mouse) may have more than 50% difference at the nucleotide level but the amino acid composition is highly conserved. RAS mutations have been detected in 90% of pancreatic adenocarcinomas, ~40–50% of colon adenocarcinomas and in other cancers. According to a genome-wide survey, RAS affects the expression of more than 250 genes. ▶G-proteins, ▶RAB, ▶raf, ▶BRAF, ▶RALA, ▶RALB, ▶RHO, ▶RAP, ▶RASA, ▶oncogenes, ▶signal transduction, ▶adenylate cyclase, ▶farnesyl, ▶prenylation, ▶p21, ▶GTPase, ▶MYC, ▶cell cycle, ▶retinoblastoma, ▶GEF, ▶Cdc25, ▶Sdc25, ▶GD, ▶SOS, ▶SH2, ▶SH3, ▶Grb2, ▶EF-Tu, ▶animal models, ▶Costello syndrome, ▶Seladin-1; Zuber J et al 2000 Nature Genet 24:144; Johnson L et al 2001 Nature [Lond] 410:1111; Stacey D, Kazlauskas A 2002 Current Opin Genet Dev 12:44; Quilliam LA et al 2002 Progr Nucleic Acid Res Mol Biol 71:391; Downward J 2003 Nature Rev Cancer 3:11; Asha H et al 2003 Genetics 163:203.

RASA: This is a guanosine triphosphate activating RAS protein (21 kDa [p21]) encoded by human chromosome 5q13.3 and in mouse chromosome 13. ▶RAS oncogene

rasiRNA (repeat-associated siRNA): This silences endogenous (selfish) retroelements and repetitive sequences in the *Drosophila* germ line. rasiRNA (24–29 nucleotides) is produced primarily from the antisense strand of the double-strand precursor unlike siRNA, which is made of both strands. rasiRNA does not require Dicer-1 or Dicer-2 and it functions through the Piwi system rather than through the Argonaute. ▶siRNA, ▶microRNA piRNA, ▶retroelements; Vagin VV et al 2006 Science 313:320; Lalith S et al 2007 Science 315:1587.

Raspberry (*Rubus* spp.): The majority of raspberries are diploid ($2n = 14$), loganberry is $2n = 42$, and blackberries have $2n = 28$, 42 and 56 chromosomes. It is likely that some wild blackberries are allopolyploids with $2n = 35$ and $2n = 84$; the latter is dioecious.

Rasmussen's Encephalitis: ▶epilepsy

Rassenhygiene: This is the German term for negative eugenics [often so used]. The purpose was to protect the “purity” of the Aryan (German) race and it was enforced by the laws of the Nazi state. Between 1933 and 1945, it led to 350,000 forced sterilizations, mass murder of millions and ban on marriages between genetically fit and “unfit”, and persons whose ancestry included more than 1/4 Jews, Gypsies or other racial groups. ▶eugenics, ▶racism; Hubbard R 1986 Int J Health Serv 16:227.

Rat (*Rattus norvegicus*, $2n = 42$): A genetic linkage map was published by Jacob and others (1995 Nature Genetics 9:63). A radiation hybrid map of 5,255 markers was prepared by Watanabe and associates. (1999 Nature Genet. 22:27). A high quality nucleotide sequence map covers more than 90% of the 2.75 gigabase genome (Nature [Lond] 428:493 [2004]). The chromosome number of other rat species may be different. A strain of albino rats developed by the Sprague-Dawley Animal Company is widely used in experimental work because of the calmness and ease of handling. (For EST map see Scheetz TE et al 2001 Genome Res 11:497). (See knockdowns: Tenenhouse DC et al 2006 Proc Natl Acad Sci USA 103:11246; EST map: <http://ratEST.uiowa.edu>; <http://ratmap.gen.gu.se>; <http://www.tigr.org/tdb/tgi/>; <http://rgd.mcw.edu/>; genome: <http://www.hgsc.bcm.tmc.edu/projects/rat/>; physiological studies: <http://pga.mcw.edu/>; rat resource and research center: <http://www.nrrtc.missouri.edu/>; rat genome database, strains: <http://rgd.mcw.edu/7778/strains/>; <http://www.nrrtc.missouri.edu/Straininfo.asp?appn=46>).

Rate-Limiting Step: This requires the highest amount of energy in a reaction chain or in a metabolic path, the slowest step.

Rate Matrix: Refers to base pair changes between two genomes. It is used by different algorithms to reveal the most likely evolutionary path of genomes. ▶genomics

Ratio Labeling: Using the FISH cytological technology different chromosomes may be labeled by varying proportions of the same fluorochromes to distinguish individual chromosomes in the genome by color. ▶FISH, ▶combinatorial labeling

Rationale: This is the logical basis of an act, a process or an argument.

Rationalize: Refers to an attempt to make something conform to reason. Sometimes apparent rationalization is used in an effort to explain facts or ideas for which there is no adequate justification.

Raynaud Disease (hereditary cold fingers): This condition is characterized by familial periodic numb and white finger attacks. ► [vasculopathy](#)

Raynaud Syndrome: This condition is characterized by scleroderma, cyanosis, cold intolerance, chromosomal aberrations, telangiectasia without a clear pattern of inheritance. ► [scleroderma](#), ► [telangiectasia](#), ► [cyanosis](#)

RB: Refers to the right border of T-DNA. ► [T-DNA](#)

Rb: ► [retinoblastoma](#)

RbAp: These are proteins of the WD family of wide regulators of chromatin, transcription and cell division. ► [WD-40](#); Rossi V et al 2001 Mol Genet Genomics 265:576.

rBAT/4F2hc: These are four membrane-spanning proteins involved in membrane transport or regulation of transport of neutral and positively charged amino acids. ► [cystinuria](#), ► [transporters](#); Malandro MS, Kilberg MS 1996 Annu Rev Biochem 65:305.

rbc: Denotes ribulose biphosphate carboxylase/oxidase genes. ► [chloroplast genetics](#)

RBE (relative biological effectiveness of radiation): This depends on a number of physical (type of radiation, wavelength, dose rate, temperature, presence of oxygen, hydration, etc.), physiological (developmental stage) and biological factors (species, nuclear size and DNA content, level of ploidy, repair system, etc.). The comparison usually relates to ^{60}Co gamma radiation. ► [rem](#), ► [radiation effects](#)

RBF (recoverable block of function): This system permits exogenous (conditional) regulation of fertility of plants. For example, when the barnase gene is linked to any gene it inactivates its pollen and therefore cannot be transmitted by sexual means. The expression of barnase in tobacco is under the control of sulfhydryl endopeptidase. Recovery from the barnase effect is managed by barnstar under the control of a heatshock promoter. Such a system may be used to reduce the risk of escape of transgenes from GMO plants into related organisms in the environment. ► [barnase](#), ► [barnstar](#), ► [heat-shock proteins](#), ► [terminator technology](#), ► [GMO T-GURT](#); Kuvshinov VV et al 2001 Plant Sci 160:517.

RBM (RNA-binding-motif, also called RBMY, YRRM): This gene family is found only in the Y chromosome of mammals involved in male fertility. The HNRPG (hnRPG) gene located in human autosome 6p12 shows ~60% homology to RBM. It is assumed that this autosomal locus was retrotransposed in an early ancestor to the Y chromosome. Similarly, in Xq26 sequences virtually identical to

exon 12 of hnRPG have been found. It appears that the chromosome 6p12 sequence is a processed pseudogene of the Xq26 sequence and there are similar sequences in chromosomes 1, 4, 9 and 11, all retrotransposed from Xq26. BFLS actually manifests hypogonadism and it is assigned to the same location as RBM. ► [DAZ](#), ► [boule](#), ► [PABp](#), ► [chromosome](#), ► [Borjeson-Forssman-Lehmann syndrome \[BFLS\]](#), ► [NRY](#), ► [azoospermia](#)

R2Bm: This is a silkworm retroelement without long terminal repeats. ► [retrovirus](#), ► [silkworm](#); Luan DD et al 1993 Cell 72:595.

RBMY: ► [RBM](#)

RBTN (rhombotin): A cystine-rich oncoprotein family (encoded in human chromosome 11) containing a LIM domain. ► [LIM domain](#); Chan SW, Hong W 2001 J Biol Chem 276:28402.

Rbx1: A ring finger protein homolog of APC (anaphase-promoting complex) which is required for SCF and VCB-mediated ubiquitination of Sic1 and probably other proteins. ► [ubiquitin](#), ► [APC](#), ► [ring finger](#), ► [SCF](#), ► [Sic1](#); Carrano AC, Pagano M 2001 J Cell Biol 153:1381.

RCA (regulators of complement activation): ► [MCP](#), ► [complement](#)

RCA (replication competent adenovirus): This should be kept as low as possible (<1 RCA/dose) for adenoviral vectors to avoid damage. RCA reduction can be accomplished by deleting the E1 region of the vector and shortening the potentially complementing tract of the host. ► [adenovirus](#)

RCAF (replication-coupling assembly factor): Mediates chromatin organization into nucleosomes during replication. It consists of Asf1 protein, H3 and H4 histones. ► [nucleosomes](#), ► [CAF](#), ► [ASF1](#); Tyler JK et al 1999 Nature [Lond] 402:555.

RCC1: This is a chromatin-bound guanine nucleotide release factor that forms complexes with RAN (a G protein). Its deficiency interferes with the cell cycle progression, chromosome decondensation, mating, RNA export and protein import. It is a part of the nuclear pore complex. Its yeast homolog is Prp20p. ► [RAN](#), ► [cell cycle](#), ► [nuclear pores](#), ► [RNA transport](#), ► [TPX](#); Hood J 2001 Trends Cell Biol 11:321; Renault L et al 2001 Cell 105:245.

RCC (renal cell carcinoma, human chromosome 3p14.2): RCC gene product frequently interacts with that of the von Hippel-Lindau (VHL) gene. ► [renal cell carcinoma](#), ► [von Hippel-Lindau disease](#)

RCR: Denotes recombination competent retrovirus. ► [retrovirus](#), ► [retroviral vectors](#), ► [gene therapy](#)

RcsC: Refers to *E. coli* kinase affecting capsule synthesis regulator RcsB. (See Davalos-Garcia M et al 2001 J Bacteriol 183:5870).

RcsG: A 30.6 kDa protein with a C-terminal motif and a N-terminal sequence similar to that of DnaJ. In concert with RcsC/B and DnaK and GrpE, it induces the *cps* capsule polysaccharide operon of *E. coli*.
 ▶DnaJ, ▶RcsC

RDA (representational difference analysis): This is a genome scanning procedure for the detection and identification of genetic markers representing disease, other genes and chromosomal aberrations. The cellular DNA is cut by restriction endonuclease(s) and the smaller fragments are amplified by PCR. DNA samples from affected and disease-free samples are denatured and the mixtures of the two samples are allowed to anneal. The sequences which do not match fail to hybridize and are believed to cause the disease. In principle, the process is similar to cascade hybridization. The relatively rapid mass screenings were expected to identify individuals predisposed to particular hereditary differences (diseases). The same procedure may be applicable to non-disease genes of eukaryotes. RDA and GDRDA procedures can be used to generate genetic maps in organisms with a paucity of chromosomal markers. ▶cascade hybridization, ▶PCR, ▶GMS, ▶GDRDA, ▶genetic screening, ▶positional cloning, ▶RNA fingerprinting, ▶genomic subtraction, ▶comparative genomic hybridization; Lisitsyn N et al 1993 Science 259:946; Tyson KL et al 2002 Physiol Genomics 9:121; copy number variations between normal and tumor specimens of mice: Lakshmi B et al 2006 Proc Natl Acad Sci USA 103:11234.

RdDM (RNA-dependent DNA methylation): DNA sequences identical to silenced RNA are methylated at cytosine residues in plants (Cao X et al 2003 Curr Biol 13:2212) but not necessarily in mammalian cells (Park CW et al 2004 Biochem Biophys Res Commun 323:275). ▶RNAi, ▶methylation of DNA

rDNA: Refers to DNA complementary to ribosomal RNA. The ribosomal RNA genes are in the nucleolar organizer region of the eukaryotic chromosomes and there are multiple tandem repeats of transcriptional units consisting of 18S, 5.8S, 5S and 26S RNAs. The mature rRNAs are cleaved from the large transcripts. In yeast the *FOB1* gene enhances recombination in rDNA. ▶ribosome, ▶rRNA; Long EO, Dawid IB 1980 Annu Rev Biochem 49:742.

RdRP (RNA directed RNA polymerase, RDR): This may be involved in gene silencing by synthesizing antisense transcripts from aberrant RNA and thereby causing PTGS. RdRP may generate double-stranded

RNA of single-strand transcripts and play a role in RNAi production. RdRP may convey virus resistance to plants and various types of post-transcriptional gene silencing (Sugiyama T et al 2005 Proc Natl Acad Sci USA 102:152). ▶PTGS, ▶epigenesis, ▶antisense RNA, ▶RNAi, ▶host-pathogen relation, ▶RNAi; Cheng J et al 2001 Virus Res 80:41.

Reaction, Chemical: Denotes a change in the atoms in or between molecules.

Reaction Intermediate: Refers to a short life chemical in a reaction path.

Reaction Norm: This denotes the range of phenotypic potentials of expression of a gene or genotype. Usually, the genes do not absolutely determine the phenotype but they permit a range of expressions, depending on the genetic background, developmental and tissue-specificity conditions and the environment. ▶genotype, ▶phenotype, ▶regulation of gene activity, ▶epigenesis, ▶plasticity, ▶homeostasis, ▶fitness, ▶adaptation, see Fig. R15; Wolterreck R 1909 Verhandl Dtsch Zool Ges p 110.

Figure R15. Reaction norm of water lily (farnwort): above water the leaves are different from below water (Goebel, K. 1893 Pflanzenphysiologische Schilderungen Elvert, Marburg, Germany)

Reactivation: ▶multiplicity reactivation, ▶Weigle reactivation, ▶marker rescue

Reactivity in Hybrid Dysgenesis: ▶VAMOS

Reactome: Refers to protein interaction pathways database (formerly called the genome knowledge base). ▶protein interaction, ▶genetic networks; <http://www.reactome.org/>.

Read: This is a nucleotide sequence determined in a single gel.

Reading Disability: ▶dyslexia

Reading Frame: The triplet codons can be read in three different registers, starting with the first, second or third, however, only one may spell the correct protein.
 ▶open reading frame, ▶frameshift mutation

Readout: The DNA sequence recognition by proteins may be *direct* (by hydrogen bonding) or *indirect* when the DNA conformation also plays a role. [▶binding proteins](#)

Readthrough: The ribosome continues translation downstream of a stop codon. On an average human hereditary disease is due to the inability to read-through translation-termination nonsense mutation. Some antibiotics (gentamycin) promote readthrough. Unfortunately, it is not useful for clinical purposes because the effective dose produces serious side effects. On the basis of a screening of 800,000 low molecular weight compounds, one report identified PTC124 (3-[5-(fluorophenyl)-[1,2,4]oxadiazol-3yl])-benzoic acid that promoted UGA nonsense suppression at a maximal effective concentration of 3 μM (852 ng mL⁻¹). PTC124 promoted dystrophin production in humans afflicted by muscular dystrophy and in a comparable mutant mice model. Muscle function was restored within 2–8 weeks of exposure to the drug. It was effective to a lesser degree in the case of UAG and UAA nonsense codons. No serious side effects were observed (Welch EM et al 2007 Nature [Lond] 447:87). [▶translation termination](#), [▶autogenous suppression](#), [▶nonsense codon](#), [▶gentamycin](#), [▶genetic medicine](#), [▶muscular dystrophy](#), [▶genetic diseases](#)

Readthrough Protein: This is formed when a suppressor tRNA inserts an amino acid at a site where chain termination is normally expected because of a nonsense codon and thus produces a fusion protein from two different “in-frame” cistrons, separated by a nonsense codon. Readthrough may be brought about by mutation in the anticodon of a tRNA or modification of the tRNA, e.g., selenocysteinyl-tRNA inserts selenocysteine into glutathione oxidase by recognizing the UGA (opal) stop codon. [▶gene fusion](#), [▶transcriptional gene fusion](#), [▶translational gene fusion](#), [▶trapping promoters](#)

Real Time: This means the actual time during which the physical process takes place.

Realized Heritability: [▶gain](#)

Reannealing (reassociation): Double-stranded DNA can be heat denatured (strands separated) and can be restored to double-stranded form, reannealed, when the temperature falls below 60°C. [▶c₀t curve](#)

Rearrangements: These are structural changes of the chromosome(s), e.g., translocation, inversion. [▶chromosomal rearrangements](#)

Reasoning: [▶inference](#)

Reassociation Kinetics: [▶c₀t curve](#)

Reassortant: This is a new virus strain that emerges from a combination of genes of two different strains, e.g., the pandemic influenza strains of 1957 and 1968 contain elements enabling the virus to replicate in humans and the avian segment. The hemagglutinin coding-segment assists in preventing the neutralization of antibodies of humans not previously exposed to the avian flu virus. [▶pandemic](#), [▶hemagglutinin](#), [▶influenza virus](#)

Rec8: This meiotic cohesin is cleaved by separin before chiasma are resolved and meiotic anaphase I can proceed. In vertebrates cohesin is removed during prophase but Scc1 remains associated with the centromeres when separin cleaves this protein and thus facilitates the metaphase-anaphase transition. [▶cohesin](#), [▶separin](#); Buonomo SB et al 2000 Cell 103:387; Waizenegger IC et al 2000 Cell 103:399.

rec: Refers to one or another type of recombination-deficient mutation.

RecA Protein: This is a 38.5 kDa polypeptide involved in homologous recombination by promoting pairing. It is a DNA-dependent ATPase which mediates strand exchange. RecA binds to single-stranded DNA and pre-synaptic nucleoprotein molecules mediate the pairing with the duplex DNA target. The paired DNA is inside a 25 Å hole. Inside this cavity projecting toward the axis of the helix are mobile loops L1 and L2 representing the binding sites. RecA appears to play a role in the segregation of the bacterial chromosomes (Ben-Yehuda S et al 2003 Science 299:532). The RecA protein expressed in transgenic plants substantially increases recombinational repair of DNA damage inflicted by mitomycin. The RecA prokaryotic gene when equipped with the nuclear localization signal and transformed into tobacco cells increases sister chromatid exchange by ~two-threefold. Structural and functional homologs of the bacterial RecA are UvsX (phage), Rad51 (eukaryotes) and RadA (archaea). The RecA protein is required for the maintenance of around 40 proteins necessary for the continuation of replication following DNA damage (Courcelle J, Hanawalt PC 2003 Annu Rev Genet 37:611). [▶recombination molecular mechanism prokaryotes](#), [▶DNA repair](#), [▶RecA-independent recombination](#), [▶RecA1](#); Kowalczykowski SC, Eggleston AK 1994 Annu Rev Biochem 63:991; Gourves A-S et al 2001 J Biol Chem 276:9613; Bar-Ziv R, Libchaber A 2001 Proc Natl Acad Sci USA 98:9068; Robu ME et al 2001 Proc Natl Acad Sci USA 98:8211; Gasior SL et al 2001 Proc Natl Acad Sci USA 98:8411; Lusetti SL, Cox MM 2002 Annu Rev Biochem 71:71.

recA1: A recombination deficient mutation of *E. coli* (map position 58 min) coding for a DNA-dependent

ATPase, a 3522-amino acid residue enzyme. Plasmids carrying it remain monomeric and do not form multimeric circles. When M13 vectors carry it, the foreign passenger DNA has fewer deletions. The *recA* protein mediates the association of double-stranded DNAs by synapsis mainly in the major groove but also in the minor groove of the DNA. The RecA-mediated pairing involves a triplex structure, i.e., along parts of the sequences double-stranded DNA associates transiently with a single strand of the other DNA molecule. The pairing of the DNA molecules may be plectonemic (intertwined) and thus may not require stabilization by proteins. (The paranemic coils are only juxtapositioned and require protein to keep them together.) Experimental data have revealed that ATP hydrolysis is not required for the exchange between paired strands rather the removal of RecA requires ATP hydrolysis. In case the homology between the DNAs is not perfect, ATP is needed for the exchange. RecA is also involved in branch migration but with the assistance of RuvAB and RecG proteins. The extension of the DNA heteroduplex (at the rate of 2–10 bp/sec) in the 5'→3' direction needs ATP hydrolysis. The length of the heteroduplex may increase to 7 kbp. In both prokaryotes and eukaryotes besides RecA (or homologs), a stimulatory exchange protein, binding single strands of the DNA (SSB) is required. The SSB monomers (1/15 base in ssDNA) facilitate synapsis between the heterologous strands. After exchange RecA promotes DNA renaturation. The RecA homologs in yeast, mouse and humans are the RAD51 proteins, and Mei3 in *Neurospora*. (Recombination molecular mechanisms prokaryotes, branch migration, *recB*, other *Rec* genes, DNA repair, RuvABC, RAD).

RecA-Independent Recombination (illegitimate recombination): This may use three pathways (i) simple replication slippage, (ii) sister chromatid-associated replication misalignment, and (iii) single-strand annealing. Single-strand annealing takes place after palindromic sequences within each strand fold into hairpin structures within the strands. When a nuclease (SbcCD) opens the cruciform palindromes resection, followed by annealing of the flanking repeats brings about deletion (see Fig. R16.). RecA-independent recombination occurs at extremely low frequencies and is less responsive to the extent of homology. RecA-independent recombination in *Escherichia coli* is depressed by the redundant action of single-strand exonucleases. In the absence of multiple single-strand exonucleases, the efficiency of RecA-independent recombination events, involving either gene conversion or crossing over, is markedly increased to levels rivaling RecA-dependent events. It seems that RecA-independent recombination is not

intrinsically inefficient but is limited by the single-strand DNA substrate availability. Crossing over is inhibited by exonucleases ExoI, ExoVII, ExoX and RecJ, whereas only ExoI and RecJ abort gene-conversion events. In ExoI– RecJ– strains, gene conversion can be accomplished by the transformation of short single-strand DNA oligonucleotides and is more efficient when the oligonucleotide is complementary to the lagging-strand replication template (Dutra BE et al 2007 Proc Natl Acad Sci USA 104:216). ▶illegitimate recombination, ▶palindrome, ▶exonuclease; Bzymek M, Lovett ST 2001 Proc Natl Acad Sci USA 98:8319.

Figure R16. Palindrome

recB: *E. coli* gene (map position 60 min) encoding a subunit of exonuclease, controlling recombination and genetic repair. ▶recombination molecular mechanism prokaryotes, ▶recombination models, ▶DNA repair

RecBCD: An enzyme (ribozyme) complex functioning in recombination of prokaryotes. RecBCD is a helicase and unwinds up to 42,300 bp per molecule, it is a strand specific nuclease. The recognition sequence (also called χ , [chi]) is 5'-GCTGGTGG-3' promotes recombination in its vicinity by recruiting the RecA protein. The enzyme travels along one of the two strands of the DNA in 3'→5' direction. ▶recombination molecular mechanism prokaryotes, ▶recombination models, ▶chi, ▶DNA repair, ▶RecA, ▶AddAB; Jockovich ME, Myers RS 2001 Mol Microbiol 41:949; Taylor AF, Smith GR 2003 Nature [Lond] 423:889; Dillingham MS et al 2003 Nature [Lond] 423:893; crystal structure: Singleton MR et al 2004 Nature [Lond] 432:187.

recC: *E. coli* gene (map position 60 min) encoding a subunit of exonuclease V, controlling recombination and genetic repair. ▶recombination molecular mechanisms, ▶DNA repair; Chen HW et al 1998 J Mol Biol 278:89.

recE: This is the locus of Rac prophage (map position 30 min), encoding exonuclease VIII and promoting homologous binding between single-stranded and double-stranded DNAs. ▶RecA; Muylers JP et al 2000 Genes Dev 14:1971.

RecF: Refers to a single- and double-strand binding recombination protein. (See Nakai H et al 2001 Proc Natl Acad Sci USA 98:8247).

RecG: This unwinds the leading and lagging strands at a damaged replication fork and may contribute to replication restart if it was stalled by the damage. ▶[replication restart](#); McGlynn P, Lloyd RG 2001 Proc Natl Acad Sci USA 98:8227.

RecJ: A single-strand (5'→3') exonuclease used in recombination of *E. coli*. (Hill SA 2000 Mol Gen Genet 264[3]:268).

RecO: A bacterial homolog of the eukaryotic Rad52 protein, which stimulates Rad51 in exchange and mediates single-strand DNA annealing function in recombination. RecO bears functional similarity to bacteriophage T4 protein UvsY. The optimal functioning of RecO necessitates association with the single-strand binding (SSB) proteins in equal proportion of the two. The RecR protein stimulates RecO to facilitate the displacement of SSB by RecA. ▶[Rad51](#), ▶[RecR](#); Kantake N et al 2002 Proc Natl Acad Sci USA 99:15327.

RecQ: Refers to *E. coli* DNA helicase. Homologs of the prokaryotic enzyme exist in eukaryotes and the enzyme resolves secondary structures of the DNA at stalled or broken replication forks. It is a multidomain enzyme. The catalytic core determines the ATPase and helicase functions. The helicase RNase-D-C-terminal domain shows globular fold binding preferentially to single-stranded DNAs and this latter domain apparently determines the specificities of the enzymes found in different organisms (Bernstein DA, Keck JL 2005 Structure 13:1173). ▶[helicase](#); Wu X, Maizels N 2001 Nucleic Acids Res 29:1765; Cobb JA et al 2002 FEBS Lett 529:43; Cui S et al 2003 J Biol Chem 278:1424.

RecR: This mediates DNA renaturation during recombination of *E. coli* (Pelaez AI et al 2001 Mol Genet Genomics 265:663).

RecT: This is encoded by *recE*. It is involved in renaturation of homologous single-stranded DNA and pairing of DNA. ▶[RecE](#), ▶[pairing](#)

RecU: This is a protein in gram positive bacteria. Its absence increases sensitivity to DNA damage, reduces plasmid transformation and affects the segregation of the chromosome in *Bacillus subtilis*. It binds preferentially to single-stranded DNA and cleaves recombination intermediates (Holliday junctions) and anneals single-stranded DNA. ▶[Bacillus subtilis](#), ▶[Holliday junctions](#); Ayora S et al 2004 Proc Natl Acad Sci USA 101:452.

Receptacle: This is the widened end of a flower stalk. It also refers to a container. (See Fig. [R17](#)).

Figure R17. Receptacle

Receptin: This is a natural or engineered microbial protein which can bind to a mammalian protein. It is useful for the identification of individual components of a proteome. It is similar to lectins which bind carbohydrates. ▶[lectins](#), ▶[affibody](#), ▶[monoclonal antibody](#), ▶[MSCRAMM](#); Kronvall G, Jonsson K 1999 J Mol Recognition 12:38–44.

Receptor: This is also called an operator. The site responding to the controlling element (transposase) as originally called by Barbara McClintock the components of the *Spm* transposable systems in maize. ▶[transposable elements of maize receptors](#)

Receptor: Refers to proteins that bind to ligands with cellular signaling functions. Receptors may be located within the plasma membrane (transmembrane proteins) or are intracellular and bind ligands, which penetrate cells by diffusion. Some receptors are ligand-gated ion channels. The number of receptors in a cell may run into hundreds. Several agonists and antagonists may affect their function. Cell surface receptors mediate in some cell to cell and virus–cell interactions. Cell surfaces can be tagged by unnatural, exogenous molecules facilitating the therapeutic targeting of surface glycans and imaging disease progression (Prescher J et al. 2004 Nature [Lond] 431:873). ▶[signal transduction](#), ▶[hormone receptors](#), ▶[transmembrane proteins](#), ▶[serine/threonine kinase](#), ▶[receptor tyrosine kinase](#), ▶[receptor guanylyl cyclase](#), ▶[receptor tyrosine phosphatase](#), ▶[receptors](#), ▶[adaptor proteins](#), ▶[T cell](#), ▶[nuclear receptor](#), ▶[orphan receptor](#), ▶[TCR](#), ▶[ion channels](#), ▶[virus receptor](#); Xu L et al 1999 Curr Opin Genet Dev 9:h 40; Human plasma membrane: <http://receptome.stanford.edu/HPMR/>.

Receptor Down Regulation: Epidermal growth factor (EGF) binding receptors concentrate in coated pits after binding with these growth factors. They enter the lysosomes where degradation of the receptor and

EGF occurs. The cell surface has a reduced number of them because of receptor down regulation. ►endocytosis, ►EGF

Receptor Editing: This mechanism modifies the antigen-specificity of antigen receptors in the variable region of the antibody and may lead to immune tolerance or antibody diversification by V(D)J recombination. This mechanism eliminates the autoreactive B cells when confronted with self-antigens. ►antigen receptor, ►immune tolerance, ►V(D)J, ►immunoglobulins, ►clonal selection; Kouskoff V, Nemazee D 2001 Life Sci 69:1105.

Receptor Guanylyl Cyclase: These transmembrane proteins are associated at the cytosolic end with an enzyme that generates cyclic guanosine monophosphate (cGMP). cGMP activates cGMP-dependent protein kinase (G-kinase) that phosphorylates serine/threonine residues in proteins. ►cGMP, ►serine/threonine kinase; Kusakabe T, Suzuki N 2001 Dev Genes Evol 211[3]:145.

Receptor-Mediated Gene Transfer: Cell surface receptors may internalize their ligands by endocytosis. The ligand (peptides, lectins, sugars, antibody, glycoprotein, etc.) may form a conjugate with a polycation, e.g., polylysine. An expression vector plasmid may bind to a ligand—polycation conjugate. A fusogenic peptide or a disabled adenovirus may facilitate the entry of the complex into the cell by endocytosis and transported with the aid of an endosomal vehicle. From the endosome the DNA (gene) may be transferred to the nucleus where it may have a chance for expression. With the assistance of asialoglycoprotein receptor the gene may be targeted to hepatocytes or with a mannose receptor it may be targeted to macrophages. The transferrin receptor facilitates targeting erythrocytes; polymeric immunoglobulin receptors may aim the gene construct at the lung epithelia; other receptor and ligand combinations permit targeting to other cells or tissues. The advantage of this type of transfection is that it is not infectious, the DNA carrying more than a single gene of almost any size can be targeted. Cell division is not a requisite for expression. The transgene functions in the cytoplasm. Unfortunately, the level and duration of expression vary. The system may elicit an undesirable immune reaction. ►endocytosis, ►asialoglycoprotein receptor, ►transferrin, ►macrophage; Varga CM et al 2000 Biotechnol Bioeng 70:593.

Receptor Protein Tyrosine Phosphatase (RPTP): Refers to signaling molecules required for cell development. It dephosphorylates negative regulatory C-terminal tyrosine residues of the Src family kinases. ►signal transduction, ►Src; Carothers AM et al 2001 J Biol Chem 276:39094.

Receptor Serine/Threonine Kinases: These are the receptors of serine/threonine phosphorylating enzymes. They are the major types of plant receptor kinases, unlike in animals where receptor tyrosine kinases dominate. ►serine/threonine kinase; Choudhury GG 2001 J Biol Chem 276:35636.

Receptor Tyrosine Kinases (RTK): These bind protein tyrosine kinase enzymes (59 genes in humans) such as the receptors for the epidermal growth factor (EGF), insulin, insulin-like growth factor-1 (IGF-1), platelet-derived growth factor (PDGF), fibroblast growth factor (FGS), nerve growth factor (NGF), hepatocyte growth factor (HGF), vascular endothelial growth factor (VEGF), macrophage colony stimulating growth factor (M-CSF), RET proteins containing cadherin-like, cysteine-rich extracellular domain. Defects of the RET family of proteins include problems of the glial-cell derived neurotrophic factor, MEN2, Hirschsprung disease, familial medullary thyroid carcinoma, pheochromocytoma, hyperparathyroidism and ganglioneuromatosis. Hepatocyte growth factor receptor defects are responsible for the papillary renal cell carcinoma. Platelet-derived growth factor receptor changes activate the KIT oncogene. The insulin receptor anomalies lead to diabetes type II, leprechaunism and Rabson-Mendenhall disease. Hereditary lymphedema receptor disease is due to the vascular endothelial growth factor. Congenital pain with anhidrosis is caused by defects in the neurotrophin receptors. These receptors are transmembrane proteins and when the receptor is associated with the cognate phosphorylase enzyme both the receptor and the target protein receive γ phosphate groups from ATP at certain tyrosine residues. The phosphorylation results in dimerization or dimerization results in phosphorylation and activation. Activation increases the activity of RAS and subsequently the MAP kinases. This eventually leads to the expression of genes. The various regulatory proteins recognize the different phosphorylated tyrosine residues in the receptor. Upon binding to their specific sites they may also be phosphorylated on their own tyrosine residues and become activated. A cascade of events may follow that activate entire signaling pathways. The different receptors and the associated proteins may control the separate or interacting signaling pathways. Mutations or truncation of RTK that permit dimerization without the proper ligand may lead to carcinogenesis. The specificity of RTK (which are involved in diverse metabolic functions) is determined either by the strength or duration of the signal or it may be qualitative. The various cell types may activate RTK signaling in different ways. In craniosynostosis (Crouzon, Pfeiffer, Apert and Jackson-Weiss

syndromes) and some dwarfness (hypochondroplasia, thanatophoric dysplasia) the fibroblast growth factor receptor members of RTK are involved. ▶anoikis, ▶tyrosine kinase, ▶signal transduction, ▶SIRP, ▶RET oncogene, ▶Eph, ▶craniosynostosis syndromes, ▶biomarkers, ▶genetic medicine, ▶cancer therapy; Simon MA 2000 Cell 103:13; Robertson SC et al 2000 Trends Genet 16:265; Madhani HD 2001 Cell 106:9; Haj FG et al 2002 Science 295:1708; Baselga J 2006 Science 312:1175.

Receptor Tyrosine Phosphatase: This binds protein tyrosine phosphates and splits off phosphate groups. (See Bateman J et al 2001 Curr Biol 11:1317).

Receptor-Mediated Endocytosis: This is a very efficient delivery system of macromolecules (such as cholesterol), that adheres to coated pits, into cellular organelles. ▶coated pits

Receptors: These are proteins that bind other molecules (ligands). They can be *extracellular* receptors that respond to outside signals reaching the cells. They may be located on the *surface* of the cell membrane or *within the membrane* but their ligand-binding domains are exposed to the extracellular space. The *intracellular* receptors respond to ligands that diffuse into the cell. ▶ligand, ▶signal transduction, ▶cargo receptors, ▶receptor, ▶adaptor proteins, ▶T cell

Recessive: Such an expression of a gene means that it is not visible in heterozygotes in the presence of the wild type or other dominant alleles of the locus. Recessivity is not necessarily an absolute lack of expression of the gene (except in null alleles) because extremely low level of transcription/translation may not be observed by a particular type of study but may be detectable by a finer analysis. ▶dominance, ▶semidominance

Recessive Allele: This does not contribute to the phenotype in heterozygotes in the presence of the dominant allele. ▶pseudodominance

Recessive Epistasis: ▶epistasis, ▶modified checkerboards

Recessive Lethal: Dies when homozygous, and can be maintained only as heterozygote.

Recessive Lethal Tests, *Drosophila*: ▶*Basc*, ▶*CIB* method, ▶sex-linked recessive lethal, ▶autosomal recessive lethal assay

Recessive Oncogenes: These are tumor-suppressor genes such as encoding p53. ▶tumor suppressors, ▶p53

recF: *E. coli* gene (map position 82 min), also called *uvrF*, controls recombination and radiation repair.

▶recombination molecular mechanisms, ▶DNA repair; Bidnenko V et al 1999 Mol Microbiol 33:846.

recG: *E. coli* gene (map position 82 min) controls recombination. ▶recombination molecular mechanism; Sourcelle J, Hanawalt PC 1999 Mutation Res 435:171.

Recipient: Bacterial cells of the F⁻ state receive genetic material from the donor F⁺ strains. This is also the cell to which genetic material is transferred. ▶conjugation, ▶transformation

Recipient Site: ▶donor site

Reciprocal Crosses: For example, A × B and B × A.

In cases when cytoplasmically determined differences exist between the two parents, the F₁ offspring bears greater resemblance to the female parent that usually transmits the cytoplasm. These reciprocal differences may persist indefinitely in the advanced generations. Although reciprocal differences are normally most obvious in plants, in animal hybrids, e.g., the mule and the hinny they are easily distinguishable. ▶mitochondrial genetics, ▶chloroplast genetics, see Fig. R18.

Figure R18. Reciprocal hybrids of *Epilobium hirsutum* Essen and *Epilobium parviflorum* Tübingen. Parents are 2n = 36. In the cross at the left an *E. parviflorum* female was crossed by an *E. hirsutum* male. The two plants at the right represent the reciprocal cross when the *E. hirsutum* female provided the cytoplasm. (From Michaelis P Umschau 1965 (4):106)

Reciprocal Interchange: This is the same as reciprocal translocation of chromosomes.

Reciprocal Recombination: This is the most common exchange between homologous chromatids at the 4-strand stage of meiosis in eukaryotes. In the case of single crossing over in an interval, two parental types and two crossover strands are recovered. An exception is gene conversion where the exchange is non-reciprocal. In conjugational transfer in bacteria the reciprocal products of the event are not recovered and their fate is unknown. In sexduction and specialized transduction reciprocal recombination may also take place in bacteria (see Fig. R19).
▶crossing over, ▶recombination molecular mechanisms prokaryotes, ▶conjugation, ▶sexduction, ▶specialized transduction

| | |
|------------------------|-------------------------|
| Parental | <i>AB</i> and <i>ab</i> |
| Reciprocal recombinant | <i>Ab</i> and <i>aB</i> |

Figure R19. Reciprocal recombination

Reciprocal Selection: ▶recurrent selection

Reciprocal Translocation: Segments of non-homologous chromosomes are broken off and reattached to each other's place. As a consequence, generally 50% of the gametes of the translocation heterozygotes (formed by adjacent distributions) are defective because they do not have the correct amount of chromatin. ▶translocation

Rec-Mutant: This means deficient in recombination and possibly altered in other functions of the DNA. (See individual Rec entries).

Recoding: This mechanism may translate the same DNA sequence in more than one way. It is a common mechanism in viruses with overlapping genes. There are several other ways this can take place. Some genes utilize multiple promoters and depending on the choice of their utilization, the same RNA may code for more than one protein. Frameshifting may take place: e.g., the mRNA may show slippage on the ribosome, a tRNA^{Leu} with an anticodon GAG may recognize CUUUGA in one frame and in a shift it inserts leucine (UUU) for 4 nucleotides: CUUUGA. Similar frameshifting cassettes may be determined by the *E. coli* gene *SF2* and also in other prokaryotes. In the TY3 transposable element of yeast the GCG AGU U instead of the Ala (GCG) and Ser (AGU) it

may read GCG A GUU Ala (GCG) and Val (GUU). The code words may be interpreted in different ways and stop codons may specify selenocysteine, tryptophan and glutamine. The ribosome may also skip certain sequences, e.g., the T4 phage topoisomerase may bypass 50 contiguous nucleotides and after the long frameshift it continues translation. Variants of phage λ repressor and cytochrome b₅₆₂ when translated from mRNA without a stop codon acquire an unusual COOH end. Co-translation switches the ribosome reading from the defective mRNA to the tRNA-like *ssrA* transcript that is translated into Tyr-Ala-Leu-Ala-Ala (the normal carboxyl end would have been very similar Trp-Val-Ala-Ala-Ala). Recoding may be of importance in some human diseases, e.g., if in the cystic fibrosis transmembrane conductance regulator a glycine codon₅₄₂ or arginine codon₅₅₃ is replaced by an UGA (opal) stop codon, the disease symptoms are alleviated compared with some missense mutations because this opal codon permits some readthrough leakage. ▶overlapping genes, ▶frameshift, ▶selenocysteine, ▶topoisomerase, ▶Ty, ▶cystic fibrosis, ▶set recoding, ▶fuzzy logic; Shigemoto K et al 2001 Nucleic Acids Res 29:4079; Harrell L et al 2002 Nucleic Acids Res 30:2011.

Recoding Signal: This is required for translational recoding. ▶overlapping genes, ▶recoding

Recognition Site of Restriction Enzymes: ▶restriction enzyme

Recoil: This means to bounce back; electromagnetic radiation recoils from glass and metal. ▶Compton effect

Recombinagenic: This may be involved in genetic recombination at an increased frequency.

Recombinant: Refers to an individual with some of the parental alleles reciprocally exchanged. ▶reciprocal recombination

Recombinant Antibody (RAb): This is genetically engineered and usually includes only the variable fragments, which are fused to some other proteins. The appropriate DNA fragments are amplified by PCR and cloned in *E. coli* and a single peptide chain may contain the variable regions of both the light and heavy chains. Animal passage is not required. The antibody gene fragment can be fused to a bacterial signal sequence enabling the direction of the molecule into the periplasmic space where chaperones can properly fold the engineered protein. The

procedure may include selection by phage display. Since RAb is produced without an animal and in vitro, sources of contamination by pathogens can be eliminated. RAb is also monoclonal. Recombinant antibodies can be modified with the battery of tools of molecular biology and different properties can be added to them, e.g., the paratope can be specially targeted to tumor cells (bifunctional antibody). It can be obtained by using human gene fragments, thus precluding an immune response against the RAb. ►PCR, ►immunoglobulins, ►antibodies, ►signal sequence, ►monoclonal antibody, ►paratope, ►phage display, ►polyclonal antibody; Kortt AA et al 2001 *Biomol Eng* 18[3]:95; Karn AE et al 1995 *ILAR J* 37[3]:132.

Recombinant Congenic: An outcross is followed by several generations of inbreeding in order to minimize the background genetic variations. ►recombinant inbred strain panels

Recombinant DNA: This is a DNA that has been spliced in vitro from at least two sources with the techniques of molecular biology or that results from the replication of such molecules. From the viewpoint of safety regulations, synthetic DNA segments, which yield potentially harmful polynucleotide or polypeptide, if expressed within cells, are subject to the same regulations as any harmful natural product. Transposable elements, unless they include recombinant DNA, are not subject to the US National Institute of Health recombinant DNA regulations. ►vectors, ►cloning vectors, ►transformation genetic, ►genetic engineering, ►restriction enzymes, ►splicing; Fed. Regist. [1999] 64:25361; <http://www4.od.nih.gov/oba/rac/guidelines/guidelines.html>.

Recombinant DNA and Biohazards: Fears of this were expressed by conscientious scientists way back in the 1970s even before the impact of the new techniques could be fully assessed. Since then evidence has accumulated indicating that some of the fears were not entirely justified, except by the wisdom of caution with a hitherto unknown and unused procedure. To avoid safety risks various levels of containments were made mandatory, depending on the organisms used, to prevent the accidental escape of genetically engineered organisms. Certain types of gene transfers were entirely prohibited to avoid contagions and highly toxic products. Cloning vectors were constructed that would not survive outside the laboratory. Bacterial strain X¹⁷⁷⁶ (so designated in honor of the bicentennial anniversary of the national independence of the USA) had an absolute requirement for diaminopimelinic acid, an essential precursor of

lysine and absent from the human gut. Cloning bacterial hosts were made deficient for excision repair (*uvrB*), auxotrophic for thymidine (indispensable for DNA synthesis), mutant for recombination (*rec⁻*) and conjugational transfer of plasmids to other organisms. If reversion frequency of any of, say, 5 defects, each is in the range of 1×10^{-6} , then the joint probability of simultaneous reversion of all 5 would be $(10^{-6})^5 = 10^{-30}$. Since the mass of a single *E. coli* cell is about 10^{-12} g, only in a mass of 10^{11} metric tons of bacteria can one expect to find such a fivefold mutation. Obviously, such a mass of bacteria is not likely to occur because the earth may not support it. To get an idea of what this volume is a comparison can be made: wheat production of the world in 1980 was only 4.5×10^8 tons and the estimated mass of the planet earth 10^{20} tons. To avoid any problem, nevertheless, government authorization is required in all countries where this technology is used, for the release of any genetically engineered species (microbes, plants, animals) for the purpose of economic utilization. Objections to such carefully tested releases are still raised, based not so much on public concern as on personal or political interests and most commonly because of ignorance. During the period spanning more than two decades since recombinant DNA technology has been used, no major accident has been reported and with the guidelines available none is expected. Before recombinant DNA experiments are initiated, the plans are approved by the Institutional Biosafety Committees and Institutional Review Boards. Experiments involving cloning of toxin molecules with LD50 of less than 100 nanograms per kg body weight must be approved by the Office of Biotechnology Activities (National Institute of Health/MSB 7010, 6000 Executive Blvd., Suite 302, Bethesda, MD 20892-7010, Tel. 301-496-9838). Such toxins are botulinum, tetanus, diphtheria and *Shigella dysenteriae* neurotoxin. Specific approval is mandatory for cloning in *Escherichia coli* K12 genes coding for the biosynthesis of toxic substances, which are lethal to vertebrates at 100 ng to 100 mg per kg body weight. Special review and approval by the OBA and the RAC are required for human experimentation or treatment. The OBA sets specific guidelines for different risk categories. Working with plant and animal pathogens requires a permit from the US Department of Agriculture. According to the US National Institute of Health Guidelines, hazardous agents are classified into four groups and the pertinent agents are named according to groups, group 1 is the least hazardous and group 4 is the most dangerous. The principal investigator who is primarily responsible for the observance of the regulations must report all accidents

or any potential hazardous events. ►laboratory safety, ►containment, ►biohazards, ►recombinant DNA evolutionary potentials, ►gene therapy, ►cancer gene therapy, ►Institutional Biosafety Committee, ►RAC, ►OBA, ►GMO; <http://www4.od.nih.gov/oba/rac/guidelines/guidelines.html>.

Recombinant DNA, Evolutionary Potentials: Using molecular biology techniques genes can be transferred among organisms by means not routinely available in nature. However, it cannot be ruled out that during the process of natural evolution fragments of degraded DNA are taken up by direct transformation and exchanged between taxonomically unrelated species.

Recombinant Inbred Strain Panels: These can be used for mapping in mouse. (For information contact Jackson Laboratory Animal Resources, 600 Main Str., Bar Harbor ME 04609, USA. Phone: 1-800-422 MICE or 207-288-3371. Fax: 207-288-3398).

Recombinant Inbreds (RI): These are generated for physical mapping of DNA by selfing F1 hybrid populations and selecting single seed or animal progenies for about 8 generations until only $(0.5)^8$ (≈ 0.0039) fraction remains heterozygous for a particular marker (linkage ignored). The parental lines are chosen on the basis of differences in their DNA sequences, and from the data the map position of these physical markers can be determined genetically by a combination of molecular and progeny tests. In the case of animals, the calculation is as follows: R (the frequency of discordant individuals) is $R = (4r)/(1 + 6r)$ where r is the recombination in any single gamete. Since interference within very short distances is practically complete, the distance in cM is $d = 100r$. The recombination fraction (\hat{r}) in function of the size of the sample (N) is $\hat{r} = i/(4N - 6i)$ where i is the number of discordant strains and $\hat{d} = 100 \times \hat{r}$ in

cM. In plants, the frequency of recombinant monohybrid gametes is calculated by using the same formula $r = R/(2 - 2R)$ where R is the frequency of homozygous recombinant diploid individuals. ►RAPD, ►congenic resistant lines of mice, ►congenic strains; Bailey DW 1971 Transplantation 11:325.

Recombinant Joint: This is the site of connection of two molecules of DNA in a heteroduplex. ►heteroduplex

Recombinant Plasmid: This is generated either from two different DNAs by using the techniques of molecular biology or by spontaneous or induced genetic recombination. ►plasmid

Recombinant Vaccine: This is produced by in vitro modifications of genes/proteins; it does not carry the full complement of the infectious agent. ►vaccine

Recombinase: Refers to enzyme, mediating recombination. ►FLP/FRT, ►Cre/loxP, ►Rec, ►DMC1, ►Rec51

Recombinase System: ►immunoglobulins

Recombination: It is a process by which the linkage phase (coupling or repulsion) of syntenic genes is altered. In a broad biological sense it means the rearrangement of any molecule. Recombination is most common during meiosis but mitotic recombination also takes place. The mechanism of meiotic and mitotic events is not necessarily identical (see Fig. R20).

Independent segregation and reassortment are outside the realm of this term, according to the original definition given by H.A. Sturtevant, although some textbooks erroneously include these as well (see Fig. R21).

Recombination can be accurately assessed with the aid of sequenced genomes. Data obtained have

Figure R20. Cytological representation of recombination between homologous chromosomes in coupling phase. Each chiasma leads to crossing over and 50% recombination. The frequency of recombination depends, however, on the distance between the two loci considered. If crossing over takes place in all meocytes between the bivalents, the frequency of recombination is 50%. If only half of the bivalents undergo crossing over in that particular interval, the recombination frequency will be 25% because, say in 4 meocytes with (16 chromatids) $4/16 = 0.25$. If only two of the meocytes display crossing over then $2/16 = 0.125$ is the frequency of recombination. The maximal recombination frequency by a single crossing over is 50%; the minimal may be extremely rare in case the linkage is tight.

Figure R21. A rare photograph of the three men who independently made basic discoveries in recombination. In the middle is Alfred Henry Sturtevant who as an undergraduate student published the first linkage map of *Drosophila* in 1913 (Science 58:269). On the left is Ernest Gustav Anderson who (with C.B. Bridges in 1925) (Genetics 10:403) demonstrated that crossing over takes place at the four-strand stage. On the right is Curt Stern who demonstrated in 1931 (Biol. Zbl. 51:547) that crossing over involves the physical exchange of chromatids in *Drosophila*. [Harriet B. Creighton and Barbara McClintock also published in 1931 identical proof using maize (Proc Natl Acad Sci USA 17:492)].

revealed considerable (0 to 9 centiMorgan per megabase) variation along each chromosome. The so-called “desert” sequences display low and the “jungle” stretches high recombination and this is depicted in the diagram. (See also other recombination entries, ▶linkage, ▶repulsion, ▶coupling, ▶recombinational probe, ▶flip-flop recombination, ▶site-specific recombination, ▶hot spot, ▶cold spot, ▶sex circle model of recombination, ▶*Cre/loxP*, ▶*FLP/FRT*, ▶*rec*, ▶ectopic recombination, ▶recombination homologous, ▶linkage disequilibrium, ▶centiMorgan, ▶STRP, ▶recombination mechanisms of, ▶retroviral recombination, ▶mitotic crossing-over; Cox MM 2001 Proc Natl Acad Sci USA 98:8173; Sturtevant AH 1913 J Exp Zool 14:43, recombination in populations: Stumpf MPH, McVean GAT 2003 Nature Rev Genet 4:959; <http://www.nslj-genetics.org/soft/>; yeast meiotic recombination hot spots–cold spots: http://www.bioinf.seu.edu.cn/Recombination/rf_dymhc.htm).

Recombination by Replication: At the beginning of the twentieth century William Bateson suggested that recombination is basically associated with the process of replication.

Figure R22. Linkage disequilibrium (LD) among pairs of STRPs (microsatellite repeats) within human autosomal recombination deserts and jungles within 0.25 megabase intervals. (Courtesy of Dr. James L. Weber; see also Yu A et al 2001 Nature [Lond] 409:951)

At that time neither of these phenomena was sufficiently understood or could even be hypothesized meaningfully. On the basis of cytological evidence (1930s) for marker exchange accompanied

by chromosome exchange and later evidence that DNA exchange and phage gene exchange were correlated, the generally accepted view became that recombination does not require replication. However, the discovery of gene conversion remained a puzzling phenomenon although it was observed that about 50% of the gene conversion events involved flanking marker exchange. Holliday and other molecular models of recombination (during the 1960s and 1970s) permitted interpretation of classical crossing over and gene conversion without significant replication. Recently, it has been observed that the mutation or loss of function of the PriA DNA replication protein blocks both replication and recombination in *E. coli*.

The SOS DNA repair activates a replication process that does not require the replicational *oriC* site or the normally functioning DnaA protein but it needs RecA and RecBCD activities. It was assumed and subsequently demonstrated that double-strand breaks may be assimilated into the DNA and result in double D loops in the presence of the nearby *chi* elements. The *chi* elements block nuclease activity and assist the initiation of replication. It appears that PriA and other proteins of the primosome generate a replication fork at the D loop, and relying on the DnaB helicase and the DnaG primase, replication and recombination can be turned on. First, apparently lagging strand synthesis begins by the replisome and the lagging strand then primes the synthesis of the leading strand. Defective PriA may be compensated for by some elements of the primosome. The processes of double-strand break repair and recombination appear the same with the exception that in repair only the defective region has to be corrected whereas in recombination the entire strand must be replicated in order to recover the recombinants. Some observations have indicated the occurrence of joint processes of replicational repair and recombination in eukaryotes. ▶[reduplication theory](#), ▶[breakage and reunion](#), ▶[gene conversion](#), ▶[Holliday model](#), ▶[recombination molecular models](#), ▶[SOS repair](#), ▶[DNA repair](#), ▶[recA](#), ▶[recBCD](#), ▶[chi element](#), ▶[replication fork](#), ▶[D loop](#), ▶[replisome](#), ▶[lagging strand](#), ▶[leading strand](#), ▶[gene space](#); Michel B et al 2001 Proc Natl Acad Sci USA 98:8181.

Recombination by Transcription: Some of the instabilities may be induced by RNA polymerase II, particularly between repeats of the eukaryotic chromosomes. Some yeast mutants may increase the process by over three orders of magnitude. (See Gallardo M, Aguilar A 2001 Genetics 157:79).

Recombination Cloning: This is based on the integration/excision mechanism of the lambda phage and *E. coli* bacterium. Integration involves the λ *attP* site

within the bacterial *attB* site. The bacterial *attL* and *attR* sites flank the integrated phage genome, excision reverses the process. Such a procedure can be used for the generation of vectors with DNA-binding and activation domain sites facilitating the study of protein interaction by analogy of the two-hybrid method. ▶[att sites](#), ▶[two-hybrid method](#); Muyrers JP et al 2001 Trends Biochem Sci 26[5]:325.

Recombination Frequency: Linkage is generally noticed in F₂ when independent segregation of the genes does not occur. Two genes in the homologous chromosomes can be at two different arrangements, repulsion (*Ab/aB*) or coupling (*AB/ab*) (see Table R3). Some scholars have described repulsion as trans and coupling as cis arrangement.

Table R3. Recombination detected

| | Phenotypic Classes Expected | | | |
|---------------------------|-----------------------------|-----------|-----------|-----------|
| | <i>AB</i> | <i>Ab</i> | <i>aB</i> | <i>ab</i> |
| Independent Segregation → | 9/16 | 3/16 | 3/16 | 1/16 |
| Linkage, Repulsion → | less | more | more | less |
| Linkage, Coupling → | more | less | Less | more |

Recombination is commonly calculated as the percentage of recombinants in a test cross population. The maximum frequency is 50% because at this value the frequencies of recombinant and parental chromosomes are equal, i.e., the segregation is independent. Linkage is first observed in F₂ by deviation of the phenotypic proportions from the expectations for independent segregation (see Fig. R23). For example:

Figure R23. Aleurone color (*C*) and shrunken endosperm (*sh*) genes of maize are closely linked in chromosome 9 of maize. On the two ears these markers are in different linkage phase. (From Hutchison CB 1921 J Hered 12:76)

The linkage phase does not affect the frequency of recombination but it affects the frequency of the phenotypic classes (see Table R4). The frequency of recombination is the same in both cases $(5 + 5)/100 = 0.10 = 10\%$ as shown in the table.

Table R4. Phenotypic classes in test crosses in two linkage phases and recombination:

| | (A hypothetical case) | | | |
|--|-----------------------|----|----|----|
| | AB | Ab | aB | ab |
| Repulsion cross (<i>Ab/aB</i>) × <i>ab</i> | 5 | 45 | 45 | 5 |
| Coupling cross (<i>AB/ab</i>) × <i>ab</i> | 45 | 5 | 5 | 45 |

In F_2 recombination frequencies cannot be calculated by such a simple method because in the heterozygotes the genetic constitution of the individual chromosome strands is concealed but may be revealed in F_3 . Nevertheless, recombination frequencies can be calculated (►*F₂ linkage estimation*). Recombination takes place at the four-strand stage of meiosis (see exception of mitotic recombination). The bivalent pair and in the simplest case two chromatids exchange segments. The maximal frequency of recombination within a chromosomal interval is 50%. Recombination frequencies are converted to map units by multiplication with 100. The realistic conversion of recombination frequencies into map units requires *mapping functions* because some of the recombinational events may not be detectable if the frequency of recombination between markers exceeds 15%. In physical measures 1 map unit has a different meaning in different organisms, depending on the size of the genome in nucleotides (nucleotide pairs) and the genetic length of the genome. Thus, 1 map unit in the plant *Arabidopsis* means about 150 kbp, in maize it is around 2,140 kbp and in humans approximately 1,100 kbp. One study reported that in human male autosomes the mean meiotic recombination frequency was 8.9×10^{-3} per megabase. In human chromosome 3 female recombination frequency was 1.43 cM Mb^{-1} and male was 0.85 cM Mb^{-1} (Muzny DM et al 2006 Nature [Lond] 440:1194). Smaller chromosomes have higher rates of recombination (cM/kb) not only among lower compared to higher eukaryotes, but also within one organism (yeast). The frequency of no recombination is a function (f) of the intensity of linkage and the population size; $f = (1 - r)^n$ where r is the recombination fraction and n is the number of test cross progeny. Data on maize (Fu H et al 2002 Proc Natl Acad Sci USA 99:1082) revealed reduced frequency of recombination in regions containing methylated retrotransposons. Recombination frequency may be affected by sex and may vary in different chromosomal regions; it is also influenced by sex in either plus or minus direction. The total recombinational map length may vary in different studies and by the use of different markers. Using

different methods of human recombination, all frequencies corrected by the Kosambi mapping function indicated significantly higher recombination in females than in males ($\sim 1.6:1$) (Matise TC et al 2003 Am J Hum Genet 73:271). In dogs and pigs, female recombination is higher; in cattle the two are about the same whereas in sheep male recombination is higher. Recombination frequencies may vary according to specific chromosomes. In the centromeric region the frequency of chiasma/recombination is lower than in other regions. In the area near the telomeres recombination increases in human males. In trisomy the recombination frequency is reduced. Many human diseases are associated with chromosomal deletions or duplications and in these cases recombination is reduced. ►*mapping*, ►*mapping function*, ►*bacterial recombination*, ►*test cross*, ►*product ratio method*, ►*F₂ linkage estimation*, ►*F₃ linkage estimation*, ►*maximum likelihood method applied to recombination frequencies*, ►*recombination modification of*, ►*recombination variation of*, ►*sperm typing*, ►*chiasma*, ►*hot spot*, ►*map unit*; Lynn A et al 2004 Annu Rev Genomics Hum Genet 5:317; <http://www.nslj-genetics.org/soft/>.

Recombination Frequencies in Bacteria: ►*bacterial recombination*

Recombination, Homologous: ►*recombination*, ►*homologous recombination*

Recombination Hot Spots: Genetic recombinations do not occur uniformly along the physical length of the DNA (chromosomes). In *Arabidopsis*, 1 cM varied from 30 bp to >550,000 bp. Gene-rich regions display more exchanges than gene-poor sequences. Recombination is usually suppressed around or near the centromere or telomere. In some instances recombination near the telomere is increased. In wheat, 1 cM in gene-rich region is estimated to be 118 kb whereas it is 22,000 kb for gene-poor regions. In humans, 1 cM indicates 1 Mb but there are substantial variations. In humans, 50% of all recombination takes place in less than 10% of the DNA sequence and recombination is preferentially outside the boundary of genes (McVeanan GAT et al 2004 Science 304:581). Human crossing over frequencies are clustered into narrow recombination hot spots (Jeffries AJ et al 2005 Nature Genet 37:601). The human genome-wide hot spot numbers vary between 25,000 and 50,000 and they occur preferentially near genes with 50 kb. Hot spots are determined by a CCTCCCT or larger motif. If in the third base T is changed to C, suppression is observed. L1 elements are underrepresented in hot spots (Myers S et al 2005 Science 310:321). ►*coefficient of crossing over*,

►autopolyploids, ►alpha parameter, see Fig. R24; Luo ZW et al 2001 Genetics 157:1369; Wu SS et al 2001 Genetics 159:1339; Hackett CA et al 2001 Genetics 159:1819.

Recombination In Vitro: ►staggered extension process

Recombination, Intrachromosomal: This occurs when homologous tandem or non-adjacent duplications are present in the chromosome. ►intrachromosomal recombination

Recombination, Intragenic: ►intragenic recombination

Recombination Machine: ►recombination molecular mechanisms

Recombination, Mechanisms, Eukaryotes, Yeast: The Sep 1 (strand exchange protein) 132 kDa fragment of a 175 kDa protein of yeast initiates the transfer of one DNA strand from a duplex to a single-stranded circle with 5' to 3' polarity without an ATP requirement. It also has a 5' to 3' exonuclease activity and is probably required for the preparation of 3' end of single- and double-stranded DNA molecules for recombination. Mutation in Sep reduces mitosis, sporulation, meiotic recombination and genetic repair. (The STP β protein, encoded by gene *DST2/KEM1*, is probably identical to Sep 1). One monomer of Sep 1 binds to nearly 12 nucleotides of single-stranded DNA. This requirement is reduced by the presence of the 34 kDa protein, which at a concentration of 1 molecule per 20 nucleotides reduces the requirement for Sep 1 to about 1/100. The DPA protein (120 kDa) of yeast controls DNA pairing and promotes heteroduplex formation in a non-polar manner independently of ATP. It promotes single-strand transfer from double-strand DNA to single-stranded circular DNA if the former has single-strand tails. Protein STP α (38 kDa) increases 15-fold shortly before yeast cells are committed to recombination during meiosis. If the gene encoding it (*DST1*) mutates, meiotic recombination is greatly reduced without an effect on mitotic recombination. The *RAD50* gene product (130 kDa) has an ATP-binding domain and it binds stoichiometrically to duplex DNA. The *RAD51* gene product is homologous to the RecA protein of *E. coli* (►recombination, ►mechanism, ►prokaryotes) and binds single- and double-stranded DNA. The *DMC1* (*disrupted meiotic cDNA*) gene product appears during meiosis and along with the product of *RAD51* performs functions similar to RecA in prokaryotes. Some organisms, *Drosophila melanogaster*, *Caenorhabditis elegans* and *Neurospora* have Rad51 but lack Dmc1 and in yeast mutation in Dmc1 does not prevent recombination. It is assumed that meiotic recombination in yeast involves double-strand breaks of the DNA. The actual site of exchange

may be 25 to 200 kb away from the prominent break (Young JA et al 2002 Mol Cell 9:253). If DNA replication, which normally occurs 1.5 to 2 h before double-strand breaks, is blocked or delayed, recombination does not take place. *Drosophila*: protein Rrp 1 promotes exchanges between single-strand circular and linear duplex DNA. Its C-terminus has homology to *E. coli* exonuclease III and *Streptococcus pneumoniae* exonuclease A. Mammalian Cells: HPP-1 (human pairing protein with 5' to 3' exonuclease activity) binds to the DNA and promotes strand exchange in a 5' to 3' direction and it does not require ATP. The addition of the hRP-A (human single-strand binding) protein stimulates pairing almost 70-fold and reduces the amount of HPP-1 requirement (cf. SF1 in yeast). The precise mechanism by which the Holliday junction (see Holliday model, steps I to L) is resolved is not clear but endonuclease activity is postulated. Bacteriophage T4 gene 49 encodes endonuclease VII that under natural conditions cuts branched DNA structures. Similarly, bacteriophage T7 gene 3 product encodes endonuclease I which cleaves branched DNAs. In yeast, endonuclease XI (Endo XI, $\approx M_r$ 200,000 and other Endo proteins) has been found in cells with mutations in the RAD genes and apparently cuts cruciform DNA of the type expected by the Holliday juncture. ►recombination models, ►recombination molecular mechanisms in prokaryotes, ►recombination models, ►RAD51, ►RAG, ►recombination hot spots, ►Sep 1, ►SRS2, ►STP β , ►synaptonemal complex, ►chiasma, ►sex circle model, ►gene conversion, ►databases; Camerni-Otero RD, Hsieh P 1995 Annu Rev Genet 29:509; Baudat F, Keeney S 2001 Curr Biol 11: R45; Smith GR 2001 Annu Rev Genet 35:243, yeast proteins and models: Krogh BO, Symington LS. 2004 Annu Rev Genet 38:233; exchange of DNA in recombination: Neale MJ, Keeney S 2006 Nature [Lond] 442:153.

Recombination Minimization Map: This is based on a skeletal map. The ordering relies on the smallest number of recombinations for single intervals. ►skeletal map

Recombination Models: ►Holliday model, ►Meselson-Radding model, ►Szostak model

Recombination, Modification of: The frequency of recombination may be altered by any means that affect chromosome pairing such as chromosomal aberrations, by DNA inserts introduced through transformation, temperature (either low or high), physical mutagens, rarely by chemicals, *rec*⁻ genes, etc. In the heterogametic sex of *Drosophila* and silkworm meiotic recombination is usually absent although mitotic recombination occurs. In animals,

recombination may be more frequent in females than in males and it is attributed to imprinting. In plants, in the case of a sex difference in recombination its frequency is usually lower in the megaspore mother cell. (See individual entries, ►[coincidence](#), ►[recombination variation of](#), ►[imprinting](#); Singer A et al 2002 Genetics 160:649; Peciña A et al 2002 Cell 111:173).

Recombination, Molecular Mechanisms of: The RecA protein (M_r 37,842) directs homologous pairing by forming a right-handed helix on the DNA and it catalyzes the formation of DNA heteroduplexes. X-ray crystallography indicates that the DNA rests relaxed in the deep groove of this protein to facilitate scanning for homologous sequences. The RecA protein is also involved in DNA repair function (SOS repair). It digests the LexA bacterial repressor and instrumental indirectly in the derepression of over 20 genes involved in recombination and UV mutagenesis. The mechanism(s) of RecA activities can be studied by in vitro reactions. RecA can interact with 3 or 4 DNA strands by wrapping around the paired molecules. DNA-DNA pairing can take place between linear and circular DNA as well. Strand exchange proceeds at a slow pace (2 to 10 base/sec) in a polar fashion (5' to 3'). The transfer begins at the 3' end of the duplex and is transferred to a single strand DNA. Homology is a requisite for the RecA mediated reactions yet it tolerates some mismatches or insertions (up to even 1,000 bases or more) but these slow down the reactions. RecA can mediate pairing between two duplexes as long as there are short single-strand stretches or gaps. Low pH, intercalating chemicals, Z-configuration and other structural changes of the DNA may alleviate the difficulties of binding two duplexes. The RecA protein is a low efficiency ATPase. ATP hydrolysis is not an absolute requirement, for RecA activities in recombination but is more important for the repair reactions. In the presence of ATP the conformation of RecA is altered and in the nucleoprotein complex the DNA is substantially under-wound (the spacing between bases extends from 3.4 Å to 5.1 Å). It is assumed that the paired DNA molecules are not just juxtapositioned, but also one molecule lies in the major groove of the other. The pairing may involve three or four strands.

DNA strand exchange requires that the RecA filament rotates along the longitudinal axis and the DNA molecules are "spooled" inside where they may form the Holliday junction (►[Holliday model](#)). ATP stabilizes the RecA-DNA association and when ATP is split into ADP, the heteroduplex is released and RecA is recycled. Besides the RecA protein, recombination requires the presence

of a single-strand binding protein (SSB), DNA polymerase I, DNA ligase, DNA gyrase, DNA topoisomerase I and the products of genes *recB*, *recC*, *recD*, *recE*, *recF* (binding protein for single-strand DNA), *recG*, *recJ* (exonuclease acting on single-strand DNA), *recN*, *recO*, *recQ*, *RuvB* (helicases), *recR*, *ruvR*, *ruvB* and *ruvC*. RuvC nicks the DNA at the point of strand exchange. RecBCD is a protein-RNA complex encoded by three genes (mentioned earlier), it performs the activities of (i) ATP-dependent double-strand exonuclease, (ii) ATP-dependent single-strand exonuclease, (iii) unidirectional DNA helicase, and (iv) site-specific endonuclease to nick four to six nucleotides downstream of *chi*, a recombinational hot spot (5'-GCTGGTGG-3'). It has been suggested that RecBCD generates 3'-tails that are utilized by protein RecA for DNA strand exchange. RecB and RecC mutations can be suppressed by *sbca* and *sbcb* mutations. Mutations in *sbca* lead to the activation of the product (exonuclease VIII) of *recE*. Mutation in *sbcb* inactivates exonuclease I, an enzyme that digests single-strand DNA, and its inactivation may assist the function of RecA in recombination (►[models of recombination](#)). The precise mechanism by which the Holliday junction (►[Holliday model](#), steps I to L) is resolved is not clear but endonuclease (RuvC) activity is postulated.

Bacteriophage T4 gene 49 encodes endonuclease VII that under natural conditions splits branched DNA structures. Similarly, bacteriophage gene 3 encodes endonuclease I and cleaves branched DNAs. Some of the functions of the *ruv* operon of *E. coli* may be involved in the resolution of the Holliday junctions. *E. coli* also has in vivo systems where the molecular mechanism of resolution of recombination intermediates can be studied. Covalently closed plasmid DNA, DNA polymerase I and DNA ligase are transformed into *E. coli recA* mutants. Both monomeric and dimeric plasmid progenies are seen and the available markers permit the conclusion that crossing over occurs in 50% of the progeny. Recombination is not limited to DNA but viral RNA molecules also recombine.

The molecular mechanisms of recombination in eukaryotes have many features in common with those of prokaryotes. It appears that double-strand breaks can stimulate homologous recombination within one kilobase of the site of the break or it may affect recombination at a distance exceeding 30 kb. At the break a *recombination machine* may gain entry and as the machine moves on a heteroduplex of the DNA may be formed. At the broken ends DNA replication may be primed and there is a potential for recombination. The recombination machine is a complex of many enzymes mediating the recombination process. Recombination requires double-strand

breaks of the DNA after the S phase and ribonucleotide reductase appears to be the rate-limiting factor for double-strand breaks and it is controlled by checkpoints (Tonami Y et al 2005 Proc Natl Acad Sci USA 102:5797). ►recombination mechanisms eukaryotes, ►recombination models, ►recombinational probe, ►recombination by replication, ►chi elements, ►illegitimate recombination, ►recombination RNA viruses, ►ribonucleotide reductase, ►FK506; Camerini-Otero RD, Hsieh P 1995 Annu Rev Genet 29:509; Barre F-X et al 2001 Proc Natl Acad Sci USA 98: 8189; West SC 1992 Annu Rev Biochem 61:603; Cox MM, Lehman IR 1987 Annu Rev Biochem 56:229; Smith GR 2001 Annu Rev Genet 35:243; Krogh BO, Symington LS 2004 Annu Rev Genet 38:233.

Recombination Nodule: Refers to the suspected site of recombination seen through the electronmicroscope as a 100 nm in diameter densely stained structure adjacent to the synaptonemal complex. There are early nodules seen at the association sites of the paired meiotic chromosomes and the late nodules are visible at pachytene when crossovers are juxtaposed. Non-crossovers do not show nodules after mid-pachytene (see Fig. R25). ►synaptonemal complex, ►chiasma, ►pachytene, ►association point, ►meiosis, ►recombination, ►crossing over, ►recombination RNA viruses, ►synapsis; Zickler D et al 1992 Genetics 132:135; Anderson LK et al 2001 Genetics 159:1259.

Figure R25. Early recombination nodules on two synaptonemal complexes of *Allium cepa* (onion). At positions marked 2 there is no synapsis yet. (Courtesy of Drs. LK Anderson and SM Stack)

Recombination Proficient: This means that there are no deficiencies involving enzymes mediating recombination. (See *Rec* and *rec* entries).

Recombination Repair: ►DNA repair

Recombination Repeats: These exist in the majority of plant mitochondrial DNAs in 1 to 6 pairs. Recombination can take place between/among these repeats generating various subgenomic DNA molecules.

These repeats (264 bp to >5 kbp in maize) may not be indispensable parts of the mtDNA although they may contain genes for rRNA, cytochrome, etc. ►mitochondrial genetics, ►mtDNA, ►rRNA; Chanut FA et al 1993 Curr Genet 23:234.

Recombination, RNA Viruses: After co-infection of a cell by two different viruses recombination may take place by template switching during replication, thus it is more like a copy choice than a breakage and reunion mechanism. Recombination can take place between homologous and non-homologous strands (illegitimate recombination). The latter mechanism may lead to deletions, duplications and insertions. Among picornaviruses the recombination frequency may be as much as 0.9 in the case of high homology. Recombination in RNA viruses helps to eliminate disadvantageous sequences and can generate new variants. The estimated mutation rate per base is 6.3×10^{-4} and per genome is almost 5. The mutation rate is estimated as mutations per replication. Host genes may suppress or their absence may increase viral recombination (Serviene E et al 2005 Proc Natl Acad Sci USA 103:10545). The double-strand bacteriophages of *Cystoviridae* have their genetic material in three segments. Intra-segment recombination is rare ($\sim 10^{-7}$ /segment/generation) but reassortment between segments is high, even higher than in other taxa (Slander OK et al 2005 Proc Natl Acad Sci USA 102:19009). ►copy choice, ►breakage and reunion, ►illegitimate recombination, ►reverse transcription, ►negative interference; Keck JG et al 1987 Virology 156:331; Kirkegaard K, Baltimore D 1986 Cell 47:433; Negroni M Buc H 2001 Annu Rev Genet 35:275.

Recombination, Targeted: ►Cre/loxP, ►FLP/FRT

Recombination, Variations of: In the heterogametic sex of arthropods (male *Drosophila*, female silkworm) genetic recombination is usually absent or highly reduced. In the latter group of organisms mitotic recombination occurs, and these premeiotic exchanges may account for the observation of recombinants. The most common cause of variation is the presence of *rec-* genes. In Abbott stock 4A × Lindegren's wild type crosses of *Neurospora*, post-reduction frequency was found to be 4.6 ± 1.2 whereas in Lindegren's stock it was 13 ± 1.2 , and in Emerson's × Lindegren's crosses 27.6 ± 3.7 . LJ Stadler, a pioneer of maize genetics, considered recombination as one of the most variable biological phenomena. ►male recombination, ►recombination frequency, ►recombination modification of, ►recombination hot spots, ►tetrad analysis; Browman KW et al 1998 Am J Hum Genet 63:861.

Recombinational Hot Spot: ►hot spot, ►chi site

Recombinational Load: This may emerge from the disruption of favorable, co-adapted gene blocks.

►genetic load, ►fitness-associated recombination

Recombinational Probe: One such short probe is inserted into the 902 bp π VX mini-plasmid containing a polylinker and the *supF* suppressor gene. Lambda phage libraries containing the miniplasmid construct are then propagated. If the phage carries a *supF* suppressible amber mutation, recombination between sequences homologous to the probe can be selectively recovered by forming plaques on an *E. coli* lawn. Recombination may take place even in the absence of perfect homology; less than ca. 8% divergence may be tolerated. Very large populations may reveal recombination within 60 base or longer probes effectively (see Fig. R26). ►*rec*, ►*Rec*, ►mini-plasmid, ►*supF*, π VX, ►lawn, diagram on the use of the π VX microplasmid for the selective

isolation of eukaryotic genes by recombinational probes; Perry MD, Moran LA 1987 Gene 51:227.

Recombinational Repair: ►DNA repair

Recombinator: Refers to cis-acting chromosomal sites promoting homologous recombination. ►*chi*

Recombineering: Refers to genetic engineering by homologous recombination. With the aid of a phage vector large DNA molecules can be cloned into bacterial artificial chromosomes. One such system uses the phage lambda genes Gam (inhibits host RecBCD), Exo, which degrades each DNA in 5'→3' and thus generates single-strand 3' overhangs, Beta protects the overhangs and anneals with complementary sequences. PCR-generated sequences or single-stranded oligonucleotides can be used as recombination substrates. Double-stranded DNA with 3' overhangs may not need Exo. For the

Figure R26. Recombination probe

procedure PCR-amplified linear or double-stranded DNAs are introduced into targeting cassettes that have either short regions of homology at their end or single-stranded oligonucleotides. The inserted DNA may carry any type of mutation or modification and there is no need for restriction enzyme cuts because the insertion is by homologous recombination. The method is simpler and safer than the somewhat unstable YACs and can be applied to functional genomic studies of higher organisms, e.g., mouse. (See terms under separate entries; Copeland NG et al 2001 *Nature Rev Genet* 2:769; Court DL et al 2002 *Annu Rev Genet* 36:351; Yu D et al 2003 *Proc Natl Acad Sci USA* 100:7207).

Recombinogenic: Refers to any agent (mutagen) which increases recombination (also).

Recombinogenic Engineering: ► [recombineering](#)

Recon: This is a historical term for the smallest recombinational unit. Molecular genetics has shown that recombination can take place between two nucleotides within a codon (Benzer S 1957, p 70 In: McElroy WD, Glass B (Eds.) *The Chemical Basis of Heredity*, Johns Hopkins University Press, Baltimore, Maryland).

Recon: This is a comprehensive literature-based genome-scale metabolic reconstruction that accounts for the functions of ORFs, proteins, metabolites and metabolic and transport reactions. The information on systems biology is a step toward individualized medicine and nutrigenomics, the applications, however, need a context to integrate and analyze data, and models resulting from these reconstructions can play a significant role in fulfilling this need. However, the development of cell-type or context-specific models requires the integration of various types of data, including transcriptomic, proteomic, fluxomic and metabolomic measurements (Duarte NC et al 2007 *Proc Natl Acad Sci USA* 104:1777). ► [annotation](#), ► [transcriptome](#), ► [fluxome](#), ► [metabolome](#), ► [nutrigenetics](#), ► [ORF](#), ► [systems biology](#)

Reconstituted Cell: This is produced by fusing cytoplasts and karyoplasts. ► [transplantation of organelles](#), ► [cytoplast](#), ► [karyoplast](#)

Reconstituted Virus: Into an empty viral capsid a complete viral genetic material is introduced, e.g., into the coat of tobacco mosaic virus (TMV) the genome of the related Holmes ribgrass virus (HRV) was introduced and the new particle expressed the characteristic functions of the donor RNA.

This classic experiment proved that the genetic material could also be RNA. Influenza and other viruses can be reconstituted from cloned cDNAs. (See Fig. R27, Fraenkel-Conrat H, Singer B 1957

Biochem Biophys Acta 24:540; Neumann G et al 1999 *Proc Natl Acad Sci USA* 96:9345).

Figure R27. Reconstituted virus

Record: This is a true document of an observation or of a hypothesis which is explicitly stated.

Recoverin: ► [rhodopsin](#)

Recovery of DNA Fragments from Agarose Gel: The fragment is driven by electrophoresis on to DEAE cellulose membrane by cutting a slit in front of the band and placing the DEAE sliver in the slit. Alternatively, electroelution can be used or from agar (at low melting temperature) the DNA can be extracted by phenol and precipitated by ammonium acetate in 2-volume ethanol and collected by centrifugation. ► [electrophoresis](#), ► [DEAE cellulose](#)

RecQ: Denotes a family of helicase proteins. In the case of mutation in the coding gene, chromosomal

instability results in eukaryotes. In prokaryotes the *recQ* is involved in post-replicative repair. ►[chromosomal rearrangements](#), ►[helicase](#), ►[RecA](#), ►[RecB](#) and other *Rec* genes; Enomoto T 2001 J Biochem [Tokyo] 129:501; Wu X, Maizels N 2001 Nucleic Acids Res 29:1765; Cobb JA et al 2002 FEBS Lett 529:43.

RECQL: This is a RecQ-like protein in humans. ►[RecQ](#)

Recruitment: For the initiation of transcription some prokaryotic and eukaryotic genes require activators and the transcriptional complex will operate only if these activators are attracted to the transcriptional target. The GAL1 gene of yeast recruits four units of the GAL4 activator at about 250-base upstream to begin transcription. The GAL4 units are blocked, however, unless galactose is available in the culture medium. The activators make contact with some sites of the RNA polymerase subunits. In bacteria, typical activators are the CAP (catabolite activator protein) and also the λ repressor may bind to the σ^{70} subunit of the polymerase. In yeast, the transcription complex includes more than 30 different proteins. ►[transcription factors](#), ►[transcription complex](#), ►[activator proteins](#), ►[two-hybrid method](#); Francastel C et al 2001 Proc Natl Acad Sci USA 98:12120.

Recruitment of Exons: Evolving genes may acquire coding sequences for functional domains by borrowing exons through recombination. The recruited DNA sequences may occur in several protein genes with different function, e.g., the low-density lipoprotein (LDP) receptor (a cholesterol transport protein) has homology in 8 exons with the epidermal growth factor (EGF) peptide hormone gene. ►[exon](#), ►[LDP](#), ►[EGF](#)

R

Recruitment of Genes: Refers to acquiring new genetic information through recombination or transfection (transformation). ►[transformation](#), ►[transfection](#), ►[recruitment of exons](#)

Rectification, Inward: Through a voltage gated ion channel the current inward exceeds that of the outward. In the case of outward rectification the opposite holds. ►[ion channel](#)

Recurrence Risk: Refers to a couple's chance of having another child with the same defect (see Fig. R28). ►[risk](#), ►[empirical risk](#), ►[genetic risk](#), ►[genotypic risk ratio](#), ► [\$\lambda_s\$](#) , ►[aggregation familial](#), ►[chart](#)

Recurrent Parent: A plant or an animal is mated with selected line(s) in several cycles for one or more backcrosses. ►[recurrent selection](#)

Recurrent Selection (reciprocal recurrent selection): Refers to a variety of methods used for breeding

superior hybrids of plants and animals of high productivity. The general procedure is as follows: lines (inbred or not) A and B are crossed in a reciprocal manner, i.e., A males are crossed to B females and B males are mated with A females. The initial lines are expected to be genetically different to assure the sampling of different gene pools. In this manner several lines are mated, not just A and B. The progenies are tested for performance and only the best parents are preserved. The superior parents are mated again with representatives of their own line. On the basis of their progeny, the parents are re-evaluated. The mating cycle is then repeated. Most commonly, each male is mated with several females of the other line in order to assure the availability of a large population of offspring to be able to conduct statistically meaningful tests. The maintenance of the lines requires that females be mated with selected males within their own lines. This procedure results in inbreeding but enhances the chances of further selection. Therefore, the performance of the selected parental lines is expected to decrease but that of the hybrids will increase. An alternative simplified method involves selection for combining ability in only one set of lines. Thus, line A is mated with a previously inbred tester which has an already known combining ability and the selection is restricted to within line A. This latter modification results in faster initial progress but the final gain may be limited. ►[combining ability](#), ►[hybrid vigor](#), ►[heterosis](#), ►[QTL](#), ►[heritability](#), ►[diallele analysis](#); Hull K 1945 Amer Soc Agron 37:134.

Recursive Partitioning: This is a statistical approach used to classify information into alternative classes, e.g., normal or tumorous. It builds classification rules on the basis of feature information. The underlying principle is that observations of n units represent a vector feature of measurement. (Vector here means a single class matrix.) Or covariates (e.g., data from a type of condition) and a class label. Unlike linear discriminant analysis, it extracts homogeneous strata and constructs tree-based classification rules. (Strata here means a division of the data into parts.) The information is partitioned into increasingly smaller samples (nodes) to facilitate critical discrimination between the classes. ►[matrix algebraic](#), ►[discriminant function](#), ►[cancer classification](#); Zhang H et al 2001 Proc Natl Acad Sci USA 98:6730.

Recursive PCR: This is a method of DNA amplification. Synthetic oligonucleotide primers (50–90 bases) are used which have only terminal complementarity (17–20 bp). They are annealed at 52 °C to 56 °C. The heating cycle is 95 °C and the cooling is at 56 °C. The Vent polymerase is used at 72 °C. This thermostable polymerase has capability not

Figure R28. The risk of recurrence of some human abnormalities common to populations of Caucasian descent. The numbers along the horizontal axis refer to the frequency of traits in the population as a whole; the numbers along the vertical axis refer to the risk of occurrence of these defects among brothers and sisters of affected individuals. The heavier lines denote the risk of recurrence according to the nature of the genetic control of these traits. The meaning of dominant and recessive terms is explained in Chapter 4; h^2 stands for heritability in the broad sense (see heritability), indicating the expected inheritance of a trait controlled by several genetic factors. Because the realization of many human genetic anomalies is influenced by a number of factors, estimation of the genetic risk requires an experienced genetic counselor. This consultation will secure peace of mind, for it frequently turns out that the risk is less than feared. Open squares stand for high risks, triangles for medium risks, and solid circles for low risks. Albinism: pigment deficiency of hair, skin, and eye; achondroplasia: a type of dwarfism; anencephaly: a deficiency of brain tissue; celiac disease: an intestinal inflammation; cleft palate: an oral fissure; clubfoot: a deformation of the foot; congenital heart disease: a heart anomaly; cystic fibrosis: fibrous tissue overgrowth with cyst formation; deaf-mutism: loss of hearing and speech; diabetes: a defect of carbohydrate metabolism; dislocated hip: a bone displacement; epilepsy: seizures; exomphalos: a hernia; harelip: upper lip fissure; hemophilia: recurrent bleeding due to lack of blood coagulation; Hirschsprung's disease: a colon enlargement; hydrocephalus: fluid accumulates in the head; manic depressive: obsessive emotional dejection; mental deficiency: deterioration of the mind; microphthalmos: abnormally small eyes; multiple sclerosis: hardening spots in brain and spinal cord; otosclerotic deafness: spongy bones in the ear; osteogenesis imperfecta: brittleness of the bones; patent ductus: fetal blood vessel defect; periodic paralysis: recurrent impairments in motor functions; phenylketonuria: defect in phenylalanine metabolism; psoriasis: scaling skin plaques; pyloric stenosis: obstruction of the distal end of the stomach; retinitis pigmentosa: atrophy and pigmentation in the eyes; retinoblastoma: an eye tumor; rheumatic fever: inflammation of connective tissues; schizophrenia: a mental defect leading to loss of contact with realities; situs inversus viscerum: visceral transposition; spinal bifida aperta: a spinal defect; strabismus: a deviation in the visual axis; target-cell anemia: abnormally thin erythrocytes. (Adapted from Hartl DL 1977. *Our Uncertain Heritage*, J. B. Lippincott, Philadelphia; based on data by Newcombe HB in Fishbein M ed., 1964, 2nd Int. Cont. Congenital Malformations, Int. Med. Congr. Ltd.)

only for strand displacement, but also for exonuclease function and it carries out proofreading and therefore the fidelity of the amplification is very good. During the initial steps each 3' end is extended with the aid of the opposite strand as a template and duplex sections are thus generated. In further cycles one strand of the duplex is displaced by a primer oligonucleotide derived from a neighboring duplex. During the last step high concentration of the terminal oligonucleotides assist in the amplification of the entire duplex. ►polymerase chain reaction, ►Vent; Prodromou C, Pearl LH 1992 Protein Eng 5:827.

RED613: This is a fluorochrome, a conjugate of R-phycoerythrin and Texas Red. Its excitation maximum is at 488 nm and emission at 613 nm. ►fluorochromes

RED670: This fluorochrome is a conjugate of R-phycoerythrin and a cyanine. Its excitation maximum is at 488 nm from an argon-ion laser, emission is at 670 nm. ►excitation

Red Blood Cell: ►erythrocyte, ►blood, ►sickle cell anemia

Red-Green Color Blindness: ►color blindness

Red King Hypothesis: In mutualistic interaction the slowly evolving species is expected to gain a disproportionate share of the benefits in the population. (See Bergstrom CT, Lachmann M 2003 Proc Natl Acad Sci USA 100:593).

R

Red Queen Hypothesis: If a population does not continue to adapt at the same rate as its competitors, it will lose ecological niches where it can succeed, and if it stays put long enough it may become extinct. The hypothesis suggests that sex evolved so that the species could respond to changes in the biotic environment. Recent analysis, however, does not support the need for sex evolution in all cases of species interactions (Otto SP, Nuismer SL 2004 Science 304:1018). The name RQ was adapted from Lewis Carroll's (pen name of C. L. Dodgson) 1872 fantasy story about a chess game, *Through the Looking Glass*. ►adaptation, ►extinction, ►beneficial mutation, ►equilibrium in populations, ►genetic homeostasis, ►treadmill evolution, ►co-evolution, ►Kondrashov's deterministic model of evolution of sex, ►Muller's ratchet; Van Valen L 1973 Evol Theory 1:1.

Redifferentiation: Refers to organ or organism formation from dedifferentiated cells, such as from callus (see Fig. R29). ►callus, ►regeneration, ►dedifferentiation

Figure R29. Redifferentiation of leaves from *Arabidopsis* callus (Rédei GP unpublished)

Redox Pair: Refers to an electron donor and the oxidized derivative.

Redox Reaction: ►oxidation-reduction

Reduced Representation Shotgun: ►RRS

Reducing Sugar: Its carbonyl carbon is not involved in glycosidic bond and can thus be oxidized. Glucose and other sugars can reduce ferric or cupric ions, a property that serves for their analytical quantitation (Fehling reaction).

Reductant: An electron donor.

Reduction: Denotes the gain of electrons.

Reductional Division: In meiotic anaphase I half of the chromosomes segregate to each pole and the two daughter cells have n number of chromosomes rather than $2n$ as in the original meiocyte. In the case of uneven numbers of crossing over between the gene and the centromere the numerical reduction of the chromosomes may not result in the separation of different pairs of alleles, i.e., the reduction does not extend to the alleles. The reductional division at meiosis assures the constant chromosome numbers in the species and serves a basis for Mendelian segregation. ►prereduction, ►postreduction, ►tetrad analysis, ►meiosis

Reductional Separation: In meiotic anaphase I the parental chromosomes separate intact because there is

no recombination between the bivalents. ►[equational separation](#)

Reductionism: This refers to the practice of reducing ideas to simple forms or making efforts to explain phenomena on the basis of the behavior of elementary units (molecules). This endeavor is frequently criticized because of the complexities of biological systems. It should be borne in mind that without the analytical approach, science (molecular genetics) would not have progressed to its present level. ►[model organisms](#)

Reductive Evolution: Some obligate intracellular parasites (*Rickettsia*, *Chlamydia*, *Mycobacterium leprae*) lost during evolution a significant portion (up to 76%) of the coding capacity of their genetic material because the host metabolism provided the essential gene products. These organisms may still have many pseudogenes as well as degraded, non-functional DNA tracts. ►[Rickettsia](#), ►[leprosy](#); Pál C et al 2006 Nature [Lond] 440:667.

Redundancy: Refers to repeated occurrence of the same or similar base sequences in the DNA or multiple copies of genes. The repeated gene sequences are considered to have a duplicational origin. About 38–45% of the sampled (ca. 1/3 of all) proteins in *E. coli* are expected to be duplicated and in the much smaller *Haemophilus influenzae* genome, completely sequenced by 1995, 30% appear to have evolved by processes involving duplications. In this small genome some gene families were represented by 10 to over 40 members whereas almost 60% of the genes appeared unique. In yeast almost 60% of the genes are redundant. In the large eukaryotic genomes the repetitious sequences are represented by larger fractions. The number of protein kinases in higher eukaryotic cells may reach 2,000 and that of phosphatases nearly 1,000. Theoretically, true redundancy should succumb to natural selection unless the rate of mutation is extremely low. Besides the shared functions, if the redundant genes have unique roles, they are maintainable. Redundant genes are saved when the *developmental error* rate is high. Redundant genes may affect the fitness of an organism in a very subtle way and may not show a clear independent phenotype. Also, they may serve as an insurance for the loss or inactivation of other members of the gene family. Redundant genes may have the luxury to afford mutation to new functions. Mutation or deletion of redundant genes may not have phenotypic consequences. Some single copy genes can also be removed without any consequences for the phenotype. ►[SINE](#), ►[LINE](#), ►[LOR](#), ►[MER](#), ►[MIR](#), ►[tandem repeat](#), ►[inverted repeat](#), ►[polyploid](#); Goldberg RB 1978 Biochem Genet 1–2:45.

Reduplication Hypothesis: At the dawn of Mendelism, William Bateson postulated that genetic recombination takes place by a differential degree of replication and different associations of genes after they separated at the interphase rather than by breakage and reunion of synapsed chromosomes. ►[breakage and reunion](#), ►[copy choice](#); Bateson W, Punnett RC 1911 J Genet 1:293.

Reelin: This 420 kDa glycoprotein is encoded by the *reeler* gene in mouse and is expressed in the embryonic and postnatal periods. It is similar to extracellular matrix serine proteases involved in cell adhesion. It controls layering and positioning of neurons and mutations in gene impair coordination resulting in tremors and ataxia. In schizophrenia and bipolar psychoses at positions –134 and 139 in the promoter of reelin methylation of cytidine increases as a result of upregulation of methyltransferase (Grayson DR et al 2005 Proc Natl Acad Sci USA 102:9341). ►[ataxia](#), ►[CAM](#), ►[schizophrenia](#), ►[bipolar mood disorder](#), ►[chimpanzee](#); D’Arcangelo G et al 1995 Nature [Lond] 374:719; Keshvara L et al 2001 J Biol Chem 276:16008; Quattrocchi CC et al 2002 J Biol Chem 277:303; see retraction 2004 Science 303:1974.

REF: This RNA-binding nuclear protein facilitates the export of the spliced mRNA from the nucleus to the cytoplasm in cooperation with TAP. ►[TAP](#); Le Hir H et al 2001 EMBO J 20:4987.

Reference Library Database (RLDB): Cosmid, YAC, P1 and cDNA libraries for public use on high-density filters. Information: Reference Library Database, Imperial Cancer Research Fund, Room A13, 44 Lincoln’s Inn Fields, London WC2A 3PX, UK. Phone: 44-71269-3571. Fax: 44-71-269-3479. Refractile Bodies: *Paramecia* may contain bacterial symbionts and the bacteriophages associated with them may appear as bright (refractile) spots under a phase-contrast microscope. ►[symbionts hereditary](#), ►[killer strains](#), ►[Paramecium](#)

Refractory Genes: These interfere with the completion of the life cycle of parasites, e.g., *Plasmodium*, within the insect vector, e.g., mosquitos and can therefore be exploited for the control of malaria and other diseases. ►[Plasmodium](#), ►[malaria](#); Yan G et al 1997 Evolution 51:441.

Refractory Mutation: This may not be revealed through genetic testing although it may lead to a genetic disease, e.g., mutation in introns, promoters or

3'-downstream regulatory sequences that control transcript levels. ►[genetic testing](#)

RefSeq: This is the reference sequence for 2,400 organisms, genomes, transcripts and proteins. (See Pruitt KD et al 2005 Nucleic Acid Res 33:D501; <http://www.ncbi.nlm.nih.gov/RefSeq/>; <http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=gene>).

Refsum Diseases (10pter-p11.2, 8q21.1, 7q21-q22, 6q23-q24): These autosomal recessive disorders are manifested in adult and early onset forms. Both forms involve phytanic acid accumulation because of the deficiency of an oxidase enzyme in the peroxisomes. The symptoms include polyneuritis (inflammation of the peripheral nerves), cerebellar (hind part of the brain) anomalies and retinitis pigmentosa. The early onset form, in addition, is characterized by facial anomalies, mental retardation, hearing problems, enlargement of the liver, lower levels of cholesterol in the blood and the accumulation of long-chain fatty acids and pipecolate (a lysine derivative). The symptoms of the infantile form overlap with those of the Zellweger syndrome. ►[Zellweger syndrome](#), ►[phytanic acid](#), ►[microbodies](#), ►[retinitis pigmentosa](#); Mukherji M et al 2001 Hum Mol Genet 10:1971; van den Brink DM et al 2003 Am J Hum Genet 72:471.

Refuge: Refers to the area planted with non-transgenic crops (GMO) next to transgenic plants. The purpose is to let non-resistant insects mate with resistant insects and thus dilute out the resistant population. At the moment the best relative size of a refuge is controversial. ►[GMO](#)

Regeneration in Animals: This is more limited than in plants where totipotency is preserved in most of the differentiated tissues. Regeneration can actually be classified into two main groups of functions: one is the regular replacement of cells (e.g., epithelia, hairs, nails, feathers, antlers and production of eggs and sperms) in a wide range of animals, and the other is the capacity to regenerate body parts lost by mechanical injuries. The latter type of regeneration may involve the formation of an entire animal from pieces of the body, such as by morphallaxis in sponges, Hydra, flatworms, annelids (preferentially from the posterior segments), echinoderms, etc. A more limited type of regeneration is found in the higher forms. Arthropods may replace lost appendages of the body. Vertebrate fishes can replace lost fins, gills or repair lower jaws. The Zebrafish is capable of heart regeneration after epicardial injury (Lepilina A et al 2006 Cell 127:607). Some mouse strains (MRL) have an exceptional ability to regenerate heart tissues in vivo. Several amphibians (salamanders, newts) readily regenerate lost limbs,

tails and some internal organs. Reptile lizards can reproduce lost tails although the regenerated one is not entirely perfect. Regeneration of feathers and repair of beaks may take place in birds. In mammals lost blood cells may be replenished by bone marrow activity, or liver cells may regenerate new ones. More limited regeneration may occur in bone, muscle, skin and nerve cells but unlike in plants, complete organisms cannot be regenerated from any part, except the embryonic stem cells or possibly from other stem cells after special treatments. According to recent evidence, mesoderm, endoderm and ectoderm cell lineages can be reprogrammed, e.g., bone marrow cells can regenerate into nerve cells or muscle-derived cells and cells of the central nervous system can reconstitute other cell types. From embryonic stem cells viable, fertile adult mouse can be differentiated (Eggen K, Jaenisch R 2003 Methods Enzymol 365:25). ►[regeneration of plants](#), ►[transdetermination](#), ►[homeotic genes](#), ►[stem cells](#), ►[transplantation of nuclei](#), ►[nuclear transplantation](#), ►[dedifferentiation](#), ►[redifferentiation](#), ►[transdifferentiation](#), ►[Hydra](#), ►[zebrafish](#), ►[planarians](#), ►[newt](#); Leferovich JM et al 2001 Proc Natl Acad Sci USA 98:9830; Alsberg E et al 2002 Proc Natl Acad Sci USA 99:12025; Brockes JP, Kumar A 2005 Science 310:1919; regeneration in planarians: Sanchez AA 2006 Cell 124:241; regeneration of heart review: Laflamme MA, Murry CE 2005 Nature Biotechnol 23:845; comprehensive review of molecular mechanisms involved in regeneration of model organisms: Alvarado AS, Tsonis PA 2006 Nature Rev Genet 7:873.

Regeneration of Plants: Refers to the formation of new organs or entire organisms from dedifferentiated tissues or single cells (see Fig. R30). A higher level of ferredoxin-nitrite reductase quantitative gene locus and nitrate assimilation rice favors regeneration of transgenic plants (Nishimura A et al 2005 Proc Natl Acad Sci USA 102: 11940). ►[embryogenesis somatic](#), ►[embryo culture](#), ►[clone](#), ►[vegetative reproduction](#), ►[totipotency](#), ►[dedifferentiation](#), ►[callus](#), ►[root](#)

Figure R30. Regeneration of Arabidopsis from callus

Reglomerate: ► [aggregulon](#)

Regression: This is the measure of dependence of one variate on another in actual quantitative terms in contrast to correlation which uses relative terms from 0 to 1. Linear regression involves the independent variate to the first power. Quadratic regression involves the independent variate to the second power and cubic regression to the third power. ► [correlation for the calculation of regression coefficient](#), ► [heritability](#), ► [linear regression](#), ► [cluster analysis](#), ► [multiple regression](#)

Regulated Gene: The expression is conditional and affected by genetic and non-genetic factors. Traits associated with dynamic processes may evolve to some extent more readily through regulatory rather than coding mutations. Indeed, the evolution of complex multicellular organisms would have been all but impossible in the absence of *cis*-regulatory systems that allowed context-dependent transcriptional regulation. The expression of many genes is altered through alternative transcription start sites and splicing and post-translational modifications. Quantitative traits are typically regulated by elements in the vicinity of the gene upstream or downstream. Typical examples of *cis*-regulation are the operons. Certain *duffy* haplotypes segregating in modern human populations offer almost complete resistance to infection with *Plasmodium vivax*. Resistance is due to the lack of Duffy protein expression in erythrocytes, but not in several other cells where it is normally expressed. The causal mutation is a *cis*-regulatory single nucleotide polymorphism (SNP) which disrupts binding of the transcription factor GATA1. Lactose intolerance (LCT) is determined by the presence or absence of an SNP in an intron of minichromosome maintenance deficient 6 homologue (*MCM6*), the next gene 5' of LCT. Experimental tests demonstrate that this SNP elevates LCT transcription (Wray GA 2007 Nature Rev Genet 8:206). ► [housekeeping genes](#), ► [constitutive genes](#), ► [regulation of gene activity](#), ► [operon](#), ► [disaccharide intolerance](#), ► [Duffy blood group](#), ► [SNP](#), ► [GATA](#), ► [MCM1](#), ► [annotation](#), ► [module](#), ► [regulated sequence motifs in humans](#), ► [mouse](#), ► [rat](#); *Caenorhabditis*: <http://www.cisred.org/>; annotated regulatory sequences: <http://www.swissregulon.unibas.ch>; *cis*-regulatory mammalian modules: <http://genomequebec.mcgill.ca/PReMod>.

Regulation of Enzyme Activity: Enzyme activity is characterized by various measures of enzyme kinetics (► [Michaelis-Menten](#), ► [Lineweaver-Burk](#), ► [Eadie-Hofstee](#)). The reaction is controlled by the quantity and/or activity of an enzyme. Enzymes may enhance reaction rates by 10^{10} to 10^{23} relative to uncatalyzed

transformations in aqueous solutions (Kraut DA et al 2003 Annu Rev Biochem 72:517). The quantity of the enzyme depends on protein synthesis/degradation controlled at the level of transcription, translation, processing of the protein, and its instability (► [regulation of gene activity](#)). The substrate of the enzyme may regulate the production of the enzyme protein (► [enzyme induction](#), ► [lac operon](#), ► [catabolite repression](#), ► [attenuation](#)). *Feedback control* means that the accumulation of the product of an enzyme may shut down the operation of a pathway at any step preceding the final product. Feedback control may be simple or multiple, i.e., more than one enzyme may be affected either simultaneously or sequentially or more than a single product of the pathway may act in a concerted manner (► [feedback control](#)). Feedback control may act either at the level of the synthesis (*feedback repression*) or by *inhibition* of the activity of a steady number of enzyme molecules. In general, the inhibitors are either *competitive* (bind to the enzyme and compete with the substrate for the active site) or *non-competitive* (the inhibitors act by attaching to the enzyme at a site other than the active site yet lower enzyme activity [by allosteric effect]). *Uncompetitive inhibitors* operate by binding to the enzyme-substrate complex. *Suicide inhibitors* are converted by the enzyme into an irreversibly binding molecule that permanently damages the enzyme. The inhibitors may simultaneously affect more than one enzyme. *Mechanism-based inhibitors* are highly specific to a single enzyme and as such have great significance for medicinal chemistry. Among these are the *antisense inhibitors* (► [antisense RNA](#)). *Allosteric enzymes* may also be stimulated (*modulated*) by allosteric compounds. The modulator may be *homotropic*, i.e., essentially structurally identical to the substrate or *heterotropic* in case it is not identical to the substrate. The activity of an enzyme may require a proteolytic cleavage of the precursor protein, the *zymogen*. Thermostabilization of an enzyme (cytosine deaminase) by site-directed mutagenesis at sites identified on the basis of crystal structure using computations increased half-life at 50 °C 30-fold without lowering catalytic efficiency. The effects of the three mutations were synergistic and indicated that by purposeful design, industrially or biomedically, more useful enzymes can be produced (Korkegian A et al 2005 Science 308:857). ► [regulation of gene activity](#), ► [protein synthesis](#), ► [signaling](#), ► [allostery](#), ► [allosteric control](#), ► [feedback](#); Wall ME et al 2004 Nature Rev Genet. 5:34.

Regulation of Gene Activity: The various types of cells and differentiated tissues of an organism generally contain the same genetic material (► [totipotency](#),

►regeneration) yet their differences attest that the genes must function in diverse ways in order to bring about the variety of morphological and functional differences. Genetic regulation accounts for this variety. Many genes are expressed in every cell because they determine the metabolic functions essential for life. Another group of genes is responsible for such generally required structural elements as membranes, microtubules, chromosomal proteins. (►housekeeping, ►constitutive genes). Other genes are not constitutive, i.e., they are regulated in response to external and internal control signals; in other words, they are expressed only when they are called up for a duty. The latter group of genes is responsible for the differences within an organism. Today highly sensitive computational methods are available (PHYLONET) for the identification of phylogenetically conserved regulatory motifs by analysis of the promoter sequences of several related genomes. By this approach global regulatory networks can be identified (Wang T, Stormo GD 2005 Proc Natl Acad Sci USA 102:17400).

Pretranscriptional Regulation. The expression of genes is regulated by several means, including the structural organization of the eukaryotic chromosome. Although it was earlier believed that the DNA associated with histones was not or not efficiently transcribed. The nucleosomal organization of the DNA may not prevent transcription yet nucleosomal reorganization may be required for the proper expression of genes (►nucleosomes). For efficient transcription of genes chromatin remodeling (histone acetylation) is required. It has been known since the early years of cytogenetics that, e.g., the heterochromatic regions of the chromosomes were not associated with genes that could be mapped by recombinational analysis. It appears that these tightly condensed regions of the chromosome are not suitable for transcription in general. The coiling of the chromosomes is also genetically regulated. Position effect indicates that gene expression is altered or obliterated by transposition into heterochromatin. Similarly, lyonization of the mammalian X chromosome involves heterochromatinization and silencing of genes (►silencer). The insertion of normal genes (by transformation) into the condensed telomeric region (about 10^4 bp in length) interferes with their expression (►heterochromatin, ►position effect, ►lyonization, ►telomeres). Gene expression depends in some way on the presence of nuclease sensitive sites in the chromatin. At these nuclease hypersensitive sites, apparently the DNA is not wrapped around so tightly and is more accessible to transcription initiation (►nuclease sensitive sites). The effects of the chromatin locale on the expression of genes are clear from the large variations in the

production of a specific mRNA in various transgenic animals and plants which carry a particular gene inserted at different chromosomal locations (►LCR). Also, in order to make the gene accessible to transcription or replication, in bacteria negative supercoils are formed which must be subsequently relaxed. In eukaryotes, DNA in Z conformation may be preferentially available for initiation of transcription (►supercoiling, ►Z DNA). Some genes are regulated by transposition; this mechanism is common in prokaryotes and eukaryotes for generating defense against the immune system of the host (►phase variation, ►antigenic variation), it is also used for sex determination in yeast (►cassette model). At replication the four basic nucleotides are normally used, several nucleoside analogs (e.g., 5-bromodeoxyuridine) may be incorporated into the DNA with some effects on gene expression. In the T-even (T2, T4, T6) phages in place of cytosine 5-hydroxymethyl cytosine is found as a protection against most of the restriction enzymes. In eukaryotes 5 to 25% of the cytosine residues are 5-methylcytosine. Genes with methylated cytosine are generally not transcribed (►methylation of DNA, ►recruitment, ►SRB, ►nuclear receptors).

Figure R31. Genetic regulation

Regulation of Transcription and Transcripts.

The cells have various options for more direct regulation of transcription: (i) control of signal receptor and signal transmission circuits, (ii) construct or take apart assembly lines geared to a particular function, (iii) transcriptional control, (iv) transcript processing and alternative splicing, (v) export of the mRNA to the cytosol in eukaryotes. In prokaryotes and cellular organelles a membrane does not enclose the genetic material and transcription and translation are coupled, and (vi) selective degradation of mRNA or a carboxypeptidase may cleave the transcription factors.

Nucleotide sequences in the DNA (structural gene) specify the primary structure of the transcripts. Upstream cis elements (enhancers, promoters and

other protein binding sequences) control the attachment and function of the DNA-dependent RNA polymerases (►pol I, ►pol II and pol III RNA polymerases). Some eukaryotic genes may have more than one promoter and the tissue or cell type and the physiological conditions select the promoter to be used. Transcript length is dependent on the promoter element used and the upstream, non-translated region contains binding sequences for further regulation of gene expression. Various upstream elements of the same gene may respond differently to cytokines, phorbol esters and hormones (►hormone receptors, ►hormone response elements).

The enhancers may be positioned either upstream or downstream. Inducible genes receive cues through membrane receptors and transmitter cascades, generally regulated by kinases and phosphorylases (►signal transduction). Downstream DNA nucleotide sequences control the termination of transcription and in eukaryotes a polyA tail (exceptions are the histone genes) is added enzymatically without the use of a DNA template (►polyadenylation signals, ►transcription termination in eukaryotes and prokaryotes, ►self-cleavage of RNA, ►RNAi, ►micro-RNA, ►small RNA; Chen K, Rajewsky N 2007 Nature Rev Genet 8:93).

Gene expression begins by the initiation of transcription (►transcription, ►protein synthesis). The DNA displays some specific sequences in the major grooves of the double helix that are recognized by DNA-binding proteins. (►lac operon, for the *E. coli* lac repressor binding site and the CAP site for binding of the catabolite activator protein). In phage λ the *cI* repressor binding element controls by repression several genes (►lambda phage). The consensus sequence of the budding yeast GAL4 upstream element (►galactose utilization), for the mating type $\alpha 2$ consensus (►mating type determination) and for the transcription factor GCN4 (►GCN4) that regulate specific genes. In plants, the core sequence for a transcriptional activator protein is shown under the G-box element. The binding proteins have a short α helix or a β sheet that fits into the major groove of the DNA at the specific sequence motif (►helix-turn-helix, ►Zinc finger, ►leucine zipper, ►helix-loop-helix). Specific activators may also regulate transcription (Spiegelman BM 2004 Cell 119:157). The activation may require a positive or negative control process (►arabinose operon, ►lac operon, ►CAT). For the initiation of transcription in eukaryotes, the presence of a general transcription factor protein complex is essential (►open transcription complex). Additional specific transcription factors may modulate transcription (►transcription factors inducible). In the DNA there are also a number of *response elements* or regulatory sequences that bind

several specific proteins and the proteins in turn may bind additional modules (►response elements, ►hormone response elements). The inducible transcription factors in the eukaryotic nuclei help in the assembly of the transcription complex and activate or repress genes by assembling modules. The interacting elements are responsible for fine-tuning metabolic pathways and regulating morphogenesis. These transcription factors may or may not be syntenic with the genes they act on, and their number may vary depending on the gene concerned. The binding proteins may pile up in a specific way at the promoter after DNA looping brings them to that area. Also, the binding proteins may attract other molecules that act in an activating or silencing manner. In an absolutely abstract form this may be visualized with a few computer symbols.

The bacterial DNA-dependent RNA polymerase (►pol) attaches to the double-stranded DNA, and generates an open promoter complex and proceeds with the transcription (►open promoter complex). The bacterial RNA polymerase may rely on different σ subunits for transcribing various bacterial or viral genes. In some instances bacterial and eukaryotic genes also use activators of transcription to assist the RNA polymerase enzyme to generate the open promoter complex. These proteins may attach to the DNA in an area some distance from the gene (enhancer) and looping may bring the protein to the promoter site (►looping of DNA).

The likelihood of association of two DNA sites by looping reaches an optimum at a distance of about 500 bp and it is considerably reduced when they are very close. Some of the enhancer DNA elements (binding sites for regulatory proteins) may be several thousands of nucleotides apart upstream or downstream of the structural gene (►enhancer). The various binding proteins (symbolized by: \cup , \cap , Ψ , Ω , \clubsuit , \spadesuit , ∇) may associate with the general transcription factors and with each other in different combinations and numbers either to activate or suppress, or to modulate or silence the gene (see Figs. R32, R33, and R34).

Figure R32. Several different proteins (represented by abstract symbols) can bind upstream of the promoters

The open promoter complex includes the general transcription factors, RNA polymerase II, the TATA box and the transcription initiator (INR). These crude schematic figures do not properly represent the interacting complexes that are required for turning on, turning off and modulating expression as needed

Figure R33. DNA looping

Figure R34. Promoter bound transcription factors regulate transcription

for the orchestration of intricate processes such as the temporal and topological control of morphogenesis ([▶morphogenesis](#)). The transcription factors regulate these processes but the transcription proteins themselves are subject to regulation by metabolic and environmental cues. These processes include conformational changes, combinatorial assembly of subunits, ligand binding, phosphorylation and dephosphorylation, presence of inhibitors and activators ([▶signal transduction](#)). In eukaryotes there may be a need for chromatin remodeling to enable the activators and the TATA box binding protein to access the DNA ([▶nucleosome](#)). For this process a histone acetylase or SWI/SNF complex may have to be recruited in preparation for transcription. In both prokaryotes and eukaryotes special control mechanisms have evolved for the termination of transcription ([▶transcription termination](#)). The regulation of the transcriptional process and the turnover of the transcripts determine the quantity of the transcripts. Many bacterial genes are organized into coordinated regulatory units employing negative, positive or a combination of these two controls of transcription ([▶lac operon](#), [▶arabinose operon](#)). In these operons the genes are either exactly ([▶tryptophan operon](#)) or with some modification ([▶histidine operon](#)) arranged according to the order of the biosynthetic pathway. The amino acid operons use, in addition, *attenuation* for controlling the quantity of the transcripts for maximal economy ([▶attenuator region](#), [▶tryptophan operon](#)). The operons are characterized by coordinated regulation of the transcription of several genes belonging to the same transcriptional unit and transcribe them into a polycistronic mRNA.

Eukaryotes usually do not produce polycistronic mRNAs but the rRNA and tRNA transcripts are processed into functional units post-transcriptionally. Elements of a coordinated unit may not all be juxtapositioned ([▶regulon](#), [▶arabinose operon](#)). The small phage (ϕ X174 [can be found under F]) and retroviral genomes may have overlapping genes that specify more than one protein, depending on the register they are transcribed ([▶overlapping genes](#), [▶recoding](#), [▶retroviruses](#)). The need for the protein products of these overlapping genes transcribed with the aid of the same promoter, may be not the same. Some proteins, e.g., viral coat proteins may be needed in larger quantities than the replicase enzymes. Therefore, mechanisms have evolved to by-pass internal stop signals and produce some fusion proteins that assist in achieving this goal ([▶overlapping genes](#), [▶recoding](#)). In bacterial, plant and animal viruses, another means of regulation of gene activity at different steps has evolved that involves the use of antisense RNA. This mechanism is being explored so as to develop particular drugs for the highly specific regulation of genes with minimal side effects or for the development of new, selective antimicrobial agents and more desirable crop plants without reshuffling the entire genome ([▶antisense technologies](#)). Short RNAs use various means to regulate transcription ([▶repressor](#), [▶RNAi](#), [▶microRNA](#)).

In prokaryotes a special short transcribed stretch of nucleotides, the Shine-Dalgarno box, controls the attachment of the mRNA to the small (30S) ribosomal subunit. For the same task, eukaryotes use “ribosome scanning”, i.e., the mRNA tethers a 40S ribosomal subunit and by reeling locates the first initiator codon. Eukaryotic 40S ribosomal subunits can enter circular mRNAs if they contain internal ribosomal entry sites (IRS).

The primary transcripts are generally not suitable for translation into a protein or for a RNA product (rRNA, tRNA). The transcripts are processed to mRNA and/or other RNA units. Introns are excised and the sequences corresponding to exons are spliced and may even be transspliced with the cooperation of spliceosomes ([▶intron](#), [▶exon](#), [▶spliceosome](#), [▶alternative splicing](#), [▶hnRNA](#), [▶snRNA](#)). The splicing itself

may be genetically and organ-specifically regulated. The transposition of the P element of *Drosophila* is relatively rare in the soma but five times more common in the germ line because one intron is not excised from the transposase transcripts in the somatic cells (►hybrid dysgenesis). Tissue-specificity and function-specificity of many proteins is partly controlled by alternative splicing (►immunoglobulins, ►sex determination). Mitochondrial RNA transcripts may be modified by replacing C residues with Us (►RNA editing).

The eukaryotic mRNAs are capped while still in the nucleus. The transcript is cut at the appropriate guanylic residue and it is then modified (►cap, ►capping enzymes). Capping increases the stability of the mRNA, facilitates its transport to the cytosol and assists in the initiation of translation by being recognized by initiation protein factors eIF-4F, eIF-4B, etc. (►cap, ►eIF).

The tail of the eukaryotic mRNAs (with few exceptions, e.g., histones) is equipped with 50–250 adenylic units to increase their stability. Polyadenylation is controlled separately from transcription because a special enzyme adds these nucleotides after processing of the transcript. Generally, the genes carry a short A-rich consensus (►polyadenylation signal) in the DNA that instructs the RNA polymerase to terminate transcription after the enzyme passes through the signal and also indicates the need for polyadenylation. Eventually, the poly-A tail is reduced to about 30 A units. In eukaryotes, the 3' tail may be substantially regulated by specific, extrinsic genes (Kakoki M et al 2004 Dev Cell 6:597).

Some of the transmembrane proteins have a hydrophobic amino acid sequence in the section that is going to be located within the membrane, whereas the cytosolic end contains a longer hydrophilic carboxyl end. The positioning of the transmembrane proteins shows substantial variations, depending on the intrinsic properties of proteins. The transcript of the same coding sequences is differentially cut in a manner as to assure such a terminus is formed for the membrane-bound proteins whereas a shorter hydrophilic end terminates the otherwise identical circulating immunoglobulin molecules.

After these intricate preparatory processes, the eukaryotic mRNA is transported to the cytosol through the nuclear pores. Prokaryotes do not have membrane-enclosed nuclei but only nucleoids, anchored to the cell membrane, and there the translation proceeds *pari passu* with transcription. (See Carlson M 1997 Annu Rev Cell Dev Biol 13:1; Holstege FC et al 1998 Cell 95:717).

Post-Transcriptional Regulation. The mRNA may be degraded before it is translated into polypeptide chains. About half of the prokaryotic

mRNAs may be degraded within 2–3 min after their synthesis. Eukaryotes have long-lived mRNAs, which usually last for at least three times longer but at times in special dormant tissues of plants they may remain intact for years. The degradation is mediated by special endonucleases that recognize mRNAs. Also, A-U sequences in the non-translated downstream regions may remove the poly-(A) tails and thus stability is reduced in both cases.

Translation in eukaryotes begins with the transport of the capped mRNA outside the nucleus, into the cytosol. The mRNA tethers several ribosomes and the polysomal structures are formed. Some mRNAs are equipped with a signal coding sequence, coding for a special tract of 15 to 35 amino acids. That directs it toward the *signal sequence recognition particle* after only a few dozen amino acids are completed on the ribosome. The *signal peptide* then transports the nascent peptide chain into the lumen of the endoplasmic reticulum, Golgi vesicles, lysosomes and mitochondria, plastids, etc. This mechanism facilitates the subcellular localization of the emerging proteins at places where they are most needed and from where they may be diffused in a gradient as required for embryonic differentiation (►signal sequence, ►signal peptide, ►signal sequence recognition particle, ►morphogenesis in *Drosophila*). Various control mechanisms have been involved in the generation of protein products of genes: (i) translational control, (ii) post-translational modification of the polypeptides, (iii) control of polypeptide assembly into proteins, (iv) regulation of protein conformation, (v) compartmentalization of proteins, (vi) interaction of protein products and ribozymes, (vii) feedback controls at the level of protein synthesis and function, and recently (viii) the wide scale role of small RNAs was discovered (►induction, ►repression, ►attenuation, ►inhibition, ►silencers, ►small RNAs, ►non-coding RNA, etc.). These may be involved before, during and after the final protein products are made.

The state of phosphorylation of the eukaryotic initiation factor, eIF-2 is critical for the translation process. This protein may form a complex with guanosyl triphosphate (GTP) and can assist in the attachment of the initiator tRNA^{Met} to the P site of the small subunit (40S) of the ribosome and scans the mRNA until it finds a methionine codon (AUG). This occurs after the large ribosomal (60S) subunit joins the small subunit to form the 80S ribosome and at the same time one molecule of inorganic phosphate and the inactivated eIF-2 and GDP are released. Then eIF-2 can acquire another GTP and the initiation process is repeated (►protein synthesis).

Although all polypeptide chains start with a formyl-methionine (prokaryotes) or methionine (eukaryotic),

the final product is frequently truncated at both the amino and carboxyl termini. Many proteolytic enzymes are translated as large units and become activated only after cleaving off certain parts of the original protein. To become active insulin is initially made as a pre-proinsulin that must be tailored in steps: first pre-, followed by pro-insulin and finally insulin. Several viral proteins, secreted hydrolytic proteins, peptide hormones and neuropeptides are made as polyprotein complexes which have to be broken down into active units in the trans-Golgi network, secretory vesicles or even in the extracellular fluids to become fully functional. The formation of polyproteins appears to be justified as a protective measure against destruction in the cytosol until they can be sequestered and confined into some vesicles. The loaded vesicles then migrate to predetermined sites where upon receiving the cognate signals they release the active protein. The signals can be chemical, physical (electric potentials) or topological. The release of the members of the polyprotein group may be selective regarding the site of release; different proteins can be released at different anatomical sites.

Some proteins are synthesized in separate polypeptide chains but must be folded and/or assume a quaternary structure, e.g., $\alpha\beta\gamma$ may even have to acquire a prosthetic group such as heme, a vitamin or other organic or inorganic group(s). The folding in prokaryotes begins after completion of the chain. In eukaryotes the folding may begin before the completion of a polypeptide and thus higher complexity is generated in the large proteins. The mRNA may be degraded before it can be translated into polypeptide chains.

Proteins are commonly acetylated after translation, carbohydrate side chains are added (glycoproteins), prenylated, linked by covalent disulfide bonds, special amino acids (serine, threonine, tyrosine) are phosphorylated by kinase enzymes, lysine residues may be methylated, and extra carboxyl groups may be attached to aspartate and glutamate residues.

Engineered Regulation. Using a genetic vector, it is feasible to introduce into somatic cells a structural gene *A* for a protein of a special need. With the aid of another vector it is possible to introduce gene *B* encoding its special transcription factor. The latter transcription factor gene is equipped with a promoter which responds to a specific drug (or to a specific temperature or to any other conditional factor) regulating its transcription. Thus, supplying the drug at variable dosage, the expression of gene *A* can be modulated by the controlled response of gene *B*. Such a system may permit the controls to be fine-tuned and secure compensation for a genetic defect or improve productivity.

According to some estimates, there are about 2,000 different protein kinases and 1,000 phosphatases in a higher eukaryotic cell. They must be regulated in time, space, and for other specificities. This regulation is an extremely complex task and is expected to be mediated by associations with modular, adaptor, scaffold and anchoring proteins working in sequential cooperation through signal transduction pathways. The availability of complete information on nucleotide sequence of both prokaryotic and eukaryotic genomes as well as microarray hybridization permits the assessment of the simultaneous expression of thousands of genes. Eventually, by using appropriate computer technologies the study of the coordinated regulation of the function of entire genomes will become a reality. ▶transcription, ▶transcriptional activator, ▶co-activator, ▶transcriptional modulation, ▶mediator complex, ▶transcription factories, ▶protein synthesis, ▶polysome, ▶endoplasmic reticulum, ▶chromatin, ▶chromatin remodeling, ▶high mobility group of proteins translation initiation, ▶translation, ▶regulation of enzyme activity, ▶axotomy, ▶signal transduction, ▶serine/threonine phosphoprotein phosphatases, ▶cell cycle, ▶LCR, ▶RNA polymerase, ▶DNA looping, ▶insulator, ▶transcription complex, ▶SL1, ▶TBP, ▶TAF, ▶attenuation, ▶open promoter complex, ▶RAD25, ▶signaling to translation, ▶DNA grooves, ▶elongation factors, ▶DNA chips, ▶microarray hybridization, ▶genetic network, ▶networks, ▶regulation of transcription, ▶transcription factors, ▶RNAi, ▶microRNA, ▶combinatorial gene control; Tautz D 2000 Curr Opin Genet Dev 10:575; Lemon B, Tjian R 2000 Genes Dev 14:2551; Rao CV, Arkin AP 2001 Annu Rev Biochem Eng 3:391; Emerson BM 2002 Cell 109:267, reviews in Cell 108:439 ff [2002], Wang W et al 2002 Proc Natl Acad Sci USA 99:16893; Pawson T, Nash P 2003 Science 300:445; Alonso CR, Wilkins AS 2005 Nature Rev Genet 6:709; transcriptional regulation in humans: Maston GA et al Annu Rev Genomics Hum Genet 7:29; <http://www.gene-regulation.com/>; <http://regulondb.ccg.unam.mx:80/index.html>; Gene Resource Locator: <http://www.gene-regulation.com/pub/databases.html#transcompel>; regulatory motif detection tool: <http://159.149.109.16/modtools/>; composite regulatory signatures: <http://140.120.213.10:8080/crsd/>.

Regulator Gene: This controls the function of other genes through transcription. ▶regulation of gene activity, ▶enhancer, ▶silencer, ▶activator, ▶co-activator, ▶operon

Regulatory Elements: These upstream (enhancer) sequences are located within 100 to 400 bp from the translation initiation nucleotide (+1) and control cell and developmental specificities. Some enhancers

may be located at more distant positions and also downstream. The enhancer region provides binding sites for regulatory proteins. ▶[basal promoter](#), ▶[regulation of gene activity](#), ▶[regulator gene](#), ▶[UAS](#)

Regulatory Enzyme: Allosteric or other modifications alter its catalytic activity rate, thus affecting other enzymes involved in the pathway. The Arg5.6 mitochondrial metabolic enzyme can regulate the expression of genes by association with mitochondrial DNA (Hall DA et al 2004 Science 306:482).

Regulatory Sequence in DNA: This binds transcription factors, RNA polymerase and so regulates transcription. The mammalian genomes contain many short (e.g., 8-mer) sequences, which are binding sites to specific proteins. The TGACCTTG sequence occurs in at least 434 human promoters and has been found 162 times in the mouse, rat and dog genomes at a rate of conservation of 37%. The Err- α (estrogen-related receptor) protein binds this octamer (Xie X et al 2005 Nature [Lond] 343:338) or the TNAAGGTCA element (Sladek R et al 1997 Mol Cell Biol 17:5400). An analysis of the 3' untranslated region of the four mammalian genomes has revealed 106 short motifs, which probably mediate post-transcriptional regulation. About 20% of the human genes seem to be regulated by microRNAs. ▶[transcription factors](#), ▶[open transcription complex](#), ▶[enhancer](#), ▶[operon](#), ▶[attenuator site](#), ▶[UAS](#), ▶[nuclear receptors](#), ▶[regulation of gene activity](#), ▶[microRNA](#)

Regulon: This non-contiguous set of genes is controlled by the same regulator gene. The different sections may communicate through looping of the DNA. Proteins mediate the coordination of mRNA (Keene JD 2007 Nature Rev Genet 8:533). ▶[looping of DNA](#), ▶[arabinose operon](#), ▶[regulation of gene activity](#); Manson McGuire A et al 2000 Genome Res 10:744; Huerta AM et al 1998 Nucleic Acids Res 26:55; conserved microbial regulon targets: <http://210.212.212.6/icr/index.html>.

Regulome: Refers to the complete set of transcription factors and their co-regulators.

Reifenstein Syndrome (Xq11-q12): In this condition the individual has XY chromosomal constitution but there is an insufficient production of androgen receptor during fetal development. The individual manifests male pseudohermaphroditism with hypospadias, hypogonadism and gynecomastia yet defective germ cells are present and fertility may be possible by early treatment with testosterone. ▶[androgen-insensitivity](#), ▶[hypospadias](#), ▶[hypogonadism](#), ▶[gynecomastia](#), ▶[testosterone](#), ▶[pseudohermaphroditism](#)

Reinitiation: The eukaryotic ribosomes can terminate an open reading frame and initiate another downstream (at low efficiency). Reinitiation occurs when the translation of one reading frame is completed and the process moves on to the next cistron. In an unfavorable nucleotide context, translation may be reinitiated not at the first AUG codon but at the next one downstream. Translation factor eIF2 may play an important role in the process. ▶[backtracking](#), ▶[regulation of gene activity](#), ▶[transcription](#), ▶[eIF2](#), ▶[translation](#), ▶[cistron](#); Kozak M 1999 Gene 234:187; Park HS et al 2001 Cell 106:723; Kozak M 2001 Nucleic Acids Res 29:5226.

Reinitiation of Replication: The genome of eukaryotes replicates at many points along the chromosomes. To avoid chaos in the nucleus it is important to prevent restart of replication. Reinitiation is prevented by cyclin-dependent kinases (CDKs) by phosphorylation of origin recognition complex (ORC), down-regulation of Cdc6 and the exclusion of MCM2-7 complex from the nucleus. ▶[CDK](#), ▶[Cdc6](#), ▶[ORC](#), ▶[MCM](#); Nguyen VQ et al 2001 Nature [Lond] 411:1068.

Reinitiation of Transcription: For a second cycle of transcription, transcription factors and the RNA polymerase must be re-attracted to the promoter. Reinitiation appears to be a faster process than initiation. TFIID and TFIIA transcription factors do not leave the promoter when the remaining part of the transcription complex is released. The reinitiation intermediate includes TFIID, TFIIA, TFIIF, TFIIE and the Mediator. Subsequently the complete transcription complex, including activators, is reformed depending on ATP and TFIIF. ▶[backtracking](#), ▶[preinitiation complex](#), ▶[transcription factors](#), ▶[mediator](#); Hahn S 1998 Cold Spring Harbor Symp Quant Biol 63:181.

Reiter Syndrome: This is a complex anomaly generally accompanied by overproduction of HLA-B27 histocompatibility antigen. It is characterized by arthritis, inflammation of the eyes and the urethra (the canal that carries the urine from the bladder and in males also serves as the genital duct). The inflammations may be related to sexually transmitted and intestinal infections. ▶[HLA](#), ▶[rheumatic fever](#), ▶[arthritis](#), ▶[connective tissue disorders](#)

Reiterated Genes: These are present in more than one copy, possibly many times.

Rejection: This is an immune reaction against foreign antigens such as may be present in transfused blood or grafted tissue. The rejection of pig organs by humans and Old World monkeys is caused by the presence of α -1,3-galactosyl epitopes on the

pig epithelia. During evolution the rejecters lost the appropriate galactosyltransferase gene and as a consequence developed antibodies against the epitope of the foreign tissue transplant. This immune reaction cannot be satisfactorily mitigated through affinity absorption or complement regulators or other means of immunosuppression (drugs) even in transgenic animals. A better solution appears to be the inactivation of the gene and generation of clones by nuclear transfer into enucleated pig oocytes. When fully developed, this procedure may permit xenotransplantation of pig organs into humans who have serious organ defects. ▶immune reaction, ▶HLA, ▶nuclear transplantation, ▶transplantation of organs, ▶xenotransplantation; Lai L et al 2002 Science 295:1089; Prather R et al 2003. Rejoining: ▶breakage and reunion, ▶breakage-fusion-bridge cycles

rel (REL) Oncogene (2p13-p12, 11q12-q13): This is a turkey lymphatic leukemia oncogene, a transcription factor homologous with NF-κB. c-Rel as a homodimer or as a heterodimer with p50 or p52 is a strong transcriptional activator. In its absence or inactivation, the production of IL-3 and the granulocyte—macrophage colony-stimulating factor is impaired. Rel domains occur in several proteins such as NF-κB, NFAT and another ca. 12. *RelA* encodes the guanosine tetraphosphate synthetase (ppGpp), *RelBE* in *E. coli* encodes the toxin-antitoxin proteins. The toxin severely inhibits bacterial growth as a stringent control whereas the antitoxin is a repressor of the translation of the RelB toxin. ▶NF-κB, ▶NFκB, ▶NFAT, ▶IL-3, ▶GMCSF, ▶oncogenes, ▶morphogenesis in *Drosophila*{3}, ▶p50, ▶stringent response, ▶magic spots; Gugasyan R et al 2000 Immunol Rev 176:134; Christensen SK et al 2001 Proc Natl Acad Sci USA 98:14328; Jaque E et al 2005 Proc Natl Acad Sci USA 102:14635.

Relapsing Fever: ▶Borrelia

Relaxase: ▶relaxosome

Relatedness, Degree of: This term is used in genetic counseling to indicate the probability of sharing genes among family members. In first-degree relatives such as a parent and child half of their genes are in common. In second-degree relatives such as a grandparent and a grandchild 1/4 of their genes are identical. In population genetics, mathematically simpler terms such as the inbreeding coefficient, consanguinity and coefficient of coancestry are preferred. (See these concepts under separate entries, ▶relationship coefficient, ▶MLS; Weir BS et al 2006 Nature Rev Genet 7:771.

Relational Coiling: ▶chromosome coiling

Relationship, Coefficient of: $r = \frac{2F_{IR}}{\sqrt{(1+F_I)(1+F_R)}}$ where F_I and F_R are the coefficients of inbreeding of I and R. If they are not inbred, F_I and F_R equal 0. ▶coefficient of inbreeding, ▶relatedness degree

Relative Biological Effectiveness: ▶RBE

Relative Fitness: ▶selection coefficient

Relative Molecular Mass (M_r): Expresses molecular weight relative to ^{12}C isotope (in $1/12$ units). It is comparable to molecular weight in daltons but it is not identical to molecular weight (MW) represented by the mass of atoms involved. ▶dalton

Relative Mutation Risk: This is equivalent to 1/doubling dose. ▶doubling dose, ▶genetic risk

Relative Sexuality: The intensity of sexual determination may be expressed in degrees in some organisms. In extreme cases a normal female gamete may behave like a male gamete toward a strong female gamete. ▶isogamy, ▶pseudohermaphroditism, ▶intersex

Relaxed Circular DNA: This is not supercoiled because of one or more nicks. ▶nick, ▶supercoiled DNA

Relaxed Control Mutants (*relA*): They have lost stringent control and continue RNA synthesis during amino acid starvation of bacteria. ▶stringent control, ▶fusidic acid

Relaxed Genomes: The organelle DNAs are not replicated in lockstep with the nuclear genome and their replication may be reinitiated during the cell cycle. The distribution of the organelles may not necessarily be equational during cytokinesis. ▶cytokinesis, ▶stringent genomes

Relaxed Replication Control: The plasmids continue to replicate even when the bacterial divisions stop. ▶replication

Relaxin: This water-soluble protein in the corpus luteum mediates the relaxation of the pubic joints and the dilation of the uterine cervix in some mammals. Its two receptors, LGR7 and LGR8, are heterotrimeric G protein binding proteins and are widely distributed among organs indicating their roles in diverse functions. ▶corpus luteum; Hsu SY et al 2002 Science 295:671.

Relaxosome: This DNA protein structure mediates the initiation of conjugative transfer of bacterial plasmids. It contains a *nic* site at the origin of transfer (*oriT*). Relaxase catalyzes the nicking and it becomes covalently linked to the 5' end through a tyrosyl residue. A single strand is then transferred to the recipient by a rolling circle mechanism.

►conjugation, ►rolling circle, ►nick; Xavier Gomis-Rüth F et al 2001 Nature [Lond] 409:637.

Relay Race Model of Translation: A ribosome after passing a chain termination signal of an ORF does not completely disengage from the mRNA and may reinitiate protein synthesis if an AUG codon is within short distance downstream. ►translation, ►regulation of gene activity, ►reinitiation, ►ORF; Ranu RS et al 1996 Gene Expr 5[3]:143.

Release Factor (RF): When translation reaches a termination codon, the release factors allow the polypeptide to be free from the ribosome. In prokaryotes there are two direct release factors RF-1 (specific for UAG/UAA) and RF-2 (specific for UGA/UAA) and a third factor RF-3 stimulates the activity of RF 1 and 2. RF-1 and RF-2 can discriminate between the termination and sense codons by 3 to 6 orders of magnitude effectiveness. In RF-1 a Pro-Ala-Thr and in RF-2 a Ser-Pro-Phe tripeptide, respectively, recognizes the appropriate stop codon. The eukaryotic release factors, eRF and eRF-1 alone can recognize all three stop codons. RF-3 and eRF-3 are GTP-binding proteins. RF-3 is a GTPase on the ribosome in the absence of RF-1 and RF-2; eRF3 requires eRF-1 to act as a GTPase. eRF-1 alone may be sufficient for termination in yeast. It has been suggested that all release factors are homologous to elongation factor G which mimics tRNA in its C-terminal domain and this is the basis of recognition of the RFs of the ribosomal A site. The activity of Class 1 release factors depends on the presence of Gly-Gly-Glu (GGQ) motif in the peptidyl transferase center for the release. In ciliates the stop codons vary and so do the release factors. ►transcription termination, ►protein synthesis, ►regulation of gene activity, ►EF-G, ►eRF; Inagaki Y, Doolittle WF 2001 Nucleic Acids Res 29:921; Zavialov AV et al 2001 Cell 107:115; Ito K et al 2002 Proc Natl Acad Sci USA 99:8494; Klaholz BP et al 2004 Nature [Lond] 427:862.

Releasing Factors: The hormones of the pituitary gland are released under the influence of hypothalamic hormones. ►animal hormones

Relics: These are genes with major lesions (insertions and deletions) in one or more components; they are similar to pseudogenes. ►pseudogenes

REM: An acronym of röntgen equivalent man. It is the product of REB × rad. Generally, 1 rem is considered to be equivalent to 1 rad of 250 kV X-rays; 1 rem is equal to 0.01 Sv (Sievert). ►R unit, ►rad, ►Gray, ►Sievert, ►REB, ►BERT

REM (Ras exchanger motif): This is required in signal transduction for interaction with RAS in GDP exchange for GTP using the GEF motif (Cdc25

homology catalytic unit) of SOS. ►signal transduction, ►RAS, ►SOS, ►GEF, ►Cdc25

REMI (restriction enzyme-mediated integration): An integrating vector is transformed into a cell in the presence of a restriction enzyme that facilitates insertion at the cleavage sites and may bring about insertional mutagenesis. ►insertional mutation, ►restriction enzyme; Thon MR et al 2000 Mol Plant Microbe Interact 13:1356.

Renal Carcinoma, Hereditary Papillary (HPRC): This is frequently caused by triplication (trisomy) and/or mutation of the MET oncogene, a cell surface tyrosine kinase, encoded at human chromosome 7q31.

Renal Cell Carcinoma (RCC): This commonly involves translocation breakage points in human chromosome 3p, each representing a different type. The 3p14.2 region includes the gene for protein tyrosine phosphatase gamma (PTPγ). This region also contains a fragile site, FHIT (fragile histidine triad) and the von Hippel-Lindau syndrome gene. ►hypernephroma, ►papillary renal cell cancer, ►tyrosine phosphatase, ►von Hippel-Lindau syndrome, ►fragile site; Zanesi N et al 2001 Proc Natl Acad Sci USA 98:10250.

Renal-Coloboma Syndrome: Is caused by mutation of the PAX2 (paired-box) gene at 10q24-q25.1 affecting the development of the kidney, eye and ear nerve. ►coloboma; Sanyanusin P et al 1996 Genomics 35:258.

Renal Dysplasia and Limb Defects: This condition is characterized by autosomal recessive underdevelopment of the kidney and the urogenital system, accompanied by defects of the bones and genitalia. ►kidney disease, ►limb defects

Renal Dysplasia and Retinal Aplasia: An autosomal recessive condition kidney developmental anomaly is associated with eye defects. ►kidney disease, ►eye disease

Renal Glucosuria (16p11.2, 6p21.3): Refers to dominant glycosuria which may not be related to diabetes.

Renal-Hepatic-Pancreatic Dysplasia (polycystic infantile kidney disease, ARPKD): Autosomal recessive phenotypes include cystic (sac-like structures) kidneys, liver and pancreas, sometimes associated with other anomalies such as blindness. The polycystic kidney disease of adult type dominant (ADPKD, human chromosome 16) is often associated with internal bleeding or arterial blood sacs (aneurysm). ►kidney disease

Renal Tubular Acidosis: The 17q21-q22 dominant type I defect is primarily in the distal tubules with normal bicarbonate content in the serum. Type II is recessive and the defect is in the proximal tubules and there is a low level of bicarbonate in the urine. Another recessive form involves mutation in the B1 subunit of H^+ -ATPase; in human chromosome 2cen-q13 nerve deafness is present. A proximal type is X-linked recessive. Recessive distal tubular acidosis with normal hearing (rdRTA2) has been assigned to gene ATP6N1B at 7q33-q34. The gene encodes an 840 amino acid subunit of a kidney vacuolar proton pump. The excretion of ammonium is reduced and the urine pH is usually above 6.5 in contrast to types I and II where it is around 5.5. Other variations have also been observed. ▶[kidney diseases](#)

Renal Tubular Dysgenesis: An autosomal recessive defect in the development of kidney tubules. It generally results in perinatal death because of the reduced amount of amniotic fluid (oligohydramnios), absence of urine secretion (anuria) and underdevelopment of the lung (pulmonary hypoplasia) caused by rennin-angiotensin defects. ▶[rennin](#), ▶[angiotensin](#); Gribouval O et al 2005 Nature Genet 37:964; Allanson JE et al 1992 Am J Med Genet 43:811.

Renaturation: Complementary single DNA strands reform double-strand structure by reannealing through hydrogen bonds. ▶[C₀t curve](#), ▶[denaturation](#)

Renilla GFP (from sea pansy): This is a green fluorescent protein with similarities to aequorin but it has only one absorbance and emission peak and its extinction coefficient is higher. ▶[aequorin](#)

Renin (chymosin, rennet): Protein hydrolase reacts with casein in cheese making. It is present in the kidneys and splits pro-angiotensin from α -globulin. ▶[angiotensin](#), ▶[pseudoaldosteronism](#); Kubo T et al 2001 Brain Res Bull 56:23; Krum H, Gilbert RE 2007 J Hypertens 25:25.

Renner Complex: Refers to the chromosomal translocation complex that is transmitted intact. ▶[translocation](#), ▶[translocation complex](#)

Renner Effect: ▶[megaspore competition](#); Renner O 1921 Ztschr Bot 13:609.

Reoviruses: Double-stranded RNA viruses cause respiratory and digestive tract diseases and arthritis-like symptoms in poultry and mammals, in humans, however, the infection usually does not involve serious symptoms. The internal capsid particle transcribes (+)-strand copies from the 10 genomic segments. The transcript carries a cap and it is exported to the cytoplasm of the infected cell. ▶[oncolytic virus](#), ▶[PKR](#), ▶[rotaviruses](#), ▶[cap](#), ▶[plus strand](#); Joklik WK, Roner MR 1996 Progr Nucleic Acid Res Mol Biol 53:249.

REP: Refers to repetitive extragenic consensus of 35 nucleotides, containing inverted sequences, in the bacterial chromosome. There are over 500 copies of it in *E. coli* in intergenic regions at 3' end of the genes. They are transcribed but not translated and appear to be the bacterial version of "selfish" DNA. ▶[selfish DNA](#); Herman L, Heyndrickx M 2000 Res Microbiol 151[4]:255.

Rep: An *E. coli* monomeric or dimeric binding protein and helicase. ▶[binding protein](#), ▶[helicase](#), ▶[monomer](#); Bredeche MF et al 2001 J Bacteriol 183:2165.

rep: The acronym of röntgen equivalent physical, a rarely used unit of X- and γ radiation delivering the equivalent of 1 R hard ionizing radiation energy to water or soft tissues (≈ 93 ergs). ▶[R](#)

Repair Genetic: ▶[DNA repair](#), ▶[unscheduled DNA synthesis](#)

Repairosome: Refers to the protein complex mediating DNA repair. ▶[DNA repair](#)

Repbase: Repetitive DNA database <http://www.girinst.org/>.

Repeat, Direct: This is (tandem) duplication of the same DNA sequence. It may be present at the termini of transposable elements ABC-----ABC. The hexameric CeRep26 repeat of *Caenorhabditis elegans* (TTAGGC) occurs at the telomeres and also at many additional chromosomal regions. The 711 copies CeRep11 are distributed over the autosomes but only one is in the X chromosome. In yeast most of the tandem repeats are in intergenic regions. The majority of them encode cell wall proteins. These repeats recombine frequently with pseudogenes and it is suspected that in pathogenic microbes they contribute to functional diversity of surface antigens, which play an important role in elusion of the host immune defense (Verstrepen KJ et al 2005 Nature Genet 37:986). ▶[transposable element](#), ▶[transposon](#), ▶[interspersed repeats](#), ▶[tandem repeat](#), ▶[homoepitope](#); interspersed repeat [fossile mobile element] tool: <http://repeats.abc.hu/cgi-bin/plotrep.pl>; tool for detection of interspersed repeats: <http://www.repeatmasker.org>.

Repeat-Induced Gene Silencing: ▶[co-suppression](#)

Repeat, Inverted: The double-stranded DNA carries inverted repeats such as transposable elements. The single strands can fold back and form *stem* (by complementarity) and *loop* (no complementarity) structure (see Fig. R35). In the sequenced *Caenorhabditis elegans* inverted repeats represent 3.6% of the genome and occur on an average 1/4.9 kb, introns contain 45% of them and 55% are in intergenic regions. Inverted repeats may increase inter- and

intrachromosomal recombinations by orders of magnitude and are responsible for a large part of the genetic instabilities. Mutation in the *MRE11/RAD50/XRS2* and *SAE2* genes of yeast interferes with the repair of hairpins and contributes to instability of the genome. ▶ **tandem repeats**, ▶ **transposable elements**, ▶ **LIR**; Lobachev KS et al. 1998 Genetics 148:1507; Waldman AS et al 1999 Genetics 153:1873; Lin C-T et al 2001 Nucleic Acids Res 29:3529; Lobachev KS et al 2002 Cell 108:183.

Figure R35. Inverted repeats

Repeat-Associated Short Interfering RNA (rasiRNA): This guides mRNA degradation or chromatin modification and silencing gene expression. ▶ **RNAi**

Repeats, Short Tandem (STR): With the aid of polymerase chain reaction, they serve for individual (forensic) discrimination or for the identification of human cell lines, which may or may not be contaminated. ▶ **PCR**, ▶ **low-copy repeats**; Oldroyd NJ et al 1995 Electrophoresis 16:334; Masters JR et al 2001 Proc Natl Acad Sci USA 98:8012.

Repeats, Trinucleotide: ▶ **fragile sites**, ▶ **trinucleotide repeats**

Repertoire, Antigenic: This is the complete set of antigenic determinants of lymphocytes.

Repertoire Shift: After a secondary immunization with a hapten, following a primary immunization, the variable heavy/variable light (V_H/V_L) immunoglobulin genes show an altered spectrum of somatic mutations. ▶ **immunoglobulins**, ▶ **hapten**; Meffre E et al 2001 J Exp Med 194:375.

Repetitive DNA (repetitious DNA): Refers to similar nucleotide sequences occurring many times in eukaryotic DNA. Some of these sequences represent transposable or retrotransposable elements, others such as ribosomal genes are called to duty when there is a special need for high gene activity, e.g., during embryonal development. More than 40% of the human genome appears highly or moderately repetitive and only about 3% may be genetically functional. ▶ **SINE**, ▶ **LINE**, ▶ **redundancy**, ▶ **pseudogenes**, ▶ **α -satellite DNA**, ▶ **co-suppression**, ▶ **microsatellite**, ▶ **minisatellite**; Britten RJ, Kohne DE 1968 Science 211:667; Toder R et al 2001 Chromosome Res 9[6]:431; Jurka J

et al 2007 Annu Rev Genomics Hum Genet 8:241; Rebase: <http://www.girinst.org>.

Replacement Theory: ▶ **out-of Africa**

Replacement Vector: By homology it recognizes and then replaces a particular segment (gene) of the target. It has a pair of restriction enzyme recognition sites within the region of “non-essential” genes. Non-essential means that their removal and replacement do not impair packaging and propagation in *E. coli* by sequences of interest to the experimenter. ▶ **vectors**, ▶ **stuffer**

Replica Plating: This is designed for efficient selective isolation of haploid microbial mutants. Mutagen-treated cells are spread in a greatly diluted suspension on the surface of complete medium and incubated to allow growth. Because of the dilution, each growing colony represents a single original cell (clone). Then impressions are made of this master plate on minimal medium where only the wild type cells can grow. The absence of growth on the minimal media plates indicates that auxotrophs exist at the spots where no growth was obtained.

The impressions also represent a map of the colonies on the original, complete medium, master plate. Thus, the experimenter can obtain cells from the original colonies and test them for nutritional requirement on differently supplemented media. This procedure thus permits the isolation of mutants and the identification of the nutrient requirement. (See Fig. R36, ▶ **mutant isolation**; Lederberg J, Lederberg EM 1952 J Bacteriol 63:399).

Replicase: This is RNA-dependent RNA polymerase enzyme of viruses encoded by the viral RNA and packed to the progeny capsid so that upon entry to a cell replication of the infective *negative-strand RNA* (influenza, Stomatitisvirus [causing inflammation of mucous membranes]) forms the template for replication but does not code for viral proteins. Without the replicase this negative strand would not be able to function. The *positive-strand RNA* viruses (e.g., poliovirus) are directly transcribed into the protein, including the replicase, and in this form it can be infectious. The DNA-dependent DNA polymerase enzymes are also called replicase. ▶ **replication**, ▶ **RF**, ▶ **positive strand**; Tayon R Jr et al 2001 Nucleic Acids Res 29:3576.

Replicating Vector: ▶ **transformation genetic**, ▶ **yeast**

Replication: ▶ **DNA replication**, ▶ **replication fork**, ▶ **chromosome replication**

Replication Banding: Using sequential 5-bromodeoxyuridine incorporation for the determination of early and late replicating chromosomal regions.

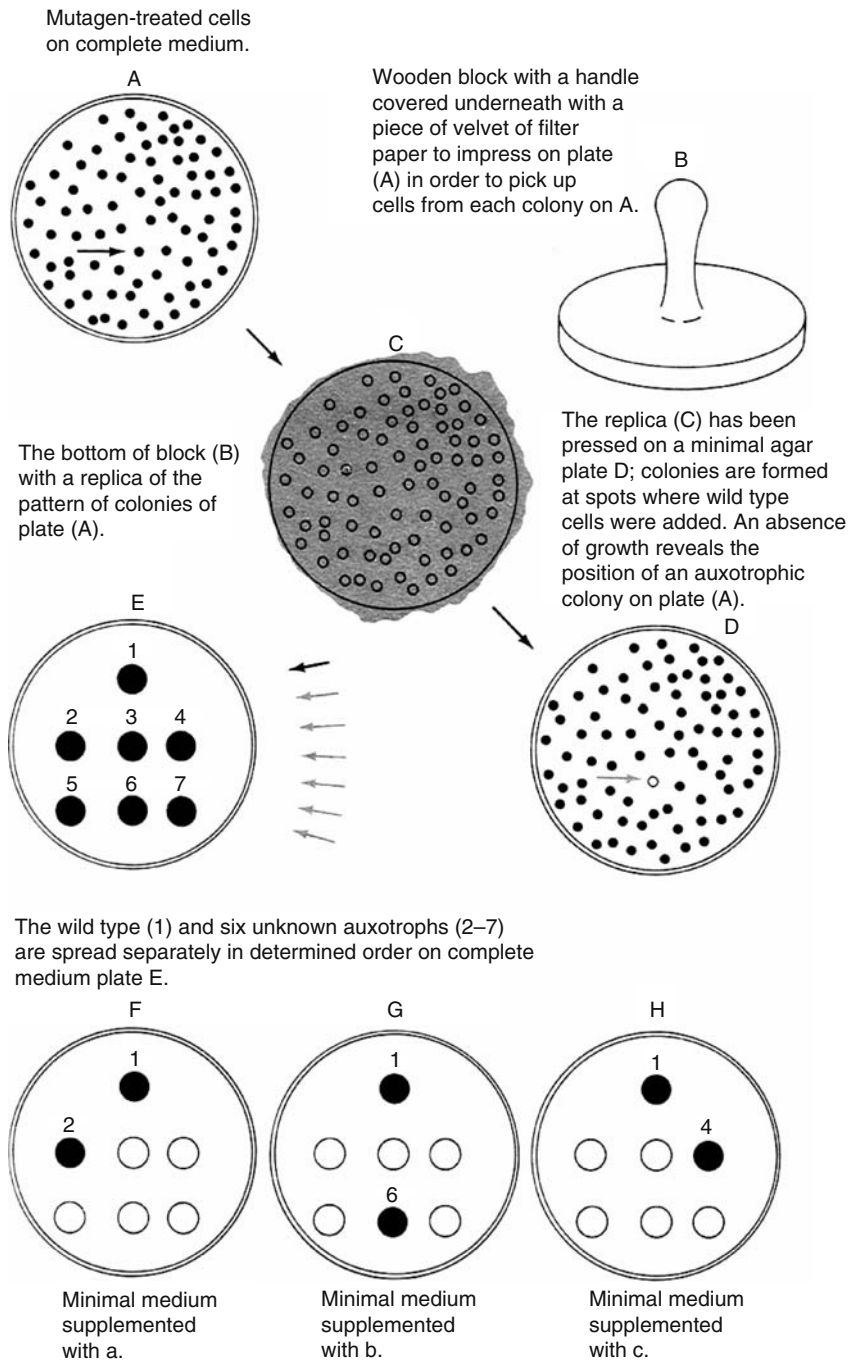

Figure R36. Replica Plating

Replication, Bidirectional: This is the mode of replication in bacteria as well as in the eukaryotic chromosome. Replication begins at an origin and proceeds in the opposite direction on both the old strands of the DNA double helix. The helicase subunits encoded by the xeroderma pigmentosum genes XPB and XPD of the transcription factor TFIIH unwinds the DNA in both

directions. Electron microscope reveals a θ (theta) resembling structure of the circular DNA whereas in the linear eukaryotic DNA bubble-like structures are visible. In prokaryotes this replication is mediated by DNA polymerase III, and in eukaryotes a DNA polymerase α type enzyme. Termination of replication in *E. coli* requires 20 base long Ter elements and the

associated protein Tus (termination utilization complex, M_r 36 K) (see Fig. R37). While replicating the template strand T7 RNA polymerase can by-pass up to 24 nucleotide gaps by making a copy of the deleted sequence using the corresponding non-template tract.

►DNA replication eukaryotes, ►DNA replication prokaryotes, ► θ replication, ►replication bubble, ►pol III, ►pol α , ►replication fork, ►xeroderma pigmentosum, ►transcription factors

Figure R37. Replication in *E. coli*. (Diagram after Kamada K et al 1996 Nature [Lond] 383:598)

The *TerA*, *D* and *E* stop the replication in an anticlockwise direction and *TerC*, *B* and *F* halt replication of the strand elongated clockwise. The Tus-Ter complex probably blocks the replication helicase. Similar mechanisms operate in most bacteria but replication fork arresting sites are also found in eukaryotes, including humans. (See Hiasa H, Marians KJ 1999 J Biol Chem 274:27244; Abdur-asidova G et al 2000 Science 287:2023; Gerbi SA, Bielinsky AK 1997 Methods 13:271).

Replication Bubble (replication eye): This is an indication of strand separation in a replicon (see Fig. R38). In an eukaryote nucleus an estimated 10^3 to 10^5 replication initiations occur during each cell cycle without any reinitiation per site, thus ensuring that the gene number is maintained. In yeast the dynamics of chromosome replication can be studied with the aid of DNA microarrays and it appears that the two ends of each chromosome replicate rather synchronously but the replication forks move differently in other regions.

►replication bidirectional, ►DNA replication, ►replication fork, ►replicon, ►promoter bubble, ►ORC, ►replication protein A, ►FFA, ►geminin; Diffley JFX 2001 Curr Biol 11: R367; Raghuraman MK et al 2001 Science 294:115.

Figure R38. Replication Bubble

Replication, Conservative: A historical model of DNA replication, assuming that the two old (original) DNA strands produce two new copies which then anneal to each other. In other words, double-stranded DNA is not composed of an old and a new strand as revealed by the current and experimentally demonstrated semiconservative replication mechanism.

►semi-conservative replication; Delbruck M, Stent GS 1957, p 699 In: McElroy WD Glass B (Eds.) The Chemical Basis of Heredity, Johns Hopkins Press, Baltimore, MD.

Replication Defective Virus: This is a mutant for the replication function or the lost genes required for producing infective particles.

►replicase

Replication, Dispersive: This refers to an unproven old idea that old and new double-strand DNA tracts alternate along the length of the molecule.

►replication, ►replication fork; Delbruck M, Stent GS 1957, p 699 In: McElroy WD, Glass B (Eds.) The Chemical Basis of Heredity, Johns Hopkins Press, Baltimore, MD.

Replication during the Cell Cycle: Eukaryotic DNA replication takes place predominantly during the S phase of the cell cycle although some repair synthesis (unscheduled DNA synthesis) may occur at other stages. In prokaryotes the replication is not limited to a particular stage and DNA synthesis may proceed without cellular fission. Such a phenomenon (endoreduplication) is exceptional in eukaryotes and is commonly limited to certain tissues only, e.g., to the salivary gland chromosomes of insects (*Drosophila*, *Sciara*) or a rare non-repeating process (endomitosis) that doubles the number of chromosomes. Replication in eukaryotes is an oscillatory process tied to the S phase of the cell cycle. The process of replication shows some variations even among the different eukaryotes and the process described here is modeled after that of *Saccharomyces cerevisiae* (the best known). During the G1 phase, from the pre-origin-of-replication complex (pre-ORC) the ORC (origin of replication complex) is assembled after the cyclosome (APC) proteases degraded the cyclin B-cyclin-dependent kinase (Cyclin B-CDK). The cis-acting *replicator* element and the *initiator* proteins bind at each origin of replication (hundreds or thousands in eukaryotes). The replicator (0.5–1 kb) is a multimeric complex itself and its indispensable component is the A unit but B1, B2 and B3 are also used. The A, B1 and B2 form the core of the replicator and B3 is an enhancer that binds to the *autonomously replicating sequence* (ARS)-binding protein factor 1 (ABF1). The replicator (A + B1) hugs the ORC (origin recognition complex) composed of 6 subunits that form the hub of the replication process and attract

other critical regulatory proteins. The site of the initiation in mammals may extend to 50 kb. At the origin, the nucleosomal structure is remodeled and during S, G2 and early M phase DNase hypersensitive sites are detectable that disappear before the anaphase. It appears that protein Cdc7 is needed for the remodeling. CDC6 (or the homologous Cdc18 protein of fission yeast) is required in G1 or S phase for DNA synthesis (the cells may proceed to an abortive mitosis and aneuploidy in its absence). CDC6 seems to be essential for the formation of the pre-ORC complex. Overexpression of this protein leads to polyploidy. The replication also requires a Replication Licensing Protein (RLF) and members of the MCM (minichromosome maintenance) proteins. Cyclin-dependent kinases (CLB5 and CLB6) are also required to establish the pre-initiation complex but after the assembly is completed some of them may be degraded. Some cyclin-dependent kinases block the reinitiation of the complex until the cell passes through mitosis. Cyclin B5—cyclin-dependent kinase (Clb5-CDK) is inhibited by Sic1 (S phase inhibitory complex) that is removed by ubiquitin-mediated proteolysis at the START point before the S phase is fired on. CDC34, CDC53, CDC4 SKP1, CLN1-Cdc28, CLN2-CDC28 and the APC proteins promote ubiquitination. The initiation of DNA replication may also proceed through another pathway mediated by CDC7 and DNA-binding factor 4 (DBF4). ▶cell cycle, ▶replication fork, ▶CLB, ▶DNA replication eukaryotes, ▶replication protein A, ▶DNA replication prokaryotes, ▶DNA replication in mitochondria, ▶rolling circle replication, ▶ θ (theta) replication, ▶ORC, ▶RNA replication, ▶reverse transcription, ▶bidirectional replication, and other proteins and terms listed under separate entries; Waga S, Stillman B 1998 Annu Rev Biochem 67:721; Kelly TJ et al 2000 Annu Rev Biochem 69:829; Chakalova L et al 2005 Nature Rev Genet 6:669.

Replication Error: This source occurs when a nucleic acid base analog is incorporated into the DNA at the structurally acceptable site but during the following replication, being only an analog, it may cause a replicational error that leads to the replacement of the original base pair by another. E.g., BrU—A base pair in the following replication is converted by error into BrU—G pair which eventually results in the base substitution of C=G at a site that was formerly T=A. Mismatching—in the absence of base analogs—can also occur, e.g., A=C, and the frequency of such errors is within the range of 10^{-4} to 10^{-6} . ▶base substitution, ▶incorporation error, ▶bromouracil,

Replication Eye: ▶replication bubble, ▶DNA replication eukaryotes, ▶replication bidirectional

Replication Factor A: ▶RF-A, ▶helix destabilizing protein

Replication Factor C: ▶RF-C

Replication Factory: This is the same as replication machine. ▶DNA replication prokaryotes

Replication Fork: Represents the growing region of the DNA where the strands are temporarily separated. The simplest diagram of the replication fork is reproduced here showing the new (thin line) facing the polymerase with the 3' end. The leading strand is below and the lagging strand is above (see Fig. R39).

Figure R39. Replication fork

Replication is a very complex process requiring two different polymerases (δ and α for the leading and lagging strand, respectively) and several proteins. ▶DNA replication eukaryotes, ▶chart, ▶DNA replication prokaryotes, ▶nucleoid, ▶GP32 protein, ▶PriA, ▶replication bubble, ▶replication bidirectional, ▶replication licensing, ▶primase, ▶Okazaki fragment, ▶alpha accessory protein, ▶processivity, ▶replication machine; Waga S, Stillman B 1998 Annu Rev Biochem 67:721.

Replication Intermediate: ▶lagging strand, ▶Okazaki fragment, ▶replication fork

Replication Licensing Factor (RLF): The initiation of replication requires two competency signals: the binding of the RLF and S phase promoting factors. The sequential action of these two signals secures the accurate replication of the chromosomes. RLF has two elements: RLF-M and RLF-B. RLF-M is a complex of MCM/P1. RLF-M protein binds to the

chromatin early during the cell cycle but it is displaced after the S phase. ►MCM1, ►MCM3, ►ORC, ►replication, ►cell cycle, ►replication bubble, ►Cdt1, ►geminin; Chong JP, Blow JJ 1996 *Progr Cell Cycle Res* 2:83; Nishitani H et al 2001 *J Biol Chem* 276:44905.

Replication Machine: It has been demonstrated that the *replication machine* of bacteria (*B. subtilis* and probably others) occupies a stationary central position in the cell and initially the twin PolC subunits are located in the replicational origin (O) of the bidirectionally replicating double-stranded DNA ring (see Fig. R40). The simultaneously replicating leading and lagging DNA strands are spooled through the twin machines. The machines contain the polymerase and several accessory proteins (also called replication factory). The eukaryotic replication

bubbles are operated in a similar manner but there are nearly 100 machines per nucleus and each of them handle about 300 replication forks. ►DNA replication prokaryotes, ►DNA replication eukaryotes, ►replication fork, ►clamp-loader; Ellison V, Stillman B 2001 *Cell* 106:655; Bruck I, O'Donnell M 2000 *J Biol Chem* 275:28971; Turner J et al 1999 *EMBO J* 18:771, replicons forming factories: Kitamura E et al 2006 *Cell* 125:1297.

Replication Origin (o): Refers to the point in the genetic material where replication begins. ►CLB, ►replication bubble; isolation of replication origin in complex genomes: Mesner LD et al. 2006 *Mol Cell* 21:719.

Replication Protein A (RPA, RFA, HSSB): A complex of three different polypeptides (~70 kDa, human chromosome 17p13.3; ~32 kDa, 1p35; ~14 kDa,

Figure R40. A model of the eukaryotic replication fork based on SV40 studies. Thin lines: old DNA strands; heavy lines: new strands. The replication fork is opened at the replicational origin by helicases. The *cellular replication protein* (RPA) keeps the fork open and brings the pol α DNA polymerase complex to the replication origin. After a short RNA primer is made (not shown on the diagram) at the beginning of the first Okazaki fragment, *cellular replication factor C* (RFC) binds to the DNA and displaces pol α by pol δ. Then RFC, pol δ, and PCNA (proliferating cell nuclear antigen) form a complex on both leading and lagging strands and the two new DNA strands are replicated in concert. The synthesis of the leading strand is straightforward. The lagging strand is made of Okazaki fragments (by "backstitching") because the DNA can be elongated only by adding nucleotides at the 3'-OH ends. After an Okazaki fragment (100–200 bases) is completed, RNase H, MF1 exonuclease remove the RNA primer (jagged line) and DNA ligase I joins the fragment(s) into a continuous new strand. The long arrows indicate the direction of growth of the chain. (Redrawn after Waga S and Stillman B 1994. *Nature* 369:207.)

7p22) binds most commonly to 20–25 nucleotides (with preference for pyrimidines) of single-strand DNA, and may be the first step in DNA replication by participating in DNA unwinding by binding to A-T rich sequences. The size of these subunits varies among different organisms and despite the good homology antigenically not related they cannot be interchanged functionally. The binding to double-stranded DNA is 3–4 orders of magnitude less. RPA binds to other proteins such as the primase subunit of DNA polymerase α , DNA repair proteins. The p53 cancer suppressor gene interferes with its binding to the replication origin. RPA also plays a role in recombination and excision repair. It has affinity to xeroderma pigmentosum damage-recognition protein (XPA) and endonuclease XPG. RPA increases the fidelity of repair polymerases. During the cell cycle RPA is phosphorylated by several kinases such as DNA-PK, CDK proteins, and others. ▶RPA, ▶DNA replication eukaryotes, ▶replication fork, ▶xeroderma pigmentosum, ▶endonuclease, ▶DNA repair, ▶replication bubble, ▶FFA, ▶DNA polymerases, ▶DNA-PK, ▶CDK, ▶somatic hypermutation; Wold MS 1997 Annu Rev Biochem 66:61; Patrick SM, Turchi JJ 2001 J Biol Chem 276:22630; Mass G et al 2001 Nucleic Acids Res 29:3892.

Replication Restart: This is a pathway of the SOS repair system of the DNA bypassing the mismatch and resulting in error-free replication. In bacteria, DNA polymerase II has an important role in the process. After UV irradiation or other damage blocks DNA synthesis, DnaB helicase and in coordination with DnaG primase on both leading and lagging strands provide means to bypass the lesion and a gap is left behind the leading strand in *E. coli* (see Fig. R41). ▶DNA repair, ▶replication of DNA, ▶primase, ▶translesion; Rangarajan S et al 1999 Proc Natl Acad Sci USA 96:9224.

Figure R41. Replication fork is reinitiated after the block leaving a gap behind as primase restarts replication. (Modified after Heller RC and Marians KJ 2006 Nature [Lond] 439:557)

Replication Slippage: One of the several mechanisms generating microsatellite diversity. ▶microsatellite; Viguera E et al 2001 J Mol Biol 312:323.

Replication Speed: kbp/min: *E. coli* 45, yeast 3.6, *Drosophila* 2.6, toad 0.5, mouse 2.2.

Replication Timing: Indicates whether chromosomal sequences replicate early or late during the cell cycle. Early tracts are usually more GC-rich and contain a larger number of genes than the AT-rich late replicating zones. Within the early/late transition regions many cancer genes have been found in human chromosomes 11q and 21q. ▶heterochromatin; Watanabe Y et al 2002 Hum Mol Genet 11:13; Goren A, Cedar H 2003 Nature Rev Mol Cell Biol 4:25.

Replicational Fidelity: Refers to DNA replication error.

Replicative Aging: In yeast the number of cell divisions during the life of the cell may determine aging. ▶chronological aging, ▶longevity, ▶aging

Replicative Form (RF): Double-stranded form of a single-stranded nucleic acid virus that generates the original complementary type of single-strand (+) nucleic acid. The necessity for the double-stranded replicative form is to generate a minus strand that is the template for the plus strand and is complementary to the “sense” molecule. This assures that all the progeny is identical and of one kind. ▶DNA replication, ▶RNA replication, ▶plus strand

Replicative Intermediate: ▶replicative form, ▶replication intermediate, ▶RNA replication

Replicative Segregation: The newly formed cellular organelles display sorting out in the somatic cell lineages in the case of mutation in organelle DNA. ▶sorting out, ▶cell lineage

Replicative Transposition: ▶transposition, ▶transposable elements, ▶cointegrate, ▶Mu bacteriophage

Replicator: Refers to the origin of replication in a replicon. ▶replicon, ▶ARS

Replichore: This is the oppositely replicating half of the *E. coli* genome between the origin and the terminus of replication. ▶*E. coli*

Replicon: A replicating unit of DNA. The size of the replicational unit varies a great deal. In *E. coli*: ≈ 4.7 Mbp, *Saccharomyces cerevisiae*: (yeast): 40 kb, *Drosophila*: 40 kb, *Xenopus laevis* (toad): 200 kb, mouse: 150 kb, broad bean (*Vicia faba*): 300 kb. ▶DNA replication, ▶minireplicon; Jacob F et al 1963 Cold Spring Harbor Symp Quant Biol 18:329; Sadoni N et al 2004 J Cell Sci 117(Pt22):5353.

Replicon Fusion: ▶cointegration

Replisome: Refers to the enzyme aggregate involved in the replication of DNA of *prokaryotes* (PriA, PrB, PriC, DnaC, DnaB and other proteins). The DNA polymerase III holoenzyme consists of two functional enzyme units, one for the leading and the other for the lagging strand. The *polymerase core* contains one α subunit (for polymerization), the ϵ subunit (3'→5' exonuclease for editing repair) and the θ unit. It also includes a ring-like dimer of β *clamp* to hold on leash the DNA strands and a five-subunit *clamp loader* γ complex. There are two subunits that organize the two cores and the clamp loader into a pol III holoenzyme. The asymmetric replication of the leading and lagging strands is determined by the DnaC helicase, unwinding the double helix in front of the replisome. The helicase facilitates the hold of the complex onto the leading strand by the τ unit to make possible the continuous extension of that strand. At the lagging strand, however, the complex goes off and on as the Okazaki fragments are made. ▶[replitase](#), ▶[DNA replication prokaryotes](#), ▶[replication fork in prokaryotes](#), ▶[GP32 protein](#), ▶[DNA polymerases](#), ▶[Okazaki fragment](#); Benkovic SJ et al 2001 Annu Rev Biochem 70:181; Breier AM et al 2005 Proc Natl Acad Sci USA 102:3942; Johnson A, O'Donnell M 2005 Annu Rev Biochem 74:283.

Replitase: Refers to the replicational complex at the DNA fork in *eukaryotes*. ▶[replication fork in eukaryotes](#), ▶[replisome](#), ▶[DNA polymerases](#); Reddy GP, Fager RS 1993 Crit Rev Eukaryot Gene Expr 3[4]:255.

Replum: A central membrane-like septum ↑ inside the silique (fruit) of cruciferous plants bearing the seeds (see Fig. R42). The carpels covering it were removed. Recessive pale mutant cotyledons show through the immature seed coats. At maturity the carpels dehiscence at the base of the fruit (left end here). ▶[silique](#)

Figure R42. Replum

Reporter Gene: This is a structural gene with easily -monitored expression (e.g., luciferase, β -glucuronidase, antibiotic resistance) that reports the function as differentiation progresses, or any heterologous or modified promoter, polyadenylation or other signals attached to the gene by in vitro or in vivo gene fusion. ▶[luciferase](#), ▶[GUS](#), ▶[gene fusion](#)

Reporter Ring: According to the tracking concept of recombination between appropriate *res* (*resolvase*)

points, recombination of two DNA molecules would retain during segregation “reporter rings” catenated to one of the two DNA strands of the DNA recombination substrate during synapse and after its resolution in the product. The “reporter rings” were expected to be limited to one of the catenated product molecules but the experimental data did not support this assumption. ▶[tracking](#), ▶[resolvase](#)

Representational Difference Analysis: ▶[RDA](#)

Repressible: This means subject to potential repression. ▶[repression](#)

Repressilator: This is a synthetic oscillator system composed of several components that may turn on/off as a natural biological clock. In such a system the product of a gene is a repressor for the promoter of the next one and so on. ▶[oscillator](#); Elowitz MB, Leibler S 2000 Nature [Lond] 403:335; Garcia-Ojalvo J et al 2004 Proc Natl Acad Sci USA 101:10955.

Repression: This is the control mechanism interfering with the synthesis (at the level of transcription) of a protein. A general type of repression is attributed to histones, closely associated with the DNA in the nucleosomal structure. When histones are deacetylated they reinforce repression by co-repressors (N-CoR, mSin3). Histone acetyl transferases acylate histones with the assistance of pCAF (chromatin assembly factor) which permits the recruitment of transcription factors to the gene. PCIP = p300/CEP co-integrator associated protein (where CEP is a CREB-binding protein), CREB = cAMP-response element, CBP is a CREB-binding protein, p300 = a cellular adaptor and co-activator of some proteins. This scheme of repression is based on some eukaryotic systems. Other mechanisms are also known. Some repression mechanisms interfere with the translation, e.g., threonyl-tRNA synthetase of *E. coli* represses its own synthesis by binding to the operator. tRNA^{Thr} serves as an antirepressor and the balance between the two mechanisms determines the level of translation (see Fig. R43) (Torres-Larios A et al 2002 Nature Struct Biol 9:343). ▶[feedback control](#), ▶[regulation of gene activity](#), ▶[signal transduction](#), ▶[regulation of enzyme activity](#), ▶[MAD](#), ▶[co-activator](#), ▶[transcription factors](#), ▶[lac repressor](#), ▶[arabinose operon](#), ▶[repressor](#), ▶[tryptophan operon](#), ▶[suppression](#); Maldonado E et al 1999 Cell 99:455; Lande-Diner L, Cedar H 2005 Nature Rev Genet 6:648.

Repressor: This is the protein product of the regulator gene that interferes with the transcription of an operon. The majority of the DNA-binding proteins bind the DNA by their α helices but some of the repressors (*met*, *arc*, *mnt*) bind by β sheets or a combination of both (*trp*). Repression in eukaryotes

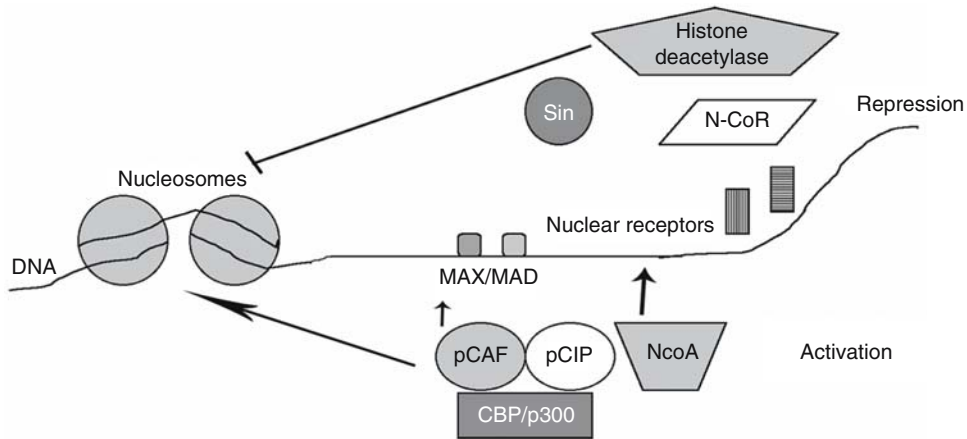

Figure R43. Proteins involved in repression and activation. (Diagram modified after Heinzel T et al 1997 Nature (Lond) 387:43)

has a variety of means for control. The short-range repressors are within 50–150 bp of the transcriptional activators. Since the promoters may be modular (repeating units), the short-range silencers may not affect other than the nearest activators. This organization assures the expression of genes controlling segmentation along the axis of the developing embryo. The long-range repressors may silence the activators from a distance of several kb. The short-range repressor proteins are monomeric whereas the long-range ones are multimeric. The repressors may be either gene-specific or more global. In the latter case in bacteria the repressor binds to the σ subunit of the RNA polymerase. Some of the more recently discovered repressors are not protein molecules but RNAs (ribozymes). In bacteria, glucosamine-6-phosphate (GlcN6P) mRNA encodes within its upstream sequence this ribozyme of ~ 75 nucleotides, which cleaves itself in the mRNA when GlcN6P reaches a sufficient level resulting in decay of the message. The regulatory response is initiated upon binding of GlcN6P to the mRNA (Winkler WC et al 2004 Nature [Lond] 428:281). [►repression](#), [►lac operon](#), [►lac repressor](#), [►arabinose operon](#), [►tryptophan operon](#), [►co-repressor](#), [►morphogenesis in *Drosophila*](#), [►transcription factors](#), [►Gene-Switch](#), [►riboswitch](#), [►tetracycline](#), [►suppression](#), [►suppressor tRNA](#); Pardee A et al 1959 J Mol Biol 1:165; Hummelke GC, Cooney AJ 2001 Front Biosci 6:D1186; Ryu J-R et al 2001 Proc Natl Acad Sci USA 98:12960.

Reproductive Isolation: Prevents gene exchange between two populations by a hereditary mechanism. Generally reproductive isolation is caused by the inability to mate (pre-mating isolation) but in some instances inviability or sterility of the offspring is the barrier (post-mating isolation). In plants, chromosomal rearrangements normally lead to gametic disadvantage or sterility. In animals, translocated chromosomes are frequently transmitted at fertilization but the duplication-deficiency zygotes are inviable. Mating *Drosophila melanogaster* with *D. simulans* a 3 kb DNA segment is inserted within the *Cyclin E* locus and causes male sterility and inviability but only a low degree of inviability or sterility in females. The *JYAlpha* gene is in chromosome 4 of *Drosophila melanogaster* but during evolution it transposed to the 3rd chromosome of *D. simulans*. In hybrids when this gene is lost hybrid male sterility occurs (Masly JP et al 2006 Science 313:1448). All members of the *Drosophila* species show reproductive isolation from *D. melanogaster*. Reproductive isolation can be associated with the pattern of single nucleotide polymorphism (Payseur BA, Hoekstra HE 2005 Genetics 171:1905). [►incompatibility](#), [►sexual isolation](#), [►isolation genetic](#), [►founder principle](#), [►drift genetic](#), [►effective population size](#), [►translocation](#), [►inversion](#), [►infertility](#), [►transcription](#), [►hybrid inviability](#), [►speciation](#), [►SNP](#); Harushima Y et al 2001 Genetics 159:883.

Reproductive Rate: (R_0) where l_x = probability that female survives to age x and m_x = expected number of female offspring produced by a female of age x .

►age-specific birth and death rate, ►population growth, ►Malthusian parameter, ►parity

$$R_0 = \sum_{X=0}^{\infty} l_X m_X$$

Reproductive Success: ►fitness, ►fertility, ►fecundity

Reproductive Technologies: ►ART

Reprogramming: During development the genome must be selectively turned on and off by epigenetic modifications such as methylation of nucleotides, acetylation and deacetylation of nucleosomes, and recruiting general and specific transcription factors. Such reprogramming which begins after fertilization of the egg is a natural and indispensable process. Problems arise, however, when diploid nuclei of somatic cells are transplanted into the eggs for the purpose of cloning. The somatic nuclei require dedifferentiation to the totipotent/pluripotent state and after transplantation the cloned embryos must be able to redifferentiate for the intended purpose. The transfer of nuclei from embryonic stem cells poses fewer problems yet in vitro culture conditions may not exactly duplicate the normal programming involved in natural fertilization of the haploid egg with the haploid sperm. Generally cloning involves developmental anomalies such as “large offspring syndrome”, various chromosomal anomalies and inviability because of lack of harmony between the donor nucleus and the recipient cytoplasm. Somatic cells may be reprogrammed by transfer into enucleated oocytes or by fusion with pluripotent embryonic stem cells (Tada M et al 2001 *Curr Biol* 11:1553; Ying QL et al 2002 *Nature [Lond]* 416:545). In cell fusion the less differentiated cell reprograms the more differentiated ones to its own features. It seems that reprogramming is a nuclear rather than a cytoplasmic process. It is unclear whether reprogramming by the use of cell extracts would be generally feasible. The cell fusions are not very useful for subsequent cloning because the nuclei are tetraploids. No practical procedure is available for reducing them to diploid level. Various culture conditions can also induce reprogramming. Blastocysts can yield pluripotent embryonic stem cells in vitro. The primordial germ cells of the genital ridge can give rise not only to germ cells (oocyte and sperm), but also to embryonic germ cells when used as explants in vitro or they can dedifferentiate into embryonic carcinoma cells. Spermatogonial stem cells can give rise to spermatzoa or in culture they can be reprogrammed into embryonic stem cell-like tissues. Bone marrow-derived adult multipotent progenitor cells can also be reprogrammed into mesenchymal or blood cells.

The *Nanog* gene (4 exons) in mouse chromosome 6 and human chromosome 12 encodes a 305-amino acid protein in humans (Chambers I et al 2004 *Cell* 113:643). This protein is essential for the maintenance of pluripotency of embryonic stem cells. The name nanog means the land of the ever young in Celtic mythology. Nanog may increase pluripotency of fused cells up to 100% (Silva J et al 2006 *Nature [Lond]* 441:997). Several other genetic factors OCTA4, SOX2 and various transcription factors have also been implicated. Mouse primordial germ cells (PGC) undergo erasure of histone 3 lysine 9 dimethylation (H3K9me2) and upregulation of histone H3 lysine 27 trimethylation (H3K27me3) in a progressive, cell-by-cell manner, presumably depending on their developmental maturation. Before or concomitant with the onset of H3K9 demethylation, PGCs enter G2 arrest of the cell cycle, that apparently persists until they acquire high H3K27me3 levels. PGCs repress RNA polymerase II-dependent transcription, which begins after the onset of H3K9me2 reduction in the G2 phase and tapers off after the acquisition of high level H3K27me3. The epigenetic reprogramming and transcriptional quiescence are independent from the function of Nanos3. Before H3K9 demethylation, PGCs exclusively repress an essential histone methyltransferase, GLP, without specifically upregulating histone demethylases (Seki Y et al 2007 *Development* 134:2627). ►nuclear transplantation, ►epigenesis, ►histone methyltransferase, ►stem cells; Rideout WM III et al 2001 *Science* 293:1093; Häkkelien A-M et al 2002 *Nature Biotechnol* 5:460; Hochedlinger K, Jaenisch R 2006 *Nature [Lond]* 441:1061.

Repolysin: A metalloproteinase involved in the regulation of morphogenesis. ►bone morphogenetic protein

Reptation: A theory about the movement of nucleic acid end-to-end in gels.

Reptin: ►chromatin remodeling

Repulsion: One recessive and one dominant allele are in the same member of a bivalent, such as *A b* and *a B*. ►coupling, ►linkage; Bateson W et al 1905 *Rep Evol Com Roy Soc II*:1.

RER: Denotes rough endoplasmic reticulum (endoplasmic reticulum with ribosomes on top of it).

Resection: Nuclease mediated production of single-strand overhangs in double-strand DNA breaks.

Resequencing: is directed to molecularly known gene(s) in order to determine mutations in the sequence (SNP, insertion, deletion) that have potential role in the expression of the gene and the disease it controls.

Capillary electrophoresis, polymerase chain reaction and automated data analysis may be used for the detection of mutations in the tract. For detection of insertions, labeled nucleotide array is hybridized to the target tract and the increase of signal indicates insertions. Loss of hybridization in a similar approach is the sign of deletion. (See Rijk PD, Del-Favero J 2007 *Methods Mol Biol* 396:331; <http://www.resequencing.mpg.de/>).

Residue: Refers to the elements of polymeric molecules, such as nucleotides in nucleic acids, amino acids in proteins, sugars in polysaccharides and fatty acids in lipids.

Resilin: This is a member of an elastic protein family, including gluten, gliadin and spider silks. ► [glutenin](#), ► [silk fibroin](#); Elvin CM et al 2005 *Nature [Lond]* 437:999.

Resistance Transfer Factors (RTF): Plasmids that carry antibiotic or other drug resistance genes in a bacterial host and are capable of conjugational transfer. ► [plasmid\(s\)](#)

Resistin: This is a 12.5 kDa cysteine-rich protein hormone of adipose tissues. The level of resistin is increased in genetically determined and diet-dependent obesity and it may cause insulin resistance and type II diabetes. ► [adipocyte](#), ► [adiponectin](#), ► [diabetes mellitus](#), ► [insulin](#); Way JM et al 2001 *J Biol Chem* 276:25651.

RESites (related to empty sites): These are genomic sites from where transposable elements moved out but left behind a footprint. Their flanking sequences are similar to insertion targets. (See Le QH et al 2000 *Proc Natl Acad Sci USA* 97:7376).

R

Resolution: Refers to the depth of details revealed by the analysis.

Resolution, Optical: Defines the ability of distinguishing between two objects irrespective of magnification. Magnification helps the human eye but does not improve optical resolution. The power of resolution depends on the wavelength of the light and on the aperture of the lens used. (The achromatic lens is free from color distortion, the apochromatic lens is free from color or optical distortions). The naked human eye may discern details larger than 100 μm , the light microscope with a good oil immersion objective lens may resolve 0.2 μm , the lowest limit for an ideal electronmicroscope is 0.1 nm, i.e., 1 Å. Under practical conditions the resolution of the electronmicroscope is about 2 nm. The resolution of the light microscope is generally defined as $\frac{0.61\lambda}{n \sin \theta}$ where λ is the wavelength of the light (for white light it may be 530 nm), n stands for the refractive index of

the immersion oil or air (when dry lens is used) and θ is half of the angular width of the cone of the light beam focused on the specimen with the condensor of the microscope ($\sin \theta$ is maximally about 1). Then $\sin \theta$ is the *numerical aperture* of the lens and using oil immersion its value may increase to 1.4. The immersion oil should be non-fluorescing, slow drying and of right viscosity for vertical or horizontal inverted views. ► [fluorescence microscopy](#), ► [phase-contrast microscopy](#), ► [Nomarski](#), ► [confocal microscopy](#), ► [electronmicroscopy](#), ► [oil immersion lens](#)

Resolvases: These are endonucleases mediating site-specific recombination and instrumental in resolving cointegrates or concatenated DNA molecules; transposon Tn3 and $\gamma\delta$ encoded proteins promoting site-specific recombination of supercoiled prokaryotic DNA containing replicon fusion, direct end repeats and internal *res* sites (see Fig. R44). ► [site-specific recombination](#), ► [recombination site-specific](#), ► [reporter ring](#), ► [TN3](#), ► [concatenate](#), ► [\$\gamma\delta\$ element](#), ► [EMC](#), ► [phase variation](#), ► [recombination molecular mechanism](#); Kholodii G 2001 *Gene* 269:121; Croomie GA, Leach DR 2000 *Mol Cell* 6:815; $\gamma\delta$ structure: Li W et al 2005 *Science* 309:1210; Kamtekar S et al 2006 *Proc Natl Acad Sci USA* 103:10642.

Figure R44. Resolvase functions

Resolving Power: This is the ability to distinguish between two alternatives or detecting an event, the probability of which is expected to be very low, e.g., recombination between two alleles of a gene.

Respiration: Electrons are removed from the nutrients during catabolism and carried to the oxygen through intermediaries in the respiratory chain. Oxygen is taken up and carbon dioxide is produced. ► [fermentation](#), ► [Pasteur effect](#), ► [chlororespiration](#), ► [mitochondria](#)

Respiratory Distress Syndrome: This condition is frequently observed in premature birth and is due to deficiency of pulmonary surfactant protein A (SFTPA2, 10q22.2-q22.3) or PFTP3 (2p12-p11.2).

Responder (*Rsp*): A component of the segregation distorter system in *Drosophila*, a repetitive DNA at the heterochromatic site in chromosome 2–62. ► [hybrid dysgenesis](#), ► [segregation distorter](#)

Response Elements: ►hormone response elements, ►transcription factors, ►inducible regulation of gene activity

Response Regulator: ►two-component regulatory system

Responsiveness: The establishment of a new steady state readily follows a change in the signal(s). ►signal, ►steady state

REST/NRSF (RE1 silencing transcription factor/neural-restrictive silencing factor): This factor blocks the expression of genes in non-neural tissues. It is a component of the histone deacetylase complex. It is involved in the regulation of chromatin and associated protein complexes. (See Kojima T et al 2001 Brain Res Mol Brain Res 90:174; Ooi L, Wood IC 2007 Nature Rev Genet 8:544).

Restenosis (recurrent stenosis): This is usually caused by therapeutic manipulation of the vascular system as an overcompensation for injury repair, e.g., after angioplasty (surgical/balloon opening of stenosis), or coronary/peripheral bypass surgery. Cell cycle inhibitors, antisense technologies, and modifying the expression of particular genes by using genetic vectors targeting particular genes involved in the cell

cycle have been considered for the prevention of this very complex process. ►stenosis, ►cell cycle, ►antisense technologies; Gordon EM et al 2001 Hum Gene Ther 12:1277.

Restitution Chromosomal: Refers to rejoining and healing of broken off chromosomes.

Restitution Nucleus: This is the unreduced product of meiosis.

Restless Leg Syndrome: This age-dependent neurological defect is characterized by compulsive movement of the legs, sleep disorder and increased tendency toward cardiovascular disease. It may affect up to 10% of the population of European descent. A genome-wide association study has revealed that the homeobox gene MEIS1 (chromosome 2p), gene BTBD9 (chromosome 6p), kinase MAP2K5 and transcription factor LBXCOR1 encoded at 15q are involved (Winkelmann J et al 2007 Nature Genet 39:1000).

Restorer Genes: ►cytoplasmic male sterility, ►fertility restorer genes

Restriction Endonuclease: ►restriction enzyme and Table R6.

Restriction Enzyme: Endonucleases cut the DNA at specific sites (generally) when the bases are not protected (modified, usually by methylation). Bacteria synthesize restriction enzymes as a defense against invading foreign DNAs such as phages and foreign plasmids. They may facilitate recombination and transposition. Three major types have been identified. Type II enzymes are used most widely for genetic engineering. Type II enzymes have separate endonuclease and methylase proteins. Their structure is simple, cleave at the recognition site(s); the recognition sites are short (4–8 bp) and frequently

palindromic, they require Mg^{2+} for cutting, the methylation donor is SAM. So far more than 3,000 Type II restriction endonucleases have been identified. Type II proteins, unless they have a similar pattern of cleavage, have relatively low sequence homologies.

Type III enzymes carry out restriction and modification with the help of two proteins which share a polypeptide. They have two different subunits.

Cleavage sites are generally 24–26 bp downstream from the recognition site. The recognition sites are asymmetrical 5–7 bp. For restriction, they require ATP and Mg^{2+} . For methylation, SAM, ATP, Mg^{2+}

are needed. *Type I* enzymes are single multifunctional proteins of three subunits, cleavage sites are random and at about 1 kb from specificity sites (crystal structure of the DNA-binding subunit: Kim J-S et al 2005 Proc Natl Acad Sci USA 102:3248). *Type I* restriction enzymes are encoded in the *hsd* (host-specificity DNA) locus with three components: *hsdS* (host sequence specificity), *hsdM* (methylation) and *hsdR* (endonuclease). Their recognition sites are bipartite and asymmetrical: TGA-N8-TGCT or AAC-N6-GTGC. For restriction and methylation, SAM, ATP and Mg^{2+} are required (see Figs. R45 and R46). Restriction enzymes may create a protruding and a receding end or the two ends may be of equal length, e.g.:

Figure R45. Crystal Structure of *Bgl*/II. In the centre is the DNA and α -helices and β -sheets embrace the DNA. Courtesy of Aggarwal AK; From Lukacs CM et al 2000 Nature Struct. Biol. 7:134

Figure R46. Protruding, receding and blunt ends of restriction fragments

Type II enzymes may be of high specificity, ambiguous, or isoschizomeric, and may be prevented from action on methylated substrates or may be indifferent to methylation. Some restriction enzymes such as *McrA*, *McrBC* and *Mrr* actually cut only methylated DNA. Approximately 3,000 *Type II* restriction enzymes with nearly 200 different specificities are known. Kilo- and Mega-base DNA substrates can be precisely cleaved by combining a DNA-cleaving moiety, e.g., copper-*o*-phenanthroline with a specific DNA binding protein (e.g., CAP). The complex thus cuts at the 5'-AAATGTGATCTAGAT-CACATTTT-3' DNA site of CAP recognition. The great specificity required that the cutting moiety would be attached to an amino acid in such a way that it would bend toward the selected target but not toward unspecific sequences. The *IIS* restriction

endonucleases cleave the DNA at a precise distance outside of their recognition site and produce complementary cohesive ends without disturbing their recognition site. By 2005, over 3,600 restriction endonucleases had been identified representing more than 250 specificities (see Table R6). ▶nucleases, ▶isoschizomers, ▶DNA methylation, ▶restriction-modification, ▶*hsdR*, ▶CAP, ▶antirestriction, ▶RNA restriction enzyme; Roberts RJ, Macelis D 2001 Nucleic Acids Res 29:268; Titheradge AJB et al 2001 Nucleic Acids Res 28:4195; Piungoud A, Jeltsch A 2001 Nucleic Acids Res 29:3705; classification: Roberts RJ et al 2005 Nucleic Acids Res 33: D233; historical perspective: Roberts RJ 2005 Proc Natl Acad Sci USA 102:5905; Brownlee C 2005 Proc Natl Acad Sci USA 102:5909; <http://www.neb.com/nebecomm/products/category1.asp?>; enzymes and genes for restriction and modification: <http://rebase.neb.com/rebase/rebase.ftp.html>.

Restriction Enzymes, Class-IIs (Enases-IIS): These have 4–7 bp, completely or partially asymmetric recognition sites and the cleavage site is at a distance of 1–20 bp. These enzymes are monomeric. They can be employed for precise trimming of DNAs, retrieval of cloned fragments, assembly of genes, cleavage of single-stranded DNA, detection of point mutations, amplification and localization of methylated bases. ▶restriction enzymes, ▶indexer; Szybalski W et al 1991 Gene 100:13.

Restriction Factor: This is a general term for various proteins, proteases, hormones and endonucleases involved in limiting or preventing growth. ▶APOPBEC3G; retrovirus restriction review: Goff SP 2004 Mol Cell 16:849.

Restriction Fragment: Denotes a piece of DNA released after digestion by a restriction endonuclease. The length of the fragments depends on how many nucleotides are situated between the two cleavage sites. From the same genomic DNA, the same enzyme generates fragments of different lengths because the nucleotide sequence varies along the DNA length. ▶restriction enzymes, ▶restriction fragment number, ▶RFLP

Restriction Fragment Length Polymorphism: ▶RFLP

Restriction Fragment Number: This can be predicted on the grounds of the number of bases at the recognition sites. Since the polynucleotide chain has four bases (A, T, G, C), four cutters can have $4^4 = 256$ bp average fragment length and six cutters $4^6 = 4096$. The average frequency of these fragments is

$0.25^4 = 0.0039$ and $0.25^6 = 0.000244$, respectively. However, these predictions are valid only if the distribution of the bases is random, but that is not the case in the coding sequences, e.g., in the ca. 49.5 kb λ DNA 12 EcoRI fragments would have been predicted but only five have been observed. Four, six cutter indicates that the enzyme cleaves the substrate at a 4 or 6 nucleotide-specified site. ►restriction enzymes, ►restriction fragment

Restriction Landmark Genomic Scanning (RLGS): This method detects cleavable restriction enzyme sites (e.g., NotI) in the genome by direct labeling and high-resolution two-dimensional electrophoresis. NotI is methylation sensitive and does not cleave at methylated sites. Tumor tissues usually display chromosomal aberrations and that may alter the restriction sites and the tissue specific differences in RLGS may be characteristic of the cancer. ►restriction enzyme, ►two-dimensional gel electrophoresis; Hirotsune IH et al 1994 DNA Res 1:239.

Restriction Map: ►RFLP

Restriction Mediated Integration: ►REMI

Restriction-Modification: The bacterial restriction enzymes are endonucleases and the modification enzymes are methyltransferases that recognize the same nucleotide sequence as the endonuclease and transfer a methyl group from *S*-adenosyl methionine either to C-5 of cytidine or to cytidine- N^4 or to adenosine- N^6 . For example, HpaII cuts C↓CGG and methylates C^mCGG, TaqI cuts T↓CGA and methylates TGC^mA. The biological purpose of this complex is to destroy invading nucleic acids (phages) by cleaving the foreign DNA with the aid of the restriction endonuclease(s), i.e., restrict the growth of the invader and the same time protect the bacterium's own genetic material by methylation. ►restriction enzymes, ►methylation of DNA, ►anti-restriction, ►methyltransferases, ►DNA uptake sequences; Kobayashi I 2001 Nucleic Acids Res 29:3742; <http://rebase.neb.com/rebase/rebase.html>.

Restriction Point: ►R point, ►checkpoint, ►cell cycle, ►cancer, ►commitment

Restriction Site: Refers to the site where the restriction enzyme cleaves. ►cloning site

Restrictive Conditions: These conditions do not permit the growth or survival of some specific conditional mutants. ►conditional mutation, ►permissive conditions

Restrictive Transduction: ►specialized transduction

Resveratrol (3,5,4'-trihydrostilbene): This is an antioxidant and an anti-inflammatory plant product. The beneficial effect of red wines is attributed to this phytoalexin. Resveratrol is an activator of sirtuin and can rescue polyglutamine-caused symptoms in *Caenorhabditis* as well in the neurons of mice (Parker JA et al 2005 Nature Genet 37:349). Resveratrol improves the health and survival of mice on a high-calorie diet (Baur JA et al 2006 Nature [Lond] 444:337). Resveratrol activates sirtuin and PGC-1 α , improves mitochondrial functions and protects against metabolic disease (Lagouge M et al 2006 Cell 127:1109). ►lipoxygenase, ►phenolics, ►phytoalexins, ►sirtuin, ►PGC

RET Oncogene (Rearranged during transfection): This is in human chromosome 10q11.2. In *Drosophila* its homolog is *tor* (see morphogenesis in *Drosophila*). The protein product is a tyrosine kinase, essential for the development of the nervous system; it is a signaling molecule for GDNF. Mutations at the RET locus may be responsible for familial medullary thyroid carcinoma (FMTc), multiple endocrine neoplasia (MEN2A and MEN2B) and Hirschsprung's disease and may involve a dominant negative effect. The RET gene has five important domains: cadherin-binding, cysteine-rich calcium-binding, transmembrane and two tyrosine kinase (TK) domains. The main course of the RET-activated signal pathway is: RET receptor→Grb2→SOS→RAS→RAF→MAPKK→MAPK→NUCLEUS (transcription factors). The RET regulatory function is preserved between zebrafish and humans without any similarity in sequence (Fischer S et al 2006 Science 312:276). ►oncogenes, ►tyrosine kinase, ►TCR, ►GDNF, ►endocrine neoplasia, ►Hirschsprung's disease, ►phaeochromocytoma, ►papillary thyroid carcinoma, ►Grb, ►SOS, ►RAS, ►RAF, ►MAPKK, ►MAPK, ►dominant negative, ►tyrosine receptor kinase, ►multiple endocrine neoplasia; Manie S et al 2001 Trends Genet 17:580.

Retardation: Denotes slower than normal growth and development. ►mental retardation, ►gel retardation assay

Reticulocyte: An immature enucleate red blood cell displays a reticulum (network) when stained with basic dyes. ►rabbit reticulocyte in vitro translation system

Reticulosis: A complex autosomal recessive disease involving anemia, lowered platelet count, nervous disorders, immunodeficiency, etc. The symptoms may overlap different types of leukemias. The prevalence is about 5×10^{-5} . Bone marrow transplantation and chemotherapy have proved to be beneficial in some cases. (See separate entries).

Reticulosis, Familial Histiocytic: This disorder involves spleen, liver and lymphnode enlargement; it is caused by mutation in the RAG1 or RAG2 genes at human chromosome 11p13. ►[RAG](#), ►[Omenn disease](#)

Retina: This is the inner layer of the eyeball connected to the optic nerve. ►[macular degeneration](#), ►[figure of eye at Iris](#)

Retinal: Refers to vitamin A aldehyde. ►[vitamin A](#)

Retinal Dystrophy (retinopathies): This is caused by defects in the rod photoreceptor—retinal pigment epithelial complex. The incident light activates rhodopsin which transmits the signal to the G protein transducin and then to a phosphodiesterase (PDE) leading to a decrease in the level of cGMP (required for the activity of the transducin) and the closure of Na^+ ion channels and cellular hyperpolarization. Arrestin and rhodopsin kinase regenerate the photoreceptor rhodopsin. Degeneration of the retinal pigment epithelium and the retinal rod receptors may cause blindness because of failure at any step in this system. Low levels of cytosolic cGMP caused by mutation in the cGMP activating protein may be the basis of amaurosis congenita. A defect in the photoreceptor-specific peripherin/RDS protein (located in the rod and cone photoreceptors' outer membranes) also results in retinal dystrophy, presumably because of the damage to anchoring the structures to the cytoskeleton. Another protein ROM1 (rod outer membrane) homologous to peripherin, associates within a tetrameric form and represents the major outer part of the photoreceptor. Peripherin variants have been implicated in some forms of other eye diseases such as retinitis pigmentosa, macular dystrophy and choroidal dystrophy. Injecting peripherin-2 gene using an adeno-associated viral vector can remedy the complex defect. The Bietti corneoretinal dystrophy due to a 32 kDa fatty acid-binding protein defect eventually causes night blindness and has been assigned to 4q25-4qtel.

Apoptosis may account for some retinal degeneration, which can be arrested by growth substances. Retinal damage may be repaired by transplantation of committed progenitor cells from the peak of the rod genesis. These transplanted cells integrate,

differentiate into rod photoreceptors, form synaptic connections and visual function in mice (MacLaren RE et al 2006 Nature [Lond] 444:203). ►[arrestin](#), ►[rhodopsin](#), ►[transducin](#), ►[ion channels](#), ►[peripherin](#), ►[phosphodiesterase](#), ►[signal transduction](#), ►[amaurosis congenita](#), ►[Oguchi disease](#), ►[night blindness](#), ►[Stargardt disease](#), ►[eye diseases](#), ►[cho-roid](#), ►[Usher syndrome](#), ►[apoptosis](#); Rattner A et al 1999 Annu Rev Genet 33:89; Allikments R 2000 Am J Hum Genet 67:793.

Retinitis Pigmentosa (RP): A group of human autosomal recessives (84%), X-linked recessive (6%, Xp11.3 and Xp21.1) or autosomal dominant (10%, 13q14, 8q11-q13) or mitochondrial diseases entailing visual defects and blindness with an onset during the first two decades of life and a prevalence rate in the range of 10^{-4} . The Xp21 (RP6) gene may form a contiguous gene syndrome in that region. Only a small fraction of cases of pigmentary defect is associated with the rhodopsin receptor, a G-protein receptor (RGR). Mutation in the TULP1 gene, expressed only in the retina, may also involve RP. (Tulp-like proteins occur in vertebrates, invertebrates and plants). Several other diseases, e.g., congenital deafness (Usher syndrome), hypogonadism, mental retardation, other neuropathies and mitochondrial deficiencies may also involve similar defects. Nearly 40 genes are probably involved in RP symptoms. A "digenic retinitis pigmentosa" is due to mutations in the unlinked loci of peripherin-2 (6p21-cen) and the ROM1 (retinal rod outer segment protein-1) in chromosome 11q13 (see Fig. R47) (Loewen C et al 2001 J Biol Chem 276:22388). Mutations in the α subunit of a cGMP phosphodiesterase (human chromosome 5q31.2-q34) gene, PDEA (phosphodiesterase A) may also cause retinitis pigmentosa. In the autosomal dominant disease, when there is single amino acid replacement in rhodopsin (His→Pro) ribozymes may discriminate against the mutant rat mRNA and destroy it when the photoreceptors are transduced by adenovirus-associated ribozyme constructs equipped with a rhodopsin promoter. The rhodopsin-like OPN2 gene has been assigned to 3q21-q24. Recessive mutations at 1q31-q32.1 also cause RP12 due to photoreceptor degeneration. The latter gene is homologous to that of *crumbs* in *Drosophila*. The MERTK receptor tyrosine kinase (2q14.1) may also be responsible for RP. A RP GTPase regulator-interacting gene (RPGIP1) has been mapped to 14q11. Dominant mutations at 17p13.3, 1q21.1 and 19q13.4 encode pre-mRNA splicing factors. Inosine monophosphate dehydrogenase gene type 1 (chromosome 7q) deficiency may also be responsible for dominant RP. ►[Lawrence-Moon syndrome](#), ►[Usher syndrome](#),

►Stargardt disease, ►rhodopsin, ►retinoblastoma, ►choroidoretinal degeneration, ►eye diseases, ►ribozyme, ►contiguous gene syndrome; Bennett J 2000 *Curr Opin Mol Ther* 2:420; Phelan JK, Bok D 2000 *Molecular Vision* 6:116; McKie AB et al 2001 *Hum Mol Genet* 10:1555; Vithana EN et al 2001 *Mol Cell* 8:375; Chakarova CF et al 2002 *Hum Mol Genet* 11:87; Kennan A et al 2002 *Hum Mol Genet* 11:547.

Retinoblastoma (RB): This is a tumor arising from the retinal germ cells, a glioma of the retina. The overall incidence is about $1\text{--}6 \times 10^{-5}$ per birth, expressed within the first two years. Almost 40% of the cases are genetically determined. The estimated mutation rate is within the range of 10^{-5} to 10^{-6} . The bilateral form is generally familial whereas the unilateral cases may be due to new mutations. A dominant RB gene has been assigned to human chromosome 13q14. The human RB1 allele may express meiotic drive, detectable by sperm typing. The mouse homolog Rb-1 is in mouse chromosome 14. Apparently RB is more frequently traced to the paternal chromosome 13 than to the maternal one. The incidence of sporadic RB is increasing with parental age. It appears that tumor growth factor B is absent in RB cells. The retinoblastoma protein (or homologs) may play a general role in tumorigenesis upon phosphorylation. RB is frequently associated with small cell lung carcinoma (SCLC), osteosarcoma, bladder cancer, breast cancer, leukemia and other types of malignancies and esterase deficiency (in deletions). Retinoblastoma is the first type of cancer with recognized recessive inheritance in humans. About 5–10% of the retinoblastomas are associated with deletions at chromosome 13q14 and rearrangements

involving that site. RB binding proteins (RBBP), with homology to the E7 transforming protein of a papilloma virus and to the large T antigen of SV40, have been identified. RBBP2/JUMONJI/JARID1A (human chromosome 12p11) demethylates H3K4, a transcriptional regulator histone (Klose RJ et al 2007 *Cell* 128:889). The normal allele of the retinoblastoma protein appears to keep in check abnormal proliferation by limiting the activity of pol III and pol I. Besides mutation in the RB gene, tumor suppressor p53 is also inactivated in retinoblastoma (Laurie NA et al 2006 *Nature [Lond]* 444:61). The retinoblastoma protein stimulates the transcription of several genes primarily by activating the glucocorticoid receptors. RB plays a decisive role at the G1 restriction point decisions (through RAS) in the cell cycle regarding differentiation or continuation of cell divisions. Transcription factor family E2F interacts with RB protein and regulates the cell cycle and cyclins. Retinoblastoma may be unilateral (the majority of the non-hereditary cases) or bilateral (about two-thirds of the hereditary cases). Defect in the RB gene may cause intrauterine death. The normal allele introduced into tumors by adenovirus vectors may slow down cancerous proliferation. Mutations in the retinoblastoma gene homolog of *Arabidopsis* plants cause female and male gametophytic lethality and abnormal nuclear proliferation of the central nucleus of the embryosac (Ebel C et al 2004 *Nature [Lond]* 429:776). ►eye disease, ►oncogenes, ►oncoprotein, ►pol III, ►deletion, ►CAF, ►papova virus, ►Simian virus 40, ►binding protein, ►sporadic, ►MDM2, ►E2F, ►ARF, ►glucocorticoid, ►restriction point, ►cell cycle, ►tumor suppressor, ►p110^{Rb}, ►E2F, ►pocket, ►cyclin, ►p53, ►RAS, ►histone deacetylase, ►papilloma virus, ►adenovirus, ►sperm typing, ►quiescent zone; Nevins JR 2001 *Hum Mol Genet* 10:699; Chan SW, Hong W 2001 *J Biol Chem* 276:28402, test for: Richter S et al 2003 *Am J Hum Genet* 72:253; epigenetic silencers (methyltransferases) and Notch collaborate in developing eye tumors in *Drosophila*: Ferres-Marco D et al 2006 *Nature [Lond]* 439:430; <http://www.es.embnet.org/Services/MolBio/rbgmdb/>.

Retinoid: ►RAR

Retinoic Acid (RA): This is a carboxylic acid derivative of vitamin A; the aldehyde form is retinol (see Fig. R48). The 11-cis retinal is the light absorbing chromophore of the visual pigments (carotenoids). Retinoic acids belong to a nuclear receptor family (RARE, RJR) and act as ligand-inducible transcription factors. Retinoids play a role in the anterior-posterior pattern of development of the body axis and

limbs of vertebrates (Vermot J et al 2005 Science 308:563). It may also have anti-cancer effects. RA activates RARE and PPAR β/δ , if it acts with RARE it may cause cell growth inhibition and if it acts with PPAR it induces pro-survival genes. A balance between CRABP-II (cellular retinoic acid binding protein) and PPAR (peroxisome proliferator activated receptor) determines these two opposing functions (Schug T et al 2007 Cell 129:723). ►transcription factors, ►RARE, ►opsin, ►PPAR

Figure R48. All-trans-retinol (vitamin A)

Retinol: Serum retinol-binding protein 4 contributes to insulin resistance and obesity and type 2 diabetes (Yanjg Q et al 2005 Nature [Lond] 436:356). ►retinoic acid, ►diabetes, formula given here.

Retinopathy: A disease of the retina. ►eye diseases

Retinoschisis: Refers to autosomal dominant, recessive or X-linked (Xp22.3-p22.1) degeneration of the retina involving splitting of that organ. ►eye diseases; Wang T et al 2002 Hum Mol Genet 11:3097.

Retra Genes: These are associated with retroviral sequences and/or transposons in the vertebrate genomes. ►retroviruses, ►transposon; Zdobnov EM et al 2005 Nucleic Acids Res 33:946.

Retroelements: ►retroposon, ►retrotransposon, ►processed pseudogene

Retrogene: This is a pseudogene with a transcriptionally active promoter. Retrogenes may be situated within the retroposon and have no introns. ►pseudogenes, ►SINE

Retrograde: This means backward. ►anterograde

Retrograde Evolution: The deletion of DNA sequences leads to adaptation to new function. Many pathogens lose genes upon becoming pathogenic. Pathogens and symbionts generally have smaller genomes than non-pathogenic or non-symbiotic relatives/ancestors. The reduction in genome size is probably the

consequence of lack of need for maintenance of metabolic functions that are available in the host. Pseudogenes represent relics of genes that are no longer required. ►pseudogenes; van Ham RCHJ et al 2003 Proc Natl Acad Sci USA 100:581.

Retrograde Regulation: The expression of nuclear genes is also controlled by mitochondrial and chloroplast factors. Genes in the cellular organelles (mitochondria and plastids) are coordinated in expression. Nuclear genes encode the overwhelming majority of functions in these organelles. In plants, the photosynthetic machinery, other plastid genes, primarily Mg-protoporphyrin IX synthetic complex and the chloroplast-localized pentatricopeptide-repeat protein GUN1 (genomes uncoupled 1) is a node where different chloroplast retrograde signals converge. The GUN complex comprises nearly 450 members and is present across the various plant species. GUN1 is the central mediator of communication with the nucleus. GUN2, 3, 4 and 5 control the MG-protoporphyrin IX system. GUN1 collects the signals and conveys them to the nuclear gene ABI4 and by binding to promoters in the DNA regulates RNA in the nucleus. Defect(s) or stress in the chloroplast leads to repression of some nuclear genes (Koussevitzky S et al 2007 Science 316:715). Similar retrograde regulation is also expressed through the mitochondria. ►chloroplasts, ►chlorophyll, ►pentatricopeptide, ►protoporphyrin, ►photosynthesis; Surpin M et al 2002 Plant Cell 14:S327; retrograde mitochondrial signaling in yeast: Liu Z, Butow RA 2006 Annu Rev Genet 40:159.

Retrohoming: ►intron homing

Retroid Virus: This has a double-stranded DNA genome (e.g., cauliflower mosaic virus, hepadnaviruses) which replicates the DNA with the aid of a RNA intermediate. ►cauliflower mosaic virus, ►hepatitis B virus, ►retroviruses

Retromer: A complex of five proteins: Vps35p, 29p, 26p, 17p and 5p. These proteins are involved in sorting endosomes to the trans-Golgi network and retrieval of the cation-independent mannose-6-phosphate receptor. Nexins are involved in the process of sorting. Retromers are essential for mammalian development. Retromers also function in yeast. ►endosome, ►Golgi; Griffin CT et al 2005 Proc Natl Acad Sci USA 102:15173.

Retron: This is responsible for the synthesis of msDNA. Retrons have several elements: the transcriptase *ret*,

the coding regions of msDNA, msdRNA and also requires RNase H. RNase HJ is needed for the maintenance of the proper structure and the termination of the transcription. ▶[msDNA](#), ▶[RNase H](#), ▶[reverse transcriptase](#), ▶[rettronphage](#); Lampson B et al 2001 *Progr Nucleic Acids Res Mol Biol* 67:65.

Retronphage: These retrons are parts of different proviruses, e.g., one in *E. coli* inserts within the selenocysteyl gene (*SecC*). ▶[retron](#), ▶[selenocysteine](#)

Retroposon (non-LTR retrotransposon): This transposable element is mobilized through the synthesis of RNA that is again converted to DNA by reverse transcription before integration into the chromosome. Some of the retroposon-derived elements acquired essential functions during evolution. An in silico assay of human genes for transcriptional activity revealed that more than 1,000 retrocopies were transcribed and ~120 developed into bona fide genes (Vickensbosch N et al 2006 *Proc Natl Acad Sci USA* 103:3220). The *Peg10* (paternally expressed, imprinted gene) of retroposon origin in the mouse is essential for placental development and embryo survival beyond day 10.5 post coitum (see Fig. [R49](#)). This gene is present in a wide variety of animals, except chicken and the *Fugu rubripes* fish (Ono R et al 2006 *Nature Genet* 38:101).

Figure R49. The expression of the *Peg10* gene (10.5. p.c.) wild type (upper row) and the knockout in mouse embryonic development (yolk sac, embryo, placenta). Courtesy of Drs. Fumitoshi Ishino and Ryuichi Ono

The retroposon may be a viral element or it may have originated from an ancient viral element. Retroposons are the long interspersed elements (▶[LINE](#)) and the short interspersed elements (▶[SINE](#)), the

copia elements in animals and several others of the hybrid dysgenesis factors, and they also occur in several species of plants. The majority of the plant retroposons have lost their ability to move. Retroposons can be distinguished from retrotransposons, the former do not have long terminal repeats (LTR) whereas the latter do. ▶[retroviruses](#), ▶[reverse transcriptase](#), ▶[copia](#), ▶[hybrid dysgenesis](#), ▶[transposable elements](#), ▶[LINE](#), ▶[SINE](#), ▶[processed pseudogene](#), ▶[knockout](#), ▶[post coitum](#); Wilhelm M, Wilhelm FX 2001 *Cell Mol Life Sci* 58:1246.

Retro-Proteins: These have inverse folding. Although folding should theoretically depend only on the amino acid sequence, they may have altered stability. The majority of genetic inversions are detrimental but the deleterious effect may not be the consequence of misfolding of proteins. ▶[inversions](#)

Retropseudogene: ▶[processed pseudogene](#)

Retroregulation: RNase III may degrade mRNA from the 3' end; some mutations in temperate phages may prevent this degradation and thus permit the translation of the mRNA. This control, operating from the end (downstream) forward (upstream), is known as retroregulation. ▶[retroviruses](#), ▶[regulation of gene activity](#), ▶[ribonuclease III](#)

Retrosequence: This is transcribed by reverse transcriptase.

Retrospective Study: This study involves the history of diseased individuals or individuals exposed to disease in the past and compares them to concurrent control cohorts. ▶[prospective study](#)

RetroTet-Art Vector: This has been designed to modulate the expression of the transgene by employing the tetracycline inducible system as well as the p16 growth arrest protein (Activators and repressors expressed together) so that during gene therapy the expression can be varied according to requirement. ▶[gene therapy](#), ▶[tetracycline](#); Rossi EM et al 1998 *Nature Genet* 20:389.

Retrotranslocation: Refers to the ejection of misfolded proteins from the endoplasmic reticulum back into the cytoplasm where they are subject to proteasome-mediated degradation. The dislocation is mediated by several Derlin proteins and p97 (Lilley BN, Ploegh HL et al 2005 *Proc Natl Acad Sci USA* 102:14296).

Retrotransposon: Refers to retrovirus-like transposable elements with long terminal repeats and position within the genome as retroviruses, however, they lack extracellular lifestyle, i.e., they cannot move from cell to cell. In *Arabidopsis* transposon Tag1, a 98 bp 5' terminal fragment containing a 22 bp inverted repeat and four copies of the AAACCX 5' subterminal repeat is sufficient for transposition, but a 52 bp 5' fragment with only one subterminal repeat is not. At the 3' end, a 109 bp fragment containing four copies of the most terminal 3' TGACCC repeat, but not a 55 bp fragment, which has no subterminal repeats is sufficient for transposition (Liu D et al 2001 Genetics 157:817).

Usually retrotransposons lack introns because they are propagated through a RNA intermediate and the introns are removed. The *Penelope* retrotransposon of *Drosophila viridis* shows a 75 bp intron with GT/AG donor/acceptor site in the 5' untranslated region. Similar elements have also been identified in some flatworms, roundworms, crustaceans, fishes and amphibians (Arkhipova IR et al 2003 Nature Genet 33:123).

Retrotransposons are common in the eukaryotic genomes and are apparently not distributed at random in the chromosomes. In mice oocytes retrotransposons, carrying promoters, can developmentally regulate the expression of multiple genes by serving as alternate promoters (Peaston AE et al 2004 Dev Cell 7:597). The VL30 retrotransposons in mice and humans are suppressors of leukemia oncogenes and also play a normal role in steroidogenesis (Song X, Garen A 2005 Proc Natl Acad Sci USA 102:12189).

The five *Ty* elements of *Saccharomyces* congregate in regions about 750 bp upstream of tRNA genes and *Ty5* is found at the telomeres.

Usually the sites of insertion are methylated and not transcribed and that protects the genome from insertional mutations. In a 280 kb region flanking the maize alcoholdehydrogenase gene (*Adh1*, chromosome 1L-128) 10 different retroelements were

found crowded with repetition and inserted within each other. The repetitive elements of the maize genome largely represent retrotransposons and constitute at least 50% of the total nuclear DNA. The size of the repeats varies from 10 to 200 kb and they are distributed throughout the genome. The maize retrotransposons with a very high copy number (10,000 to 30,000) usually do not cause insertional mutations. The elements with a small copy number (1–30) preferentially move into genic sequences. The *Arabidopsis* genome, which is about 1/20th of that of maize, contains almost 20 retrotransposons but only with 5–6 copies. In *Vicia faba* plants with a genome size of 13.3 pg (about 1.3×10^{10} nucleotide pairs), 10% of the genome comprises retrotransposable elements but in related species their number is much smaller. In *Allium* and other plants the elements are mainly in the centromeric and telomeric heterochromatin regions whereas in other organisms they may be dispersed (see Table R7). The plant retrotransposons (with the exception of the *Tnt1* of tobacco) fail to move because their transposase is pseudogenic. The major difference between retrotransposons and retroviruses is that the former do not produce envelope (Env) protein. ▶retroviruses, ▶insertion elements, ▶retroposon, see Figs. R50 and R51, ▶transposable elements, ▶transposons, ▶hybrid dysgenesis, ▶methylation of DNA, ▶Ty, ▶copia. It was expected that retrotransposons and retrotransposons (retroelements) would constitute about 5 to 10% of the human genome but the sequencing data revealed a substantially higher proportion. ▶retrotransposons, ▶SINE, ▶LINE, ▶Ty, ▶transposable elements, ▶processed pseudogene; Kumar A, Bennetzen J L 1999 Annu Rev Genet 33:479; Wang J et al 2006 Human Mutat 27:323; long terminal repeat (LTR) finder: http://tlife.fudan.edu.cn/ltr_finder/; retrotransposon and L1 signature finder: <http://www.riboclub.org/cgi-bin/RTAnalyzer/index.pl>.

Table R7. Retrotransposon and retrotransposon-like elements in *Drosophila* (*copia*), *saccharomyces cerevisiae* (*TY912*), and *Arabidopsis* (*tag-3*) all make 5 bp target site repeats. Their long direct terminal repeats are of different length yet they have highly conserved sequences (aligned in bold). Their internal domains of different length still has a few similarities although *copia* is highly mobile, whereas *tag-3* is no longer moving because its transposase gene underwent too many changes (pseudogenic). (After Voytas & Ausubel 1988 Nature [Lond] 336:242)

Figure R50. A DNA copy of a retrotransposon in the chromosome is replicated through a RNA transcript. The replication begins at the R segment of the 5' long terminal repeat (LTR) and proceeds through segment U5 and the non-repetitive internal region of the element (shown within the vertical lines) toward the 3' boundary of the R segment of the long terminal repeat. The first strand of the DNA is synthesized by the reverse transcriptase, encoded within the retrotransposon and is primed by the CCA-3'-OH end of one or another kind of host tRNA that pairs by complementarity to the upstream LTR. The reverse transcription also employs a protein-tRNA complex that binds to the tRNA-protein site (tRNA-PPS). The second strand is primed at the SSP site (second strand primer). At the target site, duplication occurs

Retroviral Recombination: Retroviruses have dimeric RNA genomes which are transcribed into double-stranded DNA after productive infection. Recombination occurs during the synthesis of the plus and minus strands. Complementarity between the palindromic sequences at the dimerization initiation sites of the hairpins is required for the two RNA chromosomes. The 5' untranslated sequence forms a kissing-loop structure (Figure R51) that contains essential replication elements. Increased homology and proximity of the homology tracts promote template switching. The diagram depicts a perfect

palindrome but the strands may not be perfectly complementary along their entire length. Circles indicate markers. ▶retrovirus, ▶kissing loop, ▶palindrome; Mikkelsen JG et al 2004 Nucleic Acids Res 32:102.

Retroviral Restriction Factors: These mammalian proteins interfere with effective infection or propagation of the retrovirus in the mammalian host cell. The APOBEC3G and ZAP inhibit the replication of the viral nucleic acid. The Friend virus susceptibility factor (Fv1) targets the incoming retroviral leukemia virus capsid. The TRIM5 factor group protects against HIV-1 and murine leukemia virus by acting after the entry of the virus into the host cell. ▶retrovirus, ▶TRIM, ▶leukemia inhibitory factor, ▶APOBEC3G, ▶ZAP; Hatzioannou T et al 2004 Proc Natl Acad Sci USA 101:10774.

Retroviral Vectors: These are capable of insertion into the chromosomes of a wide range of eukaryotic hosts. The expected important features are: (i) efficiency and selectivity for the target, (ii) safety, (iii) stable maintenance, and (iv) sufficient expression for the purpose employed. Generally, the *gag*, *pol* and *env* genes are removed but all other elements required for

R

Figure R51. Kissing loop

integration and RNA synthesis and the ψ packaging signal are retained. Usually a selectable marker neomycin [*neo*], or dehydrofolate-reductase [*dhfr*] resulting in methotrexate resistance (MTX), or bacterial hypoxanthine-phosphoribosyltransferase [*hprt*], or guanine-hypoxanthine-phosphoribosyltransferase [*gpt*], or mycophenolic acid (MPA) resistance is inserted in such a way that its initiation codon (ATG) falls into the same place as the ATG of the group-specific antigen protein (*gag*) gene. Transcription will be initiated at the 5' long terminal repeat (5'LTR) and translation will proceed from the ATG that is at the same place as that of *gag* (see Fig. R52).

The generalized vector shown here is non-infectious and requires superinfection by a helper virus. There are several other types of vector designs. After the DNA has been packaged into a virus particle the transfer of the gene is almost fully efficient as long as the cell has the appropriate receptor. By engineering the knob on the viral surface, the vector may be targeted to special cells. The recombinant DNA integrates into the host as a provirus with aid of the *integrase* protein encoded also by the *pol* gene. The most commonly used murine leukemia virus vector (MuLV) has about 6–8 kb carrying capacity. It is desirable to target the integrase to sites where the danger of insertional mutation is minimized in case the vector is used for therapeutic purposes. This goal may be difficult to achieve. Targeting to the sites of RNA polymerase III attachment with the aid of the yeast *Ty* transposons has been considered. This polymerase (pol III) transcribes ribosomal RNA genes that are present in multiple copies and thus pose a lower risk for deleterious mutations. A better approach may be using targeted homologous recombination. Targeting the transgene may be refined by the use of a cell-specific promoter.

The provirus is generally present in a single copy per cell but this *producer cell* will proceed with the production of recombinant retrovirions. The production of the recombinant virus is enhanced if initially the cell is also co-infected by a wild type proviral plasmid. However, such a system has a disadvantage because of the presence of a helper virus, which competes with a pseudovirion, and it may also be hazardous by being pathogenic. The problems related to the helper virus can be eliminated if it retains all the viral genetic sites except the packaging site (ψ) and is

therefore unable to produce infectious particles. There are several means of preventing reconstitution of an infectious viral particle which can cause disease.

Broad host range (amphotropic) viral vectors can be constructed by replacing a narrow range (ecotropic) viral envelope protein with another of an amphotropic virus. The Env protein mediates the virus/vector entry into the cell through the Pit-2 receptor. Env determines the host range. The host range may be extended by pseudotyping, i.e., co-infection of the cells with two different viruses, which results in a mixed envelope glycoprotein. Improved targeting of the retrovirus may be achieved by attaching cell specific ligands or antibodies to Env. Some of the Env proteins may elicit spongiform encephalomyelopathy. Caution must be exercised because the vector or host cell DNA and the helper virus genetic material may recombine and give rise to infectious particles. By genetic engineering additional modifications have been made in the helper virus to prevent the formation of infectious single recombinants. This has been achieved by replacing, e.g., the 3' LTR with a termination stretch of the SV40 eukaryotic virus DNA.

The *retroviral expression vectors* are more useful because they not only prove that the viral vector is present in the cell, but also propagate desirable genes (e.g., growth hormone genes and globin genes). Since retroviral vectors may carry strong promoters and enhancers within the LTR region, they can over-express some genes. They may also be employed for insertional mutagenesis because they can insert at different chromosomal locations and can be used as tools to study animal differentiation and morphogenesis. The most commonly used retroviral vectors have been derived from the Moloney murine leukemia virus (MoMuLV). In some instances the retroviral vectors within the host are silenced because the viral promoter in the 5' LTR is methylated by the host enzymes. This *promoter shutoff* may be avoided by using eukaryotic promoters. In some instances the inclusion of a locus control region (LCR) of the host may boost the expression of the transgene. The use of insulators may protect the transgene from host repressors. Also, a heterologous promoter that may drive more efficient expression (SIN vector, double copy vector) may replace the viral promoter. Retroviral vectors may permit the utilization of internal ribosomal entry sites (IRES) to drive the expression

Figure R52. of more than one gene. By using tissue-specific promoters the expression of the transgene may be limited to a certain cell type, e.g., in tumor cells. The promoter may also be selected for inducibility so that the expression may be regulated by the supply of glucocorticoids or a metal, or tetracycline, etc. Retroviral vectors are useful for gene therapy because they integrate stably into human and animal cells and are normally transmitted through mitoses. ▶**vectors**, ▶**retroviruses**, ▶**viral vectors**, ▶**double-targeted vector**, ▶**epitope**, ▶**SV40**, ▶**mycophenolic acid**, ▶**MoMuLV**, ▶**lentiviral vectors**, ▶**foamy viral vectors**, ▶**ψ**, ▶**SIN vector**, ▶**E vector**, ▶**double-copy vector**, ▶**IRES**, ▶**packaging cell lines**, ▶**gene therapy**, ▶**gene marking**, ▶**pseudotyping**, ▶**Ty**, ▶**pol III**, ▶**LCR**, ▶**insulator**, ▶**inducible gene expression**, ▶**cancer gene therapy**, ▶**biohazards**, ▶**laboratory safety**; Yee J-K 1999, p 21 In: Friedmann T (Ed.) *Development of Human Gene Therapy*, Cold Spring Harbor Laboratory Press; Smyth TN (Ed.) 2004 *Gene and Gene Therapy*, Marcel Dekker, New York; Somia N 2004 *Methods Mol Biol* 246:463.

Retroviruses (Retroviridae): These include onco-, lenti- and spumaviruses. In eukaryotes they contain dimeric single-stranded RNA, which is processed by a stringent switch (Badorrek CS et al 2006 *Proc Natl Acad Sci USA* 103:13640) as the genetic material that is replicated through a double-stranded DNA intermediate with the aid of a reverse transcriptase enzyme. Retrovirus reverse transcription usually takes place after the host has been infected. In the human foamy virus (spumavirus), the infectious particles already carry a double-stranded DNA, indicating that reverse transcription precedes infection. Besides the polymerase gene (*pol*), they all carry group-specific antigen (*gag*) and envelope (*env*) protein genes. These three viral components are

active in trans whereas the other elements require cis position. A provirus introduced into a cell by retroviral infection may become a retrotransposon (e.g., Ty element in yeast, copia in *Drosophila*). They are characterized by long terminal repeats (LTR), measuring a few thousand nucleotides in length. For infection to proceed, the viral capsid protein fiber and knob must find an appropriate receptor on the surface of the target cell.

When the virus enters the host cell its RNA genetic material is converted into double-stranded DNA, and it may be covalently integrated into a host chromosome. Although the targets for integration are spread all over the genome, transcriptionally active regions are preferred. Integration “hot spots” in chicken cells may be used by RSV a million times more often than expected by chance alone, and some sequences in mouse cells (e.g., the HGPRT gene) may be avoided. After a cell is infected by a single virion, in a day, thousands of viral particles may be produced.

Retroviruses are considered to be diploid (dimeric) because they have a pair of genomes, two identical size RNAs of 7 to 9 kb. All retroviruses minimally encode a protease, a polymerase, ribonuclease H activity of the reverse transcriptase and an integrase function. A generalized structure of retroviruses is presented in Figure R53 (individual types may display variations of this scheme):

The three proteins: gag (group-specific antigen) a polyprotein, pol (polymerase, reverse transcriptase), env (envelope protein) are transcribed in different, overlapping reading frames and then for RNA packaging into virion. The genomic subunits are the same as the mRNA, i.e., they are (+) strands. The transcript RNA has a 7-methyl-guanylate group at the 5' end and a 100 to 200 polyA tract at the 3' end, similar to eukaryotic mRNAs. The different retroviruses code for various proteins with known or yet to be identified functions. The gag-pol polyprotein complex contains

Figure R53. At the two ends of the viral genome are the *long terminal repeats* (LTR) of 2 to 8 kb. At the left and right termini of the LTRs are *attU3* and *attU5*, respectively for the attachment of the U3 (170 to 1,200 nucleotides) and U5 (80 to 120 nucleotides) direct repeats of the provirus in the host DNA. The *att* sequences at the 3' end of U5 and at the 5' end of U3' contain usually imperfect, inverted repeats where viral DNA joins the host DNA at 2 nucleotides from these ends. The terminal repeats represented by *R* (10 to 230 nucleotides) are used for the transfer of the DNA during reverse transcription. *E*: transcriptional enhancer, *P*: promoter, *PA*: signal for RNA cleavage and polyadenylation. *PBS*: binding site for tRNA primer for first strand DNA synthesis (different retroviruses use the 3'-OH end of different host tRNAs for initiation). *PPT*: polypurine sequences, which prime the synthesis of the second strand of DNA. *SD*: splice donor (the site where *gag* and *pol* and *env* messages are spliced). *SA*: splice acceptor site (the site where the second splice site joins to the first [donor] site)

information on proteolytic activities that generates a *protease* from the carboxyl end of gag and some other proteins. *Reverse transcriptase* (RT) and *integrase* (IN) and a *protease* are generated by proteolysis from the translated *pol* gene product. The SU product of the *env* gene recognizes the retroviral receptors which are transmembrane proteins of the host. The nucleocapsid proteins remain attached to the proviral DNA and facilitate the integration of the viral DNA into the host DNA. Some of the murine leukemia viruses can enter the cell nucleus only when the nuclear membrane breaks down during mitosis. Some of the lentiviruses can enter the nucleus with the assistance of the integrase and other proteins. In the human foamy virus the pol protein is translated by splicing mRNA that does not include the gag domain. The reverse transcriptase varies among the different retroviruses. The Rous sarcoma virus RT contains a RNA and DNA-directed polymerase, a RNase H as well as a tRNA-binding protein. It works with either RNA or DNA primers and synthesizes up to 10 kDa molecules from single RNA priming sites. For transcription of the viral proteins, the host RNA polymerase II is utilized. The host machinery translates the viral transcripts. The proteins may be processed in different ways by proteolysis to become functional.

Actinomycin D inhibits the replication on the DNA but not on the RNA template. Azidothymidine (AZT) inhibits polymerization and viral replication. The RNase H activity removes RNA in both 5' to 3' and 3' to 5' and digests the cap, tRNA and the polyA tail. All

retroviruses have an integrase protein derived from the C end of the gag-pol polyprotein complex. Integrase (30 to 46 kDa protein with Zn fingers) inserts the virus into the eukaryotic chromosomes (see Fig. R54).

At the site of integration there is target-duplication as the recessed ends of the target filled in by complementary nucleotides (*in italics*) (see Fig. R55). Inside the chromosomes of the host the retroviral *provirus* still carries the LTRs at both ends. After transcription, viral RNAs are produced. Following proteolytic cleavage, the polyproteins can be converted into viral proteins with the assistance of the cellular machinery. Viral particles (virions) may be assembled from the viral RNA and viral proteins at the surface of the cell and virions can exit from the cell membrane by “budding” and can infect new cells with two single-stranded RNA copies through appropriate cellular receptors.

The retroviral genome has 10^5 times increased mutability compared to cellular genes. Retroviral genomes recombine with a frequency of 10 to 30% during each cycle of replication. Integration may have a profound effect on cellular genes; it may inactivate suppressor genes controlling cellular proliferation or it may activate the transcription of cellular genes with the same effect and thus initiate carcinogenesis.

The major types of retroviruses are: (i) bird's (avian) sarcoma and leukosis viruses such as Rous sarcoma virus (RSV), avian leukosis virus (ALV) and Rous-associated viruses (RAV 1 and 2), (ii) reticuloendotheliosis viruses (hyperplasia of the net-like

Figure R54. Retroviral integration

Figure R55. Integration of the provirus into the host DNA

and endothelial [tissues lining organ cavities]), e.g., spleen necrosis virus (SNV), (iii) mammalian leukemia and sarcoma viruses, e.g., Moloney murine sarcoma virus (Mo-MSV), Moloney murine leukemia virus (MoMuLV), Harvey murine sarcoma virus (Ha-MSV), Friend spleen focus-forming virus (FSFFV), feline leukemia virus (FLV), and simian sarcoma-associated virus (SSAV), (iv) mammary tumor viruses (MMTV), (v) primate-type D viruses, e.g., Mason-Pfizer monkey virus (MPMV) and simian retrovirus (SRV-1), (vi) human T-cell leukemia-related viruses (HTLV-1 and HTLV-2), simian T cell leukemia virus (STLV) and bovine leukemia virus (BLV), (vii) immunodeficiency and lentiviruses, e.g., human immunodeficiency viruses (HIV-1 and HIV-2), Visna virus, simian immunodeficiency virus (SIV), caprine (goat) arthritis - encephalitis virus (CAEV) and equine (horse) infectious anemia virus (EIAV). (Classification provided by Varmus H, Brown P 1989). About 1% of the human genome includes retroviral sequences (human endogenous retroviruses [HERV]). During evolution these elements presumably inserted themselves and have been extensively modified. These HERV elements gave rise to transposable elements or their pseudogenic forms in the modern genome. The endogenous viruses synthesize the gag and env proteins that not only enables them to become infective, but may also prevent their transposition. The Env protein may also interfere with the viral receptors and thus limit reinfection. The HERV do not seem to have much significance for the genome at present; however, retrotransposition may lead to mutation and loss of gene function, including loss of cancer gene suppression. The resistance alleles block the integration of the viral RNA. The HIV-1 retrovirus usually integrates within the transcriptional unit of a gene. In contrast the murine leukemia virus (MLV) preferentially integrates into or around the promoter of the gene rather than into the translational unit. Typical retroviruses do not occur in plants, however the *Athila* elements of *Arabidopsis* and the *SIRE-1* of soybean come close to retroviruses in as much as they harbor envelop-like genes. ▶overlapping

Retrovirus Resistance: In general this is controlled by dominant genes in the animal host. In mice a major gene is *Fv1*, which has the *Fv1ⁿ* allele permitting the replication of the NIH Swiss mice N-tropic viruses but blocking the replication of the B-tropic (Balb/c mouse) viruses. The *Fv1^b* allele allows the replication of the B-tropic virus strains but blocks the N-tropic strains. The *n* and *b* alleles are codominant and their difference is only at two positions of their sequence. The *Fv1⁰* allele does not restrict any virus strains. The resistance genes block the integration of the cDNA of the viral genome into the host nucleus or host chromosome. Tropism may depend on a single amino acid difference of a domain of the group-specific antigen. High infection titer may, however, overcome the restriction. In human and some animal cells REF1 gene is credited with a function similar to that of *Fv1*. TRIM5α family of proteins controls simian resistance to HIV or other lentiviruses. Gene Lv2 provides resistance against HIV-2. APOBEC3G (apolipoprotein B mRNA-editing complex) fights the virus by deaminating the cytosine residues to uracil in the DNA and U-glycosylase generates an abasic site. The deficient provirus fails to code for the required proteins. An active *Vif* gene can, however, deactivate APOBEC3G. The BAF protein (barrier to autointegration factor) may prevent the viral DNA integration into the host chromosome.

Cyclophilin may have the opposite effect and can facilitate retroviral infection. Importin 7 protein may facilitate the access of HIV-1 to the nucleus. A number of other proteins may affect the infection process. ▶acquired immunodeficiency, ▶tropic, ▶provirus, ▶cyclophilins, ▶APOBEC3, ▶RNA editing; Goff SP 2004 Annu Rev Genet 38:61.

Rett Syndrome (dominant, RTT, Xq28, Xp22): This is a neurological disorder with onset after a period of normal early development. Loss of speech, motor skills, constant wringing of the hands, seizures and mental retardation are observed predominantly in girls. The prevalence rate is $\sim 1\text{--}2 \times 10^{-4}$ among girls, and in 99.5% cases is caused by new mutations occurring predominantly in the paternal X chromosome. The biochemical basis is missense or nonsense mutation in the meCP2 gene encoding a methyl-CpG-binding protein, which regulates BDNF and thus controls the syndrome (Martinowich K et al 2003 Science 302:890). MeCP2 interacts with transcriptional activators and silencers, chromatin remodeling factors—histone deacetylase and histone methyl transferase. In Rett syndrome homologous pairing in the 15q11-13 (imprinted site of Angelman's syndrome) is impaired (Thatcher KN et al 2005 Hum Mol Genet 14:785). In some atypical cases cyclin-dependent kinase 5 gene is involved (Guy J et al 2001 Nature Genet 27:322). ▶autism, ▶BDNF, ▶meCP2, ▶methylation of DNA, ▶Angelman's syndrome, ▶imprinting; Wan M et al 1999 Am J Hum Genet 65:1520; Meloni I et al 2000 Am J Hum Genet 67:982; Trappe R et al 2001 Am J Hum Genet 68:1093; Chen RZ et al 2001 Nature Genet 27:327; Shahbazian MD et al 2002 Hum Mol Genet 11:115; Bienvenu T, Chelly C 2006 Nature Rev Genet 7:415.

REV1, REV3, REV7: These are subunits of DNA polymerase ζ . REV1 is involved in DNA repair mutagenesis. This polymerase—unlike others—uses aginine³²⁴ for template after the guanine at its place is ejected and joins it by complementary hydrogen bond to deoxycytidine triphosphate (Nair DT et al 2005 Science 309:2219). Rev1 translesion DNA polymerase is functional primarily during the G₂/M phase of the cell cycle rather than during the S phase (Waters LS, Walker G C 2006 Proc Natl Acad Sci USA 103:8971). ▶DNA polymerases, ▶translesion, ▶SOS repair, ▶Y-family DNA polymerases; Lawrence CW, Hinkle DC 1996 Cancer Surv 28:21; Murakumo Y et al 2001 J Biol Chem 276:35644; Masuda Y, Kamiya K 2002 FEBS Lett 520:88.

Reverse Mutation (backmutation): This is a change from mutant to wild type allele, $a \rightarrow A$. In the experiment shown in the photo thiamine prototrophs were selected on soil among thiamine auxotrophs (see Fig. R57). The thiamine mutants died in the absence of thiamine but the revertants grew normally. The material was genetically marked at both flanks 5 and 9 map units, respectively to verify that the apparent revertants were not contaminants. The progeny of the revertants were genetically analyzed. They segregated for auxotrophy and prototrophy in the proportion of 5:3 because at the time of the reversion the diploid germ line consisted of two diploid cells. One of the cells remained

homozygous for thiamine requirement and the other became heterozygous and segregated for 3 wild type (2 heterozygotes) and for one homozygous for thiamine auxotrophy. ►Ames test, ►mutant isolation, ►mutation, ►suppressor gene

Figure R57. Reverse mutation of *Arabidopsis* thiamine mutant

Reverse-Phase Protein Array (RPPA): Samples to be assessed are robotically spotted, and an antibody is used to measure the amount of a particular protein present in the sample. In contrast to 2D-PAGE and antibody arrays, the reverse-phase methodology assesses only one protein per slide, but its advantage is that all the cell or tissue samples can be analyzed side by side in a single array. This is particularly useful in functional studies where protein levels are compared across samples rather than samples compared across protein types. This method—with modifications—has been successfully used for the study of cancer and normal cells and the progression of cancer development as well as prognosis. ►gel electrophoresis, ►microarray hybridization; Nishizuka S et al 2003 Proc Natl Acad Sci USA 100:14229.

Reverse Transcriptases: These enzymes transcribe DNA on a RNA template. An outline of the function of the enzymes within the protein coat using the diploid template is presented here. A similar process is followed in in vitro assays. Reverse transcriptases are commercially available from purified avian myeloblastosis (cancer of the bone marrow) cells or as cloned Moloney murine leukemia virus (MoMLV) gene product. The avian enzymes are dimeric and have strong reverse transcriptase and RNase H activities. The murine polymerase is monomeric

and exhibits only weak RNase H activity. Therefore, the murine enzyme is preferred when mRNA is transcribed into cDNA. Also, RNase H can degrade DNA and may reduce the efficiency of cDNA synthesis. The temperature optimum of the avian enzyme is 42° C (pH 8.3) and at this temperature the murine enzyme is already degraded. The pH optimum for the murine enzyme is 7.6. Both enzymes have much lower activity slightly below or above the pH optima. The avian enzyme more efficiently transcribes structurally complex RNAs. Reverse transcriptases are used for generating DNA from mRNA for vector construction or generating labeling probes, for primer extension, and for DNA sequencing by the dideoxy chain termination method. Since reverse transcriptase does not have an editing (exonuclease) function, it may make errors at the rate of 5×10^{-3} to 1×10^{-6} per nucleotide. This rate is orders of magnitudes higher than the error rate of most eukaryotic replicases. The HIV-1 reverse transcriptase can use as template either RNA or DNA; in the latter case it makes double-stranded DNA. Nucleoside analog-induced inhibition is effective for fighting HIV proliferation. This treatment, however, increases mutation in mtDNA because it also inhibits DNA polymerase γ (Martin AM et al 2003 Am J Hum Genet 72:549). ►retroviruses, ►cDNA, ►central dogma, ►msDNA, ►error in replication. Reverse transcriptase action is given in Figure R58.

Reverse transcription of the retroviruses follows the generalized scheme. A single-stranded viral RNA (vvvv) serves as template for the synthesis of the first strand DNA ($\rightarrow\rightarrow\rightarrow$). The synthesis is primed by a tRNA attached to the PBS (primer-binding site of the retroviral [-] strand). The host tRNA is base-paired by 18 nucleotides to a sequence next to U5. The first strand DNA (also called strong stop minus DNA) is extended at the rate of about 2 kb per h until the last part of the primer-binding site is copied. When the synthesis is extended, the copying of the second DNA strand ($\leftarrow\leftarrow\leftarrow$) begins. The process is practically the same in the cell and in vitro conditions. DNA polymerases β and γ also have some reverse transcriptase function in as much as they can copy poly(rA) by using oligo-dT primer. ►retroviruses, ►telomerase, ►transposon, ►DNA polymerases, ►mtDNA, ►HIV; Whitcomb JM, Hughes SH 1992 Annu Rev Cell Biol 8:275; Gao G, Goff SP 1998 J Virol 72:5905; Vastmans K et al 2001 Nucleic Acids Res 29:3154.

Reverse Transfection: Specific cDNAs or RNAs encapsulated in lipid are placed at defined locations on a glass slide and cells are layered on top. The cells can be transfected by the genes or by silencing RNAs. The cells isolated can then express mRNAs or

Figure R58. Reverse transcription

the silencing RNAs on microarrays. Nucleic acids when labeled by fluorescent tags can be specifically recognized. This procedure assists in the identification of drug targets or specific gene products controlling metabolism. ▶[transfection](#), ▶[RNAi](#), ▶[microarray hybridization](#); Ziauddin J, Sabatini DM 2001 Nature [Lond] 411:107.

Reverse Translation: If the protein is sequenced and the amino acids of a short segment are coded by non-degenerate or moderately degenerate codons, it is possible to synthesize a few RNAs on the basis of the presumed codon sequences, and one of them may be complementary to the DNA. This short RNA sequence can be hybridized to the DNA that codes for this particular protein. By reversing the translation and generating an appropriate probe, the gene can be isolated. ▶[probe](#), ▶[synthetic probe](#)

Reverse Two-Hybrid System: The system monitors disruptions of protein-protein interactions. ▶[two-hybrid system](#)

Reversed Genetics (inverse genetics): Nucleic acids and proteins, etc. are first isolated and characterized in vitro by molecular techniques and subsequently their hereditary role is identified. Also, gene expression can be studied by introducing into cells, by transformation, reporter genes with truncated upstream or downstream signals, in vitro generated mutations, site-specific recombination, targeting genes, etc., thereby determining the functional consequences of these alterations. Briefly stated, reversed genetics starts with molecular information and then deals with its biological role. Classical (forward) genetics recognizes genes when mutant forms become available and then studies their transmission, chromosomal location,

mechanism of biochemical function, their fate in populations and evolution. Reversed genetics is sometimes called surrogate genetics. ▶[genetics](#), ▶[inheritance](#), ▶[heredity](#); Masters PS 1999 Adv Virus Res 53:245.

Reversion: Refers to backmutation either at the site where the original forward mutation took place or in another (tRNA) gene that may act as a suppressor tRNA or the reversion is caused by correcting the frameshift. The possibility of reversion is frequently considered as evidence that the original forward mutation was not caused by a deletion. Suppressor mutation outside the mutant locus, however, may restore the non-mutant phenotype. Reversion may also take place when the mutation was caused by a duplication and a deletion evicted the duplicated sequence. ▶[backmutation](#), ▶[base substitution](#), ▶[suppressor](#), ▶[sup](#), ▶[suppressor tRNA](#), ▶[frameshift](#), ▶[reverse mutation](#), ▶[Ames test](#)

Reversion Assays in *Salmonella* and *E. coli* in Genetic Toxicology: The *Salmonella* assay has been described by the Ames test. The most commonly used *E. coli* test employs strains WP2 and WP2_{uvrA} that are deficient in genetic repair and are auxotrophic for tryptophan. They detect base substitution revertants but the assay does not respond to most frameshift mutagens (unlike some of the *Salmonella* strains TA97, TA98, TA2637 and derivatives). The *E. coli* systems do not offer any advantage over that of the *Salmonella* assay of Ames. ▶[Ames test](#), ▶[bioassays in genetic toxicology](#), ▶[mutation detection](#)

Rex Color: Refers to the color of rodent (rabbit) hair which appears in the presence of the recessive fine fur gene, *r*, in certain combinations with black (*B/b*), agouti (*A/a*) and intensifier (*D/d*).

Rex1p, Rex2p, Rex3p: These are exoribonuclease members of ribonuclease D family. ▶[ribonuclease D](#)

Rexinoids: These are agonists of RXR retinoid X receptor and regulate cholesterol absorption and bile acid metabolism/transport. ▶[agonist](#), ▶[retinoic acid](#)

Reye's syndrome: This disorder is characterized by non-genetic inflammation of the brain in infants and may lead to fever, vomiting, coma and eventually death. The use of aspirin is contraindicated in this condition. ▶[acetyl-CoA dehydrogenase deficiency](#)

Reynaud Disease: ▶[Raynaud's disease](#)

Reynolds Number: Characterizes the flow of a liquid from laminar to turbulent flow or the other way around. Reynolds number is a characteristic of the viscous drag (resistance) on a structure through a fluid medium like the cellular plasma.

RF (release factor): A protein which mediates the release of the peptide chain from the ribosome after it recognizes the stop codons. ▶[translation termination](#), ▶[release factors](#), ▶[protein synthesis](#), ▶[transcription termination in prokaryotes](#), ▶[transcription termination in eukaryotes](#); Dontsova M et al 2000 FEBS Lett 472:[2–3]:213.

RF: A replicative form of single-stranded nucleic acid viruses (DNA or RNA) where the original single strand makes a complementary copy that serves as a template to synthesize replicas of the first (original) genomic nucleic acid chain. ▶[replicase](#), ▶[plus strand](#); Buck KW 1999 Philos Trans R Soc Lond B Biol Sci 354:613.

Rf: Refers to fertility restorer genes in cytoplasmic male sterility. ▶[cytoplasmic male sterility](#)

R

Rf Value: In paper or thin-layer chromatography, the distance from the baseline of the migrated compound divided by the distance of migration of the solvent (mixture) is the Rf value. This value which is always less than 1 is characteristic of a particular compound within a defined system of chromatography. ▶[paper chromatography](#), ▶[thin-layer chromatography](#), see Fig. [R59](#).

RF-A: Replication factor A is a human single-stranded DNA binding protein, auxiliary to pol α and pol δ .

▶[pol](#), ▶[helix destabilizing protein](#), ▶[replication](#), ▶[replication fork eukaryotes](#)

RFA (replication factor A): This is the same as replication protein A (RPA). ▶[DNA replication eukaryotes](#)

Rfam: This is the database of non-coding RNAs. ▶[non-coding RNA](#); <http://rfam.janelia.org/>.

RF-C: Denotes the DNA replication factor C, a primer/template binding protein with ATPase activity. It plays a primary role in replicating the leading strand DNA in eukaryotes. RF-C loads PCNA on the DNA that tethers the DNA polymerase to the replication fork. RF-C is also called Activator I. ▶[replication fork](#), ▶[PCNA](#); Mossi R, Hubscher U 1998 Eur J Biochem 254:209.

RF-C (also RF-C): This is a cellular replication factor. ▶[DNA replication eukaryotes](#); Schmidt SL et al 2001 J Biol Chem 276:34792.

RFLP (restriction fragment length polymorphism): Restriction endonuclease enzymes cut the DNA at specific sites and thus generate fragments of various sizes in their digest, depending on the distances between available recognition sites in the genome. During evolution when base changes occurred at the recognition sites through mutation, the length of fragments (within related strains) may have changed. After electrophoretic separation, a polymorphic pattern may be distinguished. These fragments may constitute co-dominant molecular markers for genetic mapping. Restriction fragment maps can also be generated by strictly physical methods. If a small circular DNA is completely digested by a restriction enzyme yielding fragments, say A, B, C, D, E but incomplete digestion with the same enzyme produces ABD, DB, AD, BC and CE triple or double fragments, respectively but never AB, BE, DC or AC. Thus, the fragment sequence must be ADBCE because the double fragments must be neighbors. Another procedure is to digest by at least two enzymes and determine the overlaps by hybridization in a sequential manner. The overlapping fragments indicate which fragments are next to each other (see Fig. [R60](#)).

$$R_f = \frac{\text{distance} - B}{\text{distance} - A}$$

Figure R59. Definition of Rf

Figure R60. Restriction fragment length of the same DNA depending of the enzyme used

Restriction fragments can be used in genetic linkage analysis. They represent “dominant” physical markers because the DNA fragments can be recognized in heterozygotes. RFLP markers are useful for following the inheritance of linked genetic markers, which have variable expressivity and/or penetrance under unfavorable conditions. *Long-range restriction map* (macro-restriction map) represents the cutting sites of restriction enzymes along the chromosome. ▶restriction enzymes, ▶restriction fragment number, ▶restriction fragment length, ▶physical map, ▶T-RFLP; Sharma RP, Mohapatra T 1996 *Genetica* 97[3]:313; Wicks SR et al 2001 *Nature Genet* 28:160.

RFLP Marker: A restriction enzyme-generated DNA fragment which has been or can be mapped genetically to a chromosomal location and can be used for determining linkage to it. They are codominant and always expressed. Their inheritance and recombination can be determined in relatively small populations. ▶restriction enzyme, ▶RFLP, ▶physical map, ▶integrated map

RFLP Subtraction: A selective technique for the enrichment of particular polymorphic, eukaryotic genomic unique segments. Small restriction fragments are isolated and purified from one genome containing sequences that are in large fragments in another related genome of mouse. By subtractive hybridization the segments with shared sequences by both genomes are removed. Thus, small fragments unique to one or the other strain are obtained. These sequences then become mappable genetic markers. ▶genomic subtraction; Rosenberg M et al 1994 *Proc Natl Acad Sci USA* 91:6113.

RFLV: This is a RFLP variant. ▶RFLP

RFX: A human DNA binding protein that promotes dimerization of MYC and MAX and thus stimulates transcription. A group of transcription factors for the major histocompatibility complex is also designated as RFX. RFX binds cooperatively with NF-Y and X2BP. RFX has four complementation groups (CIITA [16p13], RFX5 [1q21.1-q21.3], RFXAP [13q14], RFXANK [19p12]). Their defects may be responsible for autosomal immunodeficiency syndrome. The RFX factor binds to X-boxes (5'-GTNRCC[0-3N] RGYAAC-3'] where N = any nucleotide, R = purine and Y = pyrimidine. The human RFX1 is a helix-turn-helix protein, which uses a β -hairpin (called also a wing) to recognize DNA. ▶MYC, ▶MAX, ▶MHC,

▶immunodeficiency, ▶bare lymphocyte syndrome, ▶helix-turn-helix, ▶MYC, ▶MAX, ▶NF-X, ▶X2BP; Katan-Khaykovich Y, Shaul Y 2001 *Eur J Biochem* 268:3108.

RGD: An amino acid sequence Arg-Gly-Asp in the extracellular matrix and in fibronectin is recognized by, and bound to, integrin. RGD peptides can activate caspase-3 and initiate the apoptotic pathway. RGD peptides may facilitate cell adhesion, uptake of viral vectors or polycationic synthetic vectors. ▶fibronectin, ▶integrin, ▶apoptosis, ▶amino acid symbols in protein

RGE (rotating gel electrophoresis): The gel is rotated 90° at switching the cycle of the electric pulses. ▶pulsed field gel electrophoresis

rGH (rat growth hormone): A thyroid hormone. ▶animal hormones, ▶hormone receptors, ▶hormone-response elements

RGR: A yeast gene regulating transcription by RNA polymerase II. ▶NAT, ▶RNA polymerase

RGR (retinal G protein-coupled receptor): An opsin protein encoded at human chromosome 10q23. (See Chen XN et al 1996 *Hum Genet* 97:720).

RGS (regulator of G protein signaling): RGS is actually the same as GAP (GTP-ase activating protein). The different RGS proteins have different specificities for the different $\alpha\beta$ and γ subunits of the trimeric G proteins. In mammals there are at least 19 members of this family of proteins with a common core, the RGS box. ▶G proteins, ▶GAP, ▶signal transduction, ▶conductin; Kehrl JH, Sinnarajah S 2002 *Int J Biochem Cell Biol* 34:432.

RH: ▶radiation hybrid

Rh Blood Group: The name comes from a misinterpretation of the early study, namely that this human antigen would have the same specificity as that of rhesus monkey red cells. It is now known that this was incorrect; the animal antigen is different but the name was not changed. Despite over half a century of research the Rh antigen is not sufficiently characterized. The antigen may be controlled by three closely linked chromosomal sites—C, D and E—and on this basis eight (2^3) different allelic combinations were conceivable; the triple recessive *cde* being a null combination. The eight combinations are also designated as R or r with superscripts: *CDe* (R^1 or $R^{1,2,-3,-4,5}$), *cde* (r , or $R^{-1,-2,-3,4,5}$), *cDE* (R^2 or $R^{1,-2,3,4,-5}$), *CDe* (R^0 or $R^{1,-2,-3,4,5}$), *cDe* (r' or $R^{-1,-2,3,4,-5}$), *Cde* (r' or $R^{-1,2,-3,-4,5}$), *CDE* (R^2 or $R^{1,2,3,-4,-5}$) and *CdE* (r^y or $R^{-1,2,3,-4,-5}$). The first three of these occur at frequencies about 0.42, 0.39, and 0.14, respectively in England, and the others

are quite rare. In some oriental populations, R^1 (0.73%) and R^2 (0.19%) predominate and the recessives have a combined frequency of about 2%. This is in contrast to Western populations where they occur in over 40% of people. Clinically the most important is the D antigen because 80% of the D⁻ individuals, in response to a large volume of D⁺ blood transfusion, make anti-D antibodies. The *d* alleles are amorph. The Rh genes are in human chromosome 1p. In addition, regulatory loci have also been identified in chromosome 3. For phenotypic distinction antisera anti-D, anti-C, anti-E, anti-c, and anti-e are used, and on the basis of the serological reactions 18 phenotypes can be distinguished. Anti-D antibodies are usually immunoglobulins of the G class (IgG). They develop only after immunization by Rh⁺ type blood. Anti-C antibodies are generally of IgM type and they occur along with IgG after an Rh⁻ person is immunized with Rh⁺ blood. Anti-E antibodies (IgG) are elicited in E negatives after exposure to E⁺ blood. Anti-c antibodies (IgG) occur in CDe/CDe individuals after transfusion with c⁺ erythrocytes. Anti-e antibodies are very rare (0.03). The major types of Rh antigens have several different variations. The Rh antigens are probably red blood cell membrane proteins. About 50 different Rh antigens have been identified. An Rh deficiency may also arise by the activity of a special suppressor gene in human chromosome 6p11-p21.1 or by CD47 protein, encoded at human chromosome 3q13.1-q13.2. The RG gene is situated at 1p34.3-p36.1.

It is clinically very significant that about 15% of Western populations are *cde/cde*. In Oriental populations the frequency of this genotype is very low. This type of individuals—called Rh negatives—may respond with erythroblastosis when exposed to Rh positive blood. If an Rh negative female carries a fetus with Rh positive blood type, antibodies against the fetal blood may be produced by the mother. This may then cause severe anemia with a high chance of intrauterine death and abortion. Generally, during the first pregnancy, this hemolytic reaction is absent but the chance in the following pregnancies, by when sufficient immunization has taken place by the fetal blood entering into the maternal bloodstream, the probability of erythroblastosis becomes high. Thus pregnancies of Rh negative females are monitored and appropriate serological treatment provided if antibody production is detected to prevent fetal erythroblastosis. Erythroblastosis may also occur if an Rh negative individual is transfused with Rh positive blood. The rodent antibodies responding to rhesus monkey red cells are now called the LW blood group. The physiological role of the Rh antigens is apparently in the CO₂ gas channel. ▶erythroblastosis fetalis, ▶blood groups, ▶immunoglobulins, ▶antibodies,

▶schizophrenia, ▶eclampsia; Avent ND 2001 J Pediatr Hematol Oncol 23:394; Stockman JA 3rd, de Alarcon PA 2001 J Pediatr Hematol Oncol 23:385, evolution of the Rh proteins: Huang C-H, Peng J 2005 Proc Natl Acad Sci USA 102:15512.

Rhabdomere: A rod-shaped element of the compound eye of insects. There are eight R1 to R8 neuronal photoreceptors in each of the ca. 20 cells of the *Drosophila* eyes, containing about 800 ommatidial clusters. ▶compound eye, ▶ommatidium, ▶*Drosophila*, ▶sevenless

Rhabdomyosarcoma: A type of cancer involving chromosome breakage in the Pax-3 gene 2q35 and 13q14 (Rhabdomyosarcoma-2) or other translocations involving chromosome 3 and 11 (Rhabdomyosarcoma-1). These break points may also be related to the Beckwith-Wiedemann syndrome or WAGR syndrome. The malignant rhabdoid tumor is associated with deletions in human chromosome 22q11.2 encoding the homologue (hSNF5/INI1) of the yeast chromatin remodeling protein SWI/SNF. Embryonal rhabdomyosarcoma is due to a defect at 11p15.5. Isochromosome 3q has the same effect as mutation at the ATR (ataxia telangiectasia and rad3-related site), i.e., inhibiting MyoD (myogenesis), causing cell cycle abnormalities and predisposition to cancer. ▶Pax, ▶Beckwith-Wiedemann syndrome, ▶WAGR, ▶ataxia, ▶Wilms tumor, ▶chromatin remodeling, ▶SWI, ▶nucleosome, ▶histone, ▶nuclease-sensitive sites

Rhabdoviridae: Oblong or rod-shaped (130–380 × 70–85 nm), single-stranded RNA (13–16 kb) viruses with multiple genera and wide host ranges. ▶CO₂-sensitivity in *Drosophila*

Rhalloc: The sequences mapped by radiation hybrid methods by various mapping groups. ▶radiation hybrids

Rhdb: A database containing the mapping information obtained by radiation hybrids. ▶radiation hybrids

Rheology: The study of elasticity, change of shape, viscosity and flow of materials such as blood through the vascular system of veins and heart.

Rhesus Blood Group: ▶Rh blood group, ▶LW blood group

Rhesus monkey (Macaque, *Macaca mulatta*, 2n = 42, genome size ~2.87 Gb): A representative of mainly South-East Asian and North African species of long-tail monkeys. These small intelligent animals have been used extensively for biological and behavioral studies. Rhesus monkeys separated from the human lineage about 25 million years ago and yet they retained about 93% of their identity to humans. The

sequenced genome has revealed 100 different families of DNA transposons and more than half a million recognizable copies of endogenous retroviruses (ERVs). The analysis revealed more than 1,000 rearrangement-induced break points through the HCR (Human-Chimpanzee-Rhesus) lineages, of which 820 occur between rhesus and the reconstructed human-chimpanzee ancestor. As with humans and chimpanzees, the analysis of the macaque assembly revealed an enrichment of segmental duplications near gaps, centromeres, and telomeres. Some segmental duplications contain genes of high biological significance. The statistical approach revealed that 1,358 genes were gained by duplication along the macaque lineage. The average human gene differs from its ortholog in the macaque by 12 nonsynonymous and 22 synonymous substitutions, whereas it differs from its ortholog in the chimpanzee by fewer than three nonsynonymous and five synonymous substitutions. Similarly, 89% of human-macaque orthologs differ at the amino acid level, as compared with only 71% of human-chimpanzee orthologs. Thus, the chimpanzee and human genomes are in many ways too similar for characterizing protein-coding evolution in primates, but the added divergence of the macaque helps substantially in clarifying the signatures of natural selection. Important evolutionary differences from human genes responsible for the diseases, have been detected (Gibbs RA et al 2007 Science 316:222). ►Rh blood group, ►LW blood group, ►Cercopithecidae, ►primates, ►chimpanzee

Rheumatic Fever (rheumatoid arthritis, RA, 6p21.3):

Rheumatic fever consists of ailments affecting mainly the connective tissues and joints, but it may cause also heart and nervous system anomalies. The HLA region accounts for most of the susceptibility but regions associated with other autoimmune diseases (lupus erythematosus, inflammatory bowel disease, multiple sclerosis, ankylosing spondylitis) are also implicated. The disease is complex because environmental and susceptibility factors heavily confound the direct genetic determination. For example, certain streptococcal infections can precipitate rheumatic fever. The familial forms are attributed to dominant genetic factor(s) and susceptibility has been attributed to recessive genes(s). Several antigens have been identified which appeared to be more predominant within affected kindred. One monoclonal antibody, D8/17, was present in 100% of the patients affected with the disease whereas two other monoclonal antibodies showed up between 70% to 90% coincidence and with 17% to 21% presence even among the unaffected people. One susceptibility factor is linked to IL-3. Simultaneously, blocking both B and T cell

receptors by the signaling molecule BlyS (B lymphocyte stimulator) and TACI (transmembrane/T-cell-activator and calcium-modulating and cyclophilin ligand interactor) prevented the development of arthritis in mice (Wang H et al 2001 Nature Immunol 2:632; Yan M et al ibid 638). Peptidylarginine deiminases (encoded at 1p36) post-translationally convert arginine into citrulline. Citrullinated epitopes are common targets of arthritis-specific autoantibodies directed against perinuclear factor/keratin and against the Sa system (Suzuki A et al 2003 Nature Genet 34:395). Sa is a hapten-carrier antigen in which vimentin is the carrier and citrulline is the hapten. Various forms of tumor necrosis factor (TNF) inhibitors such as TNF monoclonal antibodies and methotrexate therapy (Keystone EC et al 2004 Arthritis Rheumatism 50:1400) and recombinant TNF receptor (TNFR) and immunoglobulin-G1 fragment crystalline (Fc) fusion protein have been successfully used for clinical treatments (Morteland LW et al 1997 New England J Med 337:141). Injecting an interleukin-1 receptor antagonist (IL-1 Ra) cDNA in a retroviral vector (derived from Moloney leukemia virus) in synovial fibroblasts was beneficial without side effects (Evans CH et al 2005 Proc Natl Acad Sci USA 102:8698). In mice who have been exposed daily to 10% ethanol in drinking water the development of erosive arthritis was almost totally abrogated and they did not display any liver toxicity. In contrast, the antibody-mediated effector phase of collagen-induced arthritis was not influenced by ethanol exposure. Also, the major ethanol metabolite, acetaldehyde, prevented the development of arthritis. This anti-inflammatory and anti-destructive property of ethanol was mediated by (1) down-regulation of leukocyte migration and (2) up-regulation of testosterone secretion, with the latter leading to decreased NF- κ B activation (Jonsson I-M et al 2004 Proc Natl Acad Sci USA 104:258). ►arthritis, ►rheumatoid, ►pseudorheumatoid dysplasia, ►ankylosing spondylitis, ►HLA, ►Coxsackie virus, ►IL-3, ►IL-32, ►autoimmune disease, ►citrullinemia, ►urea cycle, ►hapten, ►vimentin, ►keratin; Jawaheer D et al 2001 Am J Hum Genet 68:927; Okamoto K et al 2003 Am J Hum Genet 72:303.

Rheumatoid: Resembling a rheumatic condition.

RHKO (random homozygous knockout): ►knockout

RhIB: A helicase of the DEAD-box family. ►helicase, ►DEAD-box, ►degradosome

RHMAP (radiation hybrid mapping): A multipoint radiation mapping procedure. It analyzes the minimal number of breaks (RHMINBRK) and may provide mapping information and by the use of the maximum likelihood procedure (RHMAXLIK) linkage information. ►radiation hybrid; Am J Hum Genet 49:1174.

RHMAXLIK: ►RHMAP

RHMINBRK: See ►RHMAP

Rho: A GTPase homolog of the RAS oncogene. It relays signals from cell-surface receptors to the actin cytoskeleton. It regulates myosin phosphatase and Rho-associated kinase. In yeast cells, a RHO protein is involved in the stimulation of cell wall β (1→3)-D-glucan synthase and the regulation of protein kinase C, and in mediation of polarized growth, morphogenesis and cell migration (metastasis). Actually, Rho is a subunit of the glucan synthase enzyme complex. Serine-threonine protein kinase and protein kinase N (PKN) are apparently activated by Rho. Rho also mediates endocytosis. Rho, in cooperation with RAF, seems to induce p21^{Waf1/Cip1} protein, which blocks the transition from the G₁ to the S phase of the cell cycle. In human chromosomes, Rhos are designated as ARH6: 3pter-p12, ARH12: 3p21, ARH9: 5q 31-qter. The Rho family includes Rac, CDC42, RhoG, RhoE, RhoL, and TC10 proteins. Increase of RhoC activity accompanies metastasis of melanoma cells. Members of the Rho family of proteins are also involved in the regulation of photoreception and developmental events mediated by light. ►RAS oncogene, ►metastasis, ►melanoma, ►RAF, ►cytoskeleton, ►receptor, ►photoreceptors, ►RAC, ►CDC42, ►endosome, ►CNF, ►p21, ►citron, ►ROCK, ►ROK, ►Yersinia; Kaibuchi K et al 1999 Annu Rev Biochem 68:459; Etienne-Manneville S,

Hall A 2002 Nature [Lond] 420:629; Katoh H, Negishi M 2003 Nature [Lond] 424:461.

rho (ρ): A designation of density; high G+C content of DNA increases it while high A+T content decreases it. ($\rho = 1.660 + [0.098 \times \{G+C\}]$ fraction in DNA). The density is determined on the basis of ultracentrifugation in CsCl and refractometry of the bands. ►buoyant density

rho Factor: A protein involved in the termination of transcription in (rho-dependent) prokaryotes. It is about 46 kDa and is a hexamer (~275 kDa). For maximal efficiency it is present in about 10% of the molecular concentration of the RNA polymerase enzyme. It is basically an ATP-dependent RNA-DNA helicase. Rho can stop elongation of the transcript only at specific termination sites in the RNA. In mitochondria, the mtTERM protein can stop transcription on both DNA strands. In yeast, the REB-1 protein terminates transcription and releases RNA from the ribosome. In mouse, the TFF-1 protein terminates the action of RNA polymerase I whereas the La protein controls RNA polymerase III. ►transcription termination in prokaryotes, ►transcription termination in eukaryotes, ►N-TEF, ►antitermination; Yu X et al 2000 J Mol Biol 299:1279; Kim D-E, Patel SS 2001 J Biol Chem 276:13902; crystal structure: Skordalakes E, Berger JM 2006 Cell 127:553.

rho Gene: The *rho* gene is responsible for the suppressive petite (mtDNA) condition in yeast. ►mtDNA

rho⁻ Mutants: The rho mutants of yeast lost from their mitochondrial DNA most of the coding sequences. They are very high in A+T content (the buoyant density of the DNA is low). ►mtDNA

rho-Dependent Transcription Termination: Actually, none of the rho-dependent bacterial strains absolutely require this protein factor for termination. ►rho factor, ►transcription termination, ►rho-independent; Konan KV, Yanofsky C 2000 J Bacteriol 182:3981.

Rhodamine B: A fluorochrome used for fluorescent microscopy; its reactive group forms a covalent bond with proteins (immunoglobulins) and other molecules. It is also a laser dye. Its absorption maxima is 543 (355) nm. Caution: It is carcinogenic. ►fluorochromes

Rhodospseudomonas palustris: A rather ubiquitous purple photosynthetic bacterium containing 5,459,213 bp in the chromosome and one plasmid of 8,427 bp. The estimated gene number is 4,835 (Larimer FW et al 2004 Nature Biotechnol 22:55).

Rhodopsin: A light-sensitive protein (opsin, $M_r \approx 28,600$, human chromosome 3q21-q24) coupled with a chromophore, 11-cis retinal, which isomerizes to all-trans retinal immediately upon the receipt of the first photon.

It functions as the light receptor molecule in the disks of the photoreceptive membrane of the photoreceptor cells of the animal retina of the eye. Rhodopsin has seven short hydrophobic regions that pass through the endoplasmic reticulum (ER) membrane in seven turns. The amino end (with attached sugars) is within the ER lumen and the carboxyl end points out into the cytosol. In the rod shape photoreceptor cells, rhodopsin is responsible for monochromatic light perception at low light intensities. In the cone shape photoreceptor cells color vision is mediated by it in bright light. The photoreceptor cells transmit a chemical signal to the retinal nerves that initiate then the visual reaction series. When the receptor is activated, the level of cyclic guanylic monophosphate (cGMP) drops by the activity of cGMP and bind phosphodiesterase and it is quickly replenished in dark by *guanylyl cyclase*. The activated opsin protein is transducin, an α , G protein subunit, that activates cGMP phosphodiesterase. When one single photon of light hits rhodopsin, through an amplification cascade, 500,000 molecules of cGMP may be hydrolyzed, 250 Na^+ channels may close, and more than a million Na^+ are turned back from entering the cell through the membrane within the time span of a second. In the dark, the sodium ion channels are kept open by cGMP; in the light the channels are closed. The sodium-calcium channels being shut, in light, the intake of Ca^{2+} is reduced and that leads to the restoration of the cGMP level through the action of the recoverin protein that cannot function well when it is bound to Ca^{2+} . Recoverin is a calcium sensor in the retinal rods. The rhodopsin gene has been assigned to human (see

Fig. R62) chromosome 3q21-qter and to mouse chromosome 6. *Drosophila* has three rhodopsin loci (*Rh2* [3-65], *Rh3* [3-70], *Rh4* [3-45]). In flies, too, the *nina* loci are involved in the synthesis of opsins affecting the ommatidia and ocelli. ▶phytochrome, ▶signal transduction, ▶G-proteins, ▶retinitis pigmentosa, ▶retinoblastoma, ▶color blindness, ▶color vision, ▶ommatidium, ▶ocellus, ▶opsins, ▶circadian rhythm, ▶night blindness, ▶proton pump; Yokoyama S 1997 Annu Rev Genet 31:315; Palczewski K et al 2000 Science 289:739; Bartl FJ et al 2001 J Biol Chem 276:30161; Sakmar TP 2002 Current Opin Cell Biol 14:189; Garriga P Manyosa J 2002 FEBS Lett 528:17; xanthorodopsin proton pump antenna: Balshov SP et al 2005 Science 309:2061, G protein-coupled receptor: Palczewski K 2006 Annu Rev Biochem 75:743.

Ri Particle: These particles are formed in cold in vitro during the 30S ribosomal subunit reconstitution experiment of rRNA and about 15 proteins. Upon heating, to assume the proper conformation, they become RI* particles. ▶**ribosome**, ▶**ribosomal RNA**, ▶**ribosomal protein**

Ri Plasmid: A root-inciting plasmid of *Agrobacterium rhizogenes*. It can be used for genetic engineering to the same way as the Ti plasmid of *Agrobacterium*

tumefaciens. The bacterium is responsible for the hairy root disease of plants. Its T-DNA contains two segments. The right T-DNA (T_R) contains genes for the production of opines, mannopine and agropine, and also for auxin. These auxin genes are highly homologous to the comparable genes in the Ti plasmid of *Agrobacterium tumefaciens*. The left portion of the T-DNA (T_L) includes 11 open reading frames with organization similar to eukaryotic genes; however this segment is different from that of the Ti plasmid. ▶**Ti plasmid**; Moriguchi K et al 2001 J Mol Biol 307:771.

RIA: ▶**radioimmunoassay**

Ribavirin: An antibiotic; its 5'-phosphate inhibits inosine monophosphate (see Fig. R64). ▶**inosine**

Figure R64. Ribavirin

Ribbon Diagram of Polypeptide Structure: An X-ray structure of a α -helix (at left) and a short β -sheet (at right ending with an arrow) (see Fig. R65). Typically, the protein structure is more complex and contains several of these elements forming multiple domains. ▶**protein structure**

Figure R65. Ribbon diagram of polypeptide structure

Riboflavin (lactoflavin, vitamin B₂): A vitamin precursor of flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD) oxidation coenzymes. Riboflavin is heat stable but rapidly decomposes in light (see Fig. R66). (See Ritz H et al 2001 J Biol Chem 276:22273).

Figure R66. Riboflavin

Ribocyte: An evolutionarily ancestral cell with RNA genetic material. ▶[RNA world](#)

Ribo-gnome: Small regulatory RNAs, such as micro-RNA, RNAi, etc. (Zamore PD, Haley B 2005 Science 309:1519).

Riboflavin Retention Deficiency: A riboflavin retention deficiency may prevent hatching of eggs in “leaky auxotrophic” chickens. The defect is not in absorption but the vitamin is rapidly excreted by a genetic default, and the *rd/rd* eggs have only about 10 µg of the vitamin rather than the normal level of about 70 µg. If 200 µg is injected into the eggs before incubation, hatching occurs.

Ribonuclease (RNases): Ribonuclease occur in a large number of specificities and they digest various types of ribonucleic acids. The bovine pancreatic ribonuclease is a small (124 amino acids) and very heat-stable enzyme. The pancreatic ribonuclease was the first enzyme chemically synthesized in the laboratory. An autoradiogram (see Fig. [R67](#)) permits the

Figure R67. Ribonucleases

distinction of the digestion enzyme control, T₁: G-specific enzyme; U₂: ribonuclease is A-specific; Phy M: *Physarum* enzyme M, specific for U + C; OH: random alkaline digest; and B_c: *Bacillus cereus* enzyme with U + C specificity. On the left side guanosine positions are indicated from the 5'-end, and on the right side the nucleotide sequences are shown as read from the gel. Ribonuclease 1: Degrades RNA I. ▶[RNA I](#); Cunningham KS, et al 2001 Methods Enzymol 342:28.

Ribonuclease II: Ribonuclease II is similar in action to Ribonuclease D; its role is not just limited to processing; it can also degrade an entire tRNA and mRNA molecule. It is an exonuclease. The enzyme has four domains: two cold-shock domains, the catalytic RNB domain, and one S1 domain. The enzyme contacts RNA in the “anchor” and “catalytic” regions. The catalytic RNB domain includes four conserved sequence motifs. This catalytic pocket is accessible only to single-stranded RNA. The structural features, shown in the Figure [R68](#), are probably characteristic for other members of this family of proteins (Frazão C et al 2006 Nature [Lond] 443:110). ▶[ribonuclease D](#); Donovan WP, Kushner SR 1986 Proc Natl Acad Sci USA 83:120.

Figure R68. Crystal structure of *E. coli* RNase II. CSD1, CSD2, S1 are oligonucleotide-binding domains. RNB is the catalytic domain. Mg²⁺ is at arrow. The docked RNA is colored from red to blue, according to atomic displacement parameters. (Courtesy of Drs. Carlos Frazão and Maria Arménia Carrondo)

Ribonuclease III (RNase III): A homodimeric phosphodiesterase; an endonuclease cutting double-strand RNA from the 3' or 5' end. It cleaves prokaryotic and eukaryotic pre-rRNA at a U3 snoRNP-dependent site. RNase III controls the maturation of cellular and phage RNAs and may determine the translation and half-life of mRNAs. In prokaryotes its cleaving action may be restricted by antideterminants. In yeast, RNA tetraloops (AGNN) are located 13–16 bp from the RNase III recognition sites (see Fig. R69). ▶trimming, ▶snoRNP, ▶antideterminant, ▶Dicer; Grunberg-Manago M 1999 Annu Rev Genet 33:193; Conrad C, Rauhut R 2002 Int J Biochem Cell Biol 34:116; crystal structure: Gan J et al 2005 Structure 13:1435; Gan J et al 2006 Cell 124:355.

Figure R69. Tetraloops of four nucleotides

Ribonuclease A: A family of RNA digesting enzymes, including pancreatic, brain ribonucleases as well the related eosinophil-derived neurotoxin (EDN), eosinophil cationic protein (ECP) and angiogenin, involved in defense functions. ▶eosinophil, ▶angiogenesis, ▶Prp75; Sheraga HA et al 2001 Methods Enzymol 341:189; Cho S et al 2005 Genomics 85:208.

Ribonuclease BN: An exonuclease that cuts tRNA. ▶exonuclease; Callahan C et al 2000 J Biol Chem 275:1030.

Ribonuclease D: RNase D processes tRNA primary transcripts at the 3' end into mature tRNA. ▶tRNA, ▶primary transcript, ▶RNAi; crystal structure: Zuo Y et al 2005 Structure 13:973.

Ribonuclease E: RNase E cleaves RNAs with secondary structure within single-stranded regions rich in A and U nucleotides, e.g., RNA I. The N-terminal domain of 1,061 amino acids functions as an endonuclease involved in mRNA and rRNA processing and degradation in *E. coli* and other bacteria. The catalytic activity of RNase E (and RNase G) is enhanced in the multimeric forms by having a monophosphate at the 5' end despite the fact that mRNA degradation begins

endonucleolytically (Jiang X, Belasco JG 2004 Proc Natl Acad Sci USA 101:9211). This enzyme also shortens the polyA and polyU tails of RNA molecules. Its C-terminus may associate with a 3'→5' exoribonuclease and other proteins in the degradosome complex. ▶RNA I, ▶*E. coli*, ▶endonuclease, ▶exonuclease, ▶degradosome, ▶tmRNA, ▶protein repair, ▶mRNA, ▶tRNA; Grunberg-Manago M 1999 Annu Rev Genet 33:193; Walsh AP et al 2001 Nucleic Acids Res 29:1864, crystal structure: Callaghan AJ et al 2005 Nature [Lond] 437:1187.

Ribonuclease G (CafA): RNase G processes the 5' end of 16S rRNA with RNase E (Feng Y et al 2002 Proc Natl Acad Sci USA 99:14746).

Ribonuclease H: RNase H digests RNA when paired with DNA but it does not cut single-strand RNA or double-strand RNA or double-strand DNA. This family of proteins includes transposases, retroviral integrase, Holliday structure resolvase and the RISC nuclease Argonaute. RNase H specifically recognizes the A form of RNA and the B form of a DNA strand (Nowotny M et al 2005 Cell 121:1005). RNase HI, as an endonuclease, can remove RNA primers (except 1 nucleotide) from the 5'-end of the Okazaki fragments. RNase H may also cleave "irrelevant sites", i.e., RNA that is imperfectly bound to DNA. RNase H can be used to prevent the translation of mRNA by recruiting it to phosphorothioated DNA. ▶DNA replication eukaryotes, ▶Rad27/Fen1, ▶Okazaki fragment, ▶antisense technologies, ▶phosphorothioate, ▶RNA I, ▶microRNA, ▶transposase, ▶integrase, ▶resolvase, ▶Aicardi-Goutières syndrome; Wu H et al 2001 J Biol Chem 276:23547, folding of RNase H: Cecconi C et al 2005 Science 309:2057.

Ribonuclease J: An exoribonuclease that can cut 5' to 3' both ribosomal and mRNA of *Bacillus subtilis*. RNase J1 plays a role in maturation and 5' stability of mRNA (Mathy N et al 2007 Cell 129:681).

Ribonuclease L: In dimeric form, RNase L cleaves single-stranded RNA. Its product may reduce viral replication in interferon-exposed cells and suppress prostate cancer. It may be induced by interferon. For activity it depends on 2',5'-oligoadenylates (2–5A). RNase L may be involved in apoptosis. The RNase L inhibitor plays important role in ribosome biogenesis and HIV capsid assembly (Karcher A et al 2005 Structure 13:649). Compounds bound to the 2–5A-binding domain of RNase L induce RNase L dimerization and activation. Low-molecular-weight activators of RNase L had broad-spectrum antiviral activity against diverse types of RNA viruses, including the human parainfluenza virus type 3, yet these compounds by themselves were not cytotoxic at

the effective concentrations (Thakur CS et al 2007 Proc Natl Acad Sci USA 104:9585). ▶**apoptosis**, ▶**RNAi**, ▶**Ire**, ▶**interferon**; Stark GR et al 1998 Annu Rev Biochem 67:227; Carpten J et al 2002 Nature Genet 30:181; Malathi K et al 2005 Proc Natl Acad Sci USA 102:14533.

Ribonuclease MRP (9p21-p12): A mitochondrially-localized enzyme involved in cleavage of pre-mRNA and pre-rRNA. Its defect affects the cell cycle, hair hypoplasia, immunodeficiency, hematological abnormalities and the assembly of the ribosomes and the degree of bone dysplasia, respectively (Thiel CT et al 2007 Amer J Hum Genet 81:519).

Ribonuclease P: RNase processes the 5' end of transfer RNA transcripts (and cleaves some other RNAs). It may process some pre-tRNAs at the 3'-end. Its catalytic subunit is a ribozyme in bacteria, a 377-nucleotide RNA that can do the processing even without the ~120-amino acid protein. However, the protein may enhance specificity and is required for ribosomal translocation. For catalytic activity the enzyme requires divalent cations (Mg^{2+}). The chloroplast enzyme is not a ribonucleoprotein but is only a protein. The size of the protein subunits in bacteria is about 14 kDa, but in eukaryotes it may exceed 100 kDa. Although at least 10 proteins are associated with RNase P, either protein Rpp29 or C5 are essential for activation of the core RNA and substrate recognition as well as for catalysis (Sharin E et al 2005 Nucleic Acids Res 33:5120). Eukaryotic RNase P RNA is also able to cleave its substrate in the absence of protein(s) although with relatively low efficiency; this suggests that the catalytic activity resides in the RNA subunit of RNase P (Kikowska E et al 2007 Proc Natl Acad Sci USA 104:2062). ▶**ribozyme**, ▶**external guide sequences**, ▶**KH domain**, ▶**RNase**, ▶**RNA maturases**, ▶**MRP**; Kurz JC, Fierke CA 2000 Curr Opin Chem Biol 4:553; Tous C et al 2001 J Biol Chem 276:29059; Gopalan V et al 2002 J Biol Chem 277:6759; Xiao S et al 2002 Annu Rev Biochem 71:165; specificity domain: Krasilnikov AS et al 2003 Nature [Lond] 421:760; structural diversity: Krasilnikov AS et al 2004 Science 306:104; crystal structure of the RNA component: Torres-Larios A et al 2005 Nature [Lond] 437:584; crystal structure of *Bacillus stearothermophilus* P RNase RNA: Kazantsev AV et al 2005 Proc Natl Acad Sci USA 102:13392; structure and function: Marquez SM et al 2006 Mol Cell 24:445.

Ribonuclease R: An RNase II homolog 3'→5' exoribonuclease of *E. coli*. RNase R and polynucleotide phosphorylase are essential for the proper assembly of ribosomes by eliminating defective rRNA monomers. ▶**ribonuclease II**, ▶**rRNA**, ▶**polynucleotide**

Ribonuclease S: RNase S enzymes are associated with self-incompatibility of plants (Ma R-C, Oliviera MM 2002 Mol Genet Genomics 267:71).

Ribonuclease T: An exonuclease of tRNA, cutting at the amino acid accepting end (CCA). ▶**tRNA**; Zuo Y, Deutscher MP 1999 Nucleic Acids Res 27:4077; Zuo Y et al 2007 Structure 15:417.

Ribonuclease T₁: RNase T₁ is specific for G (guanine) linkages in RNA. (See Kumar K, Walz FG Jr 2001 Biochemistry 40:3748).

Ribonuclease U1: A guanine-specific RNase. (See Takahashi K, Hashimoto J 1988 J Biochem [Tokyo] 103:313).

Ribonuclease U2: RNase U2 is specific for A+U nucleotides in RNA. (See Taya Y et al 1972 Biochim Biophys Acta 287:465).

Ribonuclease Z (3' tRNase): A zinc-dependent metallo-hydrolase; an endonuclease, which processes the 3'-end of most prokaryotic, cytoplasmic, and mitochondrial tRNAs (Dubrovsky EB et al 2004 Nucleic Acids Res 32:255; crystal structure: Li de la Sierra-Gallay I et al 2005 Nature [Lond] 433:657).

Ribonucleic Acid: ▶**RNA**

Ribonucleoprotein (RNP): A ribonucleic acid associated with a protein. ▶**RNP**

Ribonucleotide: A ribonucleotide contains one of the four nitrogenous bases (A, U, G, C), ribose and phosphate. It is a building block of RNA. ▶**deoxyribonucleotide**

Ribonucleotide Reductase (RNR): A ribonucleotide reductase converts ribonucleotide di- and triphosphates into deoxyribonucleotide di- and triphosphates. It is required for DNA synthesis, the completion of the cell cycle and malignancy. RNR proteins might have been instrumental in generating DNA in the RNA world. The allotetramer enzyme has a large subunit, R1, which regulates the maintenance of a deoxynucleotidetriphosphate pool; its level is constant throughout the cell cycle. The R2 subunit converts ribonucleotides to deoxyribonucleotides and it appears in G1 and vanishes at early S phase. The 351-amino acid R2 subunit is the product of the p53R2 gene, activated by p53. Gene p53R2 apparently has a DNA repair function. ▶**cell cycle**, ▶**malignant**, ▶**CDC22**, ▶**RNA world**, ▶**p53**, ▶**recombination molecular mechanism of**; Jordan A, Reichard P 1998 Annu Rev Biochem 67:71; Tanaka H et al 2000 Nature 404:42; Chimpoy K,

Ribosomal DNA: The codes for ribosomal RNAs. ▶**ribosome**

Ribosomal Filter: A hypothesis proposing that cis-regulatory sequences in the mRNA modulate its binding to the 40S ribosomal subunit by complementarity to the 18S or 28S ribosomal subunits or by affinity to specific ribosomal proteins. This binding may filter, i.e., influence the translation in a (+) or (−) manner and may be a factor in differential translation in a tissue- or development-specific manner. ▶**ribosomes**, ▶**translational control**; Mauro VP, Edelman GM 2002 Proc Natl Acad Sci USA 99:12031.

R

Ribosomal Frame Shifting (translational recoding): ▶**overlapping genes**, ▶**recoding**

Ribosomal Genes: ▶**rrn**, ▶**ribosomes**, ▶**rRNA**

Ribosomal Proteins: Ribosomal proteins are generally designated with an S or L indicating whether it is part of the small or large ribosomal subunit. The size of these 55 proteins in *E. coli* range from 6 kDa to 75 kDa. They bind to the RNAs at specific binding sites, either directly or through their association. In *E. coli* the genes for these proteins are scattered among other genes in the chromosome. One of the bacterial ribosomal proteins is present in several copies whereas the other ones occur only once per ribosome. In eukaryotes, about 80 ribosomal proteins exist encoded by a larger number of genes generally occurring in a single or a few copies. Transcription factor Ifh1 of yeast is a key regulator by association

with the promoters by the aid of the forkhead-associated factor RAP1 (Wade JT et al 2004 Nature [Lond] 432:1054). The ribosomal proteins assure the proper structural conditions on the ribosomes for translation. About 35% of the bacterial ribosomes are protein. Two-thirds of the chloroplast ribosomal proteins are imported from the cytoplasm and even larger fractions of the mitochondrial proteins are coded by the nucleus. The number of ribosomal proteins in organelles is higher than in prokaryotes. The mitochondrial ribosomes (mitoribosomes) are ~69% protein and ~31% RNA whereas the prokaryotic ribosomes are ~33% protein and ~67% RNA. The number of proteins in the mammalian mitochondrial ribosomes is about 85 and nearly all are imported. The number of ribosomal proteins in the large mitochondria of higher plants is about 65. Proteins bind only single-stranded sequences of RNA. ▶**nucleolus**, ▶**ribosomes**, ▶**RAP1**, ▶**protein synthesis**, ▶**Diamond-Blackfan anemia**; Nomura N et al 1984 Annu Rev Biochem 53:75; Kenmochi N et al 2001 Genomics 77:65; Uechi T et al 2002 Nucleic Acids Res 30:5369; Lecompte O et al 2002 Nucleic Acids Res 30:5382; <http://ribosome.miyazaki-med.ac.jp/>.

Ribosomal RNA: About 65% of the bacterial ribosomes are RNA. The 16S bacterial rRNA (1.54 kb) has short double-stranded domains and single stranded loops and about ten of the bases near the 3'-end are methylated. The 16S ribosomal RNA undergoes conformational changes (switches) before translation of the mRNA (Lodmell JS, Dahlberg AE 1997 Science 277:1262).

The 16S rRNA is frequently used for taxonomic classification. Actually, both types of base pairings have been found with physiological activity although mutations that favored the Type II conformation favored fidelity of the translation (see Fig. R71). Proteins S5 and S12 facilitate these switches that seem to also play a role in tRNA selection in algae and fungi.

Figure R71. Ribosomal RNA

The 23S rRNA (3.2 kb) carries about 20 methylated bases. The 18S mammalian rRNA (1.9 kb) has more than 40 and the 28S (4.7 kb) has more than 70 methylations. The ribosomal RNAs provide not just a niche for translation, they also interact directly with translation initiation. The 16S rRNA cooperates with

the anticodon at both the A and P sites and the 23S rRNA interacts with the CCA end of the tRNA. The ribosomal exit channel (E) plays a regulatory role in peptide elongation (Nakatogawa H, Ito K 2002 Cell 108:629). In the 23S rRNA, two guanine sites are universally conserved (G2252, G2253), and the Cytosine 74 site of the acceptor end of the tRNA (CCA) is required for their functional interaction at the P site of the ribosome for protein synthesis. Methylated sequences in the rRNA mediate, probably, the joining of the small ribosomal subunit to the large subunit after translation is initiated, and holds on to the initiator tRNA^{fMet}. Some mutations in the 16S RNA may cause an override through the stop codon and failure of termination of the translation; mutations in the 23S RNA may disturb the A and P ribosomal sites. T 23S ribosomal RNA has six domains (see Fig. R72).

Of these, domain V, in an isolated form, can perform peptide elongation even better than the intact 23S molecule. It seems that ribosomal RNA alone (without protein) is required for peptide elongation (see Fig. R73). Ribosomal ribozymes mediate peptidyl transferase functions. The prokaryotic 23S ribosomal RNA contains the pentapeptide, coding minigene (GUGCGAAUGCUGACAUAAGUA) with a canonical ribosome-binding site and appears to mediate resistance to the antibiotic erythromycin. The 5S bacterial rRNA contains 120 nucleotides and binds three proteins (L25, L18, L5). 5S RNA is also present in eukaryotes where it forms a complex with the L5 ribosomal protein. L25 binds to the E loop of 7 hydrogen-paired nucleotide pairs stabilized by Mg²⁺. The 3'-end of the small ribosomal subunit is highly conserved from prokaryotes to plants and mammals. For example, in *E. coli*, GAUCACCUCUUA-OH, in yeast, GAUCA—UUA-OH, in maize, GAUCA—UUG-OH, and in rat, GAUCA—UUA-OH, occur (the - signs are inserted for alignment). The function of rRNA synthesis is regulated by homeostasis, feedback, and by many other protein factors. Among them is *dksA*, a multicopy suppressor of a wide range of apparently unrelated functions. ▶nucleolus, ▶ribosomes, ▶ribosomal genes, ▶class I genes, ▶class

Ribosome Binding: ▶Shine-Dalgarno sequence, ▶ribosome, ▶mRNA, ▶ribosome scanning

Ribosome Binding Assay: The ribosome binding assay was used in the mid 1960s to identify several codons. RNA oligonucleotides that bound to ribosomes attached to those charged tRNA molecules which had the specific anticodons and carried the appropriate amino acids. This way, the relationship between RNA codons and amino acids was revealed. ▶genetic code, ▶decoding

Figure R72. Ribosomal RNA operon in *E. coli*; Fis (factor for inversion stimulation [an old terminology]), core: core promoter, P: promoters, 16S: 16S rRNA genes, tRNA is an intercalated transfer RNA gene, 23S: 23S ribosomal RNA genes, 5S: 5S rRNA, t1, t2 termination signals. Only 120 bp separates the stronger P1 promoter from P2. The core promoter is the landing site of the RNA polymerase and it includes several hexamers for the recognition of the σ^{70} RNA polymerase holoenzyme. Upstream of the promoters are A-T-rich sequences (UP) that enhance polymerization. The carboxyterminal domain (CTD) of the α subunit also recognizes this area. Promoters in the different systems show variations from the main scheme.

Ribosome Display: The same as RNA-peptide fusions. ►[display technologies](#); Hanes J et al 2000 Nature Biotechnol 18:1287.

Ribosome Hopping: The bypassing of the coding gaps in phage T4 genes with the assistance of a special protein factor. (See Herr AJ et al 2001 J Mol Biol 311:445).

Ribosome Recycling (RRF): After the termination of the translational process, the ribosome is disassembled into the small and large subunits. The post-termination complex in prokaryotes contains release factors RF1, RF2 and RF3, the 70S ribosome with the mRNA still attached to it, a deacylated tRNA at the P site, and an empty A site. This complex is split up by RRF (ribosome recycling factor, Agrawal RK et al 2004 Proc Natl Acad Sci USA 101:8900) and the elongation factor G (EF-G) by GTP hydrolysis. RRF structurally mimics tRNAs, except the amino acid-binding 3'-terminus. This indicates that RRF interacts with the post-termination complex in a manner similar to that of a tRNA responding to the ribosome. ►[ribosomes](#), ►[protein synthesis](#), ►[A site](#), ►[P site](#), ►[EF-G](#), ►[aminoacylation](#); Kisselev LL, Buckingham RH 2000 Trends Biochem Sci 25:561; Inokuchi Y et al 2000 EMBO J 19:3788; Hirokawa G et al 2002 J Biol Chem 277:35847.

Ribosome Scanning: Eukaryotic mRNAs do not have a Shine-Dalgarno consensus for ribosome binding. They are probably attached by the 5'-m⁷G(5')pp. The (5')mRNA sequence reels on the ribosome until the initiator methionine codon is found. Circular viral or eukaryotic RNAs, if they contain internal ribosome entry sites (IRES), may be translated without a need for a free 5'-end. The RNA helicase eIF4E and the other translation initiation factor eIF4G, as well as the cap-binding protein eIF4E and the tail-binding protein Pab1, are instrumental in a cooperative manner in the initiation of translation. ►[Cap](#), ►[Shine-Dalgarno](#), ►[protein synthesis](#), ►[IRES](#), ►[dicistronic translation](#), ►[Kozak rule](#), ►[eIF](#), ►[elongation initiation](#), ►[translation](#), ►[ribosome shunting](#); Kozak M 1989 J Cell Biol 108:229; Sachs AB 2000 Cell 101:243; Kozak M 2002 Gene 299:1.

Ribosome Shunting: The long leader sequence of viral DNA (adenovirus, cauliflower mosaic virus, etc.) may contain several short open reading frames, which usually interfere with the translation of the downstream ORFs. These impediments may be bypassed (jumped) by the formation some internal structure, e.g., stem-loop structure. It seems that for the proper scanning of the ribosome the ~100 nucleotides at the 5' and 3' ends are most essential. ►[adenovirus](#), ►[cauliflower mosaic virus](#), ►[ORF](#), ►[stem-loop](#),

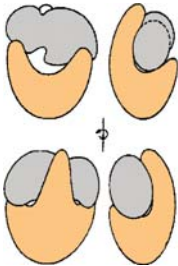

►[ribosome scanning](#); Pooggin MM et al 2001 Proc Natl Acad Sci USA 98:886.

Ribosome Skipping: The same as translational bypassing.

Ribosomes: Ribosomes provide the workshop and some of the tools for protein synthesis in all cellular organisms, including the subcellular organs, mitochondria, and chloroplasts. A yeast cell contains about 200,000–2,000,000 ribosomes. The chloroplastic ribosome genes are situated in the characteristic inverted repeats, except in some *Fabaceae* and conifers. The prokaryotic and organellar ribosomes are similar and their approximate molecular weight is 2.5×10^6 Da with a sedimentation coefficient of 70S. The higher eukaryotic ribosomes, excluding the organellar ones, have a molecular weight of about 4.5×10^6 Da, and they are ~80S. The ribosomes have both a minor and a major subunit built of RNA and protein (see Fig. R74).

The prokaryotic 30S subunit includes 20 proteins, assembled through several steps of conformational transitions as detected by pulse and chase monitored with the aid of quantitative mass spectrometry (Talkington MWT et al 2005 Nature [Lond] 438:628). The crystal structure of the 70S ribosome complexed with mRNA and tRNA has been determined (Selmer M et al 2006 Science 313:1935).

Hrr25 protein kinase-dependent phosphorylation regulates the organization of the pre-40S eukaryotic ribosomal subunit (Schäfer T et al 2006 Nature [Lond] 441:651). The large subunit, 50S is connected to the small subunit, 30S by an RNA-protein bridge. From the middle of the large subunit a tunnel runs toward the small subunit. The formation of the 80S ribosome requires the mediation of eIF5. The mitochondrial ribosomes do not contain 5S subunits but chloroplasts do have them. The number of ribosomes may greatly increase when protein synthesis is very rapid. During early embryogenesis in amphibia, the rRNA gene number may increase three orders of magnitude by a process of amplification and the extra copies of the genes are sequestered into minichromosomes forming micronuclei. Their number in some higher plants regularly runs into thousands. The bacterial ribosomes are about 65% RNA and 35% protein. On the ribosomes, several active centers can be distinguished. The A and P sites receive the tRNAs. This area extends to both the small and the large subunits. The tRNA after unloading of the amino acids leaves the ribosome at the exit site (E) of the large subunit. Some of the peptide chains exit through the tunnel of the large subunit. The translocation factor EF-G seems to occupy a space in between the two subunits. The complex crystal structure of the *E. coli* ribosome is

Figure R74. 70S prokaryotic ribosome viewed from different angles (Courtesy Tischendorf GW et al 1975 Proc Natl Acad Sci USA 72:4870). The ribosome structure is much more complex than shown in the diagram (see Brimacombe R, p 41 In: Eggleston RA et al (Eds.) The Many Facets of RNA. 1998 Academic Press, San Diego, CA, USA). By the use of crystallography, nuclear magnetic resonance, neutron diffraction and cryo-electron microscopy more detailed three-dimensional structures have been revealed. Also chemical foot printing, mutation and other probes have identified the links between ribosomal components and ribosomal sites of tRNA and mRNA.)

described at 3.5 Å resolution (Schuwirth BS et al 2005 Science 310:827). The *classical* model of translation is discussed under the protein synthesis entry. Binding of the anticodon stem-loop of P-site tRNA to the ribosome is sufficient to lock the head of the small ribosomal subunit in a single conformation, thereby preventing movement of mRNA and tRNA before mRNA decoding (Berk V et al 2006 Proc Natl Acad Sci USA 103:15830).

The newer hybrid-states model is given in the diagram. The elongation factor EF-TU may be located on the small subunit but it communicates with EF-G. The EF-Tu.GTP.tRNA ternary complex is instrumental in the delivery of the aminoacyl-tRNA to the A/T hybrid site of the peptidyl tRNA-ribosome in complex. (A is the amino acid, P the peptidyl, and T is the corresponding large subunit site.) In prokaryotes, then, the anticodon binds to the A site of the 30S ribosomal subunit. Hydrolysis of GTP is followed by the release of the elongation factor EF1A/EF-Tu. After this, the CCA end of the amino acid-charged tRNA moves to the A site of the large (50S) subunit. Peptidyl transferase (located at the end of the tunnel closest to the small subunit) then mediates peptide bond formation between the nascent peptide chain and the next incoming amino acid. After the peptide bond is initiated the peptidyl-tRNA is deacylated and is transferred to the P site on the large subunit. The anticodon stays for a while at the A site of the small subunit while the CCA end is on the P site of the large subunit. Then the anticodon moves to the P site of the large subunit and the CCA site goes to the E site of the large subunit (see Fig. R75) (Márquez V et al 2004 Cell 118:45). Meanwhile, after the recognition of the cognate codon by the

anticodon, the EF1A·GTP complex moves to the GTPase center of the ribosome, and EF1A·GDP and the tRNA are released at the E site. After the translocation from the A site to the P site, the elongation factor EF1B mediates the conversion of the inactive EF1A·GDP into the active EF1A·GTP. This and other more recent models indicate that the movement on the ribosomes involves the tRNA, but the peptidyl moiety moves very little. If the A site of a prokaryotic ribosome is unoccupied, water may carry out a nucleophilic attack on the peptidyl-tRNA at the P site. In the absence of an appropriate A-site substrate, the peptidyltransferase center can position the ester link of the peptidyl-tRNA in a conformation that prevents the nucleophilic attack by water. Protein factors may also assist in the protection (Schmeing TM et al 2005 Nature [Lond]:438:520).

Figure R75. mRNA on the ribosome. Left: Solvent site view of the 30S subunit with 5'-end (position -36) and 3'-end (position +12) of the mRNA. Right: interface view of the 30S subunit with A, P and E codons of the mRNA. Courtesy of Dr. Marat Yusupov, IGBMC, Illkirch, France; see also Yusupov, G et al. 2006 Nature [Lond] 444:391

Chloramphenicol, erythromycin, lincomycin, streptomycin, spectinomycin, kanamycin, hygromycin, etc., normally inhibit prokaryotic ribosomes. Eukaryotic ribosomes are sensitive to cycloheximide, anisomycin, puromycin, tetracyclines, etc. The ribosomes play an important role in the regulation of protein synthesis. It appears that the availability of active ribosomes is controlled at the level of the transcription of the rRNA genes. When the supply of ATP and GTP is adequate, rRNA genes are activated for transcription. In case the level of these nucleotide triphosphates is low, rRNA transcription is reduced or halted. An abundance of free ribosomal proteins may feedback-inhibit ribosomal production. The ribosome-associated Rel-A protein may mediate the formation of ppGpp from GTP (and possibly from other nucleotides). Then, ppGpp (or pppGpp) may shut off rRNA and tRNA synthesis by binding to the promoter of the RNA polymerase or to its anti-termination signal. ▶nucleolus, ▶protein synthesis, ▶ribosomal proteins, ▶E site, ▶A site, ▶P site, ▶Sec61 complex, ▶ribosomal RNAs, ▶EF-G, ▶EF-TU-GTP, ▶translocation hypothesis, ▶antibiotics, ▶discriminator region, ▶ribosome recycling, ▶ribonuclease R, ▶chloroplasts; Green R, Noller HF 1997 *Annu Rev Biochem* 66:679; Venema J, Tollervey D 1999 *Annu Rev Genet* 33:261; for crystalline structure of the small and the large subunits of bacterial ribosomes: Clemons WM Jr et al 1999 *Nature (Lond.)* 400:833; Ban N et al *ibid.* 841; Cate JH et al 1999 *Science* 285:2095; Wimberly BT et al 2000 *Nature (Lond.)* 407:327; Ban N et al 2000

Riboswitch: In certain mRNAs there are untranslated receptor elements for target metabolites. Highly selective binding of the metabolite permits a conformational switch (somewhat similar to attenuation) that may lead to modulation in the synthesis of a protein or by cutting up mRNA with the aid of a ribozyme (see Fig. R76).

In some instances, tandem riboswitches control complex regulation (Sundarsan N et al 2007 *Science* 314:300). In some cases, RNase P cleaves the riboswitch (Altman S et al. 2005 *Proc Natl Acad Sci USA* 102:11284). The crystal structure of *Arabidopsis* thiamine pyrophosphate riboswitch provides information on its basic function (Thore S et al 2006 *Science* 312:1208). More than 2% of the genes in some species are regulated by riboswitches. Riboswitches have high specificities and can discriminate even among guanine (G), adenine (A) or hypoxanthine. A more complex binding pattern has been identified in the thiamine pyrophosphate (TPP) riboswitch (Serganov A et al 2006

Figure R76. Riboswitch. Secondary structure guanine (G) and adenine (A) switches. The two switches appear highly similar, almost identical, and yet they have high specificity. The red core sequences are well conserved, except the bases represented at purple arrows. The lower-case letters represent residues not found in the original and which are introduced here to facilitate in vitro transcription. (Modified from Noeske J et al 2005 *Proc Natl Acad Sci USA* 102:1372.)

Ribothymidine: A thymine in the tRNA which is attached to ribose rather than to deoxyribose as it occurs in the DNA. ▶tRNA

Ribotype: The RNA pool (similar to genotype for DNA); the information content of the RNA. It is different from the genotype because by differential processing, splicing, editing, etc., it may convey different meanings. The processed variations—during the course of evolution—may be integrated into the DNA genetic material with the aid of reverse transcriptases and become part of the “hard heredity”. (See Herbert A, Rich A 1999 Nature Genet 21:265).

Ribozyme: A catalytic RNA possessing enzymatic activity such as splicing RNA transcripts, cleavage of DNA, amide and peptide bonds, polymerization and limited replication of RNA, etc. Thus, these ribonucleic acids carry out functions similar to those of protein enzymes. Ribozymes are generally metalloenzymes, commonly using Mg^{2+} for catalysis and stabilization.

Some viral ribozymes do not require metal ions to cleave phosphodiester bonds. Most commonly they cleave phosphodiester bonds but they can also synthesize nucleotide chains. The ribozymes are generally large molecules yet the shortest ribozyme is only UUU and it acts on CAAA. A two-base ribozyme may catalyze the formation of 3',5' phosphodiester linkages 36,000-fold faster (Reader JS, Joyce GF 2002 Nature [Lond] 420:841). Ribozymes commonly have an internal guide for substrate recognition near their 5' terminus and a *splice site* (self-cleavage or catalytic site) where they cleave and splice the molecules. Frequently, ribozymes are classified into groups such as the hammerhead ribozymes (see Fig. R78) that are used mainly by plant RNA viruses, the RNase P, the delta, group I, and hairpin ribozymes (see Fig. R77). The hammerhead ribozymes cut at the UCX sequence if the neighboring sequences are complementary and pair.

Tertiary contacts distant from the active site prime hammerhead ribozymes for catalysis (Martick M, Scott WG 2006 Cell 126:309). The hairpin ribozymes must have at least ~50 nucleotides in the catalytic domain and ~14 in the substrate domain. The two domains pair in a two-stem form separated with an unpaired loop of the ribozyme and substrate, most commonly containing a 5'-AGUC-3' sequence. Cleavage is usually between A and G of the substrate.

Figure R77. Hairpin ribozyme

Figure R78. The critical sequences in the hammerhead ribozymes (boxed nucleotides) are conserved

RNA-catalyzed RNA polymerization has also been identified. Various proteins may affect the substrate binding by base-pairing and cleavage product release. Although ribozymes may cleave molecules in trans, their efficiency is usually better for cis substrates. Ribozymes functioning as ligases or polynucleotide kinases in mRNA repair by trans-splicing. Isomerases as well as self-alkylating catalysts have also been isolated from large pools (10^{14}) of diverse RNAs.

From an evolutionary point of view these diverse ribozyme functions lend support to the ideas of the prebiotic RNA world (see Fig. R79). Ribozymes can be engineered to recognize specific mRNAs and by cleaving them prevent the expression of a particular protein. They have an advantage over protein enzymes because it is less likely that they would incite an immune reaction. Because of their small

size, their introduction into the cell is facilitated with the aid of transformation vectors. Small RNA transcription units that may accumulate up to 106 copies per cell can propagate them. Transcription units for tRNA, U6 snRNA have been used. Although these units produce high ribozyme titer in the cell, polymerase II transcribed units target the ribozymes more effectively to the desired location. In such Pol II units the ribozyme motif is inserted into the 5' untranslated sequences. Evolution of ribozymes may be a much faster process than that of protein enzymes. A single polynucleotide sequence may fold into two different conformations and display two different catalytic activities such as the Hepatitis Delta Virus self-cleaving ribozyme and a class III self-ligating ribozyme. These ribozymes may not share more than 25% (random) nucleotide identity and yet their folding pattern may satisfy the requirements of the two functions (Schultes EA, Bartel DP 2000 Science 289:448). Both hammerhead and hairpin ribozymes were introduced into human cells infected with HIV and the ribozymes reduced the level of the gag protein. Ribozyme gene therapy has been considered for malignancies caused by the human papilloma virus, Epstein-Barr virus, and hepatitis viruses. Ribozymes thus have various therapeutic potentials if an appropriate targeting system (e.g., retroviral, adenoviral vectors, cationic liposomes) is available. Ribozymes may inactivate tyrosine kinases, transcription factors, cell adhesion molecules, growth factors, telomerase, etc. The ribozyme may recognize complementary RNA targets. Problems may include low efficiency of transfection, poor target recognition, transcriptional silencing, instability, etc. Inadequate target recognition can apparently be remedied by adding a biosensor to the ribozyme, the absence of which the ribozyme is in an inactive conformation. When the sensor recognizes a specific substrate, the ribozyme conformation is changed and it is activated, and it cleaves the specific target (Bergeron LJ, Perrault J-P 2005 Nucleic Acids Res 33:1240). Ribozymes may be used in the same way as antisense constructs but with the special advantage of catalytic activity. ▶introns, ▶ribonuclease P, ▶peptidyl transferase, ▶CBP2, ▶deoxyribozyme, ▶ligase RNA, ▶kinase, ▶alkylation, ▶RNA world, ▶RNA restriction enzyme, ▶gene therapy, ▶cancer gene therapy, ▶HIV, ▶SELEX, ▶liposomes, ▶cytofectin, ▶lipids cationic, ▶viral vectors, ▶transfection, ▶antisense technologies, ▶transdominant molecules, ▶leadzyme, ▶DNA-zyme; Wadekind JE, Mckey DB 1998 Annu Rev Biophys Biomol Struct 27:475; Doherty EA, Doudna JA 2000 Annu Rev Biochem 69:597; Ferbeyre G et al

Ribulose 1,5-Bisphosphate Carboxylase-Oxidase

(Rubisco): A chloroplast-located enzyme, generally the largest amount of protein in that organelle. Its large subunit is encoded and translated by the chloroplast system; the small subunit is coded for by a nuclear gene, translated in the cytosol, and imported into the plastids. The abundance of the small subunit affects the translation of mRNA of the large subunit. Rubisco is involved in early steps of photosynthesis and works through an intermediate 3-phosphoglycerol and it is involved in oxidative and reductive carboxylation. In dinoflagellates, Rubisco is encoded by the nucleus. ▶chloroplast genetics, ▶photosynthesis, ▶Rubisco; Suss K et al 1993 Proc Natl Acad Sci USA 90:5514; Taylor TC et al 2001 J Biol Chem 276:48159; Spreitzer RJ, Salvucci ME 2002 Annu Rev Plant Biol 53:449.

Rice (*Oryza*): Gramineae, x = 12, genome size ~430 Mbp; the species is either diploid or tetraploid. The genome size was revised to 389 Mb in 2005 (see Fig. R80).

Figure R80. *Oryza*

Over 2,000 molecular markers are available in this small genome. The generation time is 90–140 days. Two genomes were sequenced by 2002 (Science 296:79 and 92) and seem to have more open reading frames (32,000–55,000) than other organisms. After sequencing the genome the total nontransposable element-related and protein-coding gene number was revised to 37,544, and 29% of them are clustered in families. 2,859 of the genes appear unique to rice and other cereals. A transcription map of 35,970 (81.9%) of the genes and the existence of 54,564 transcribed intergenic sequences is available for *indica* rice (Li L et al 2006 Nature Genet 38:124). Homologues to *Arabidopsis* appear to be 71% and 90% of the *Arabidopsis* genes are homologous to those in rice. Of the 11,487 *Tos17* retroposon sites, 3,243 are within genes. The nuclear genomes showed organellar DNA fragments in 0.38% to 0.43%. There are 80,127 polymorphic sites which distinguish the two cultivated rice subspecies, *japonica* and *indica*. Single nucleotide polymorphism was high, 0.53% to 0.78%, about 20 times higher than in *Arabidopsis* (Matsumoto T et al 2005 Nature [Lond] 436:793).

Two groups of quantitative gene loci (QTL) have been successfully identified with regard to biochemical activity and their significance in breeding more productive crops. A 383-bp deletion of a gibberellin oxidase gene (*Ph1*, plant height) lead to high-yielding short-stem strains (Sasaki A et al 2002 Nature [Lond] 416:701). Gene *Gn1*, encoding cytokinin oxidase/dehydrogenase enzyme at reduced expression and increased cytokinin level in the reproductive organs and increased grain number per panicle by 44% and consequently increased yields. Several *Gn* genes were scattered over five chromosomes (Ashikari M et al 2005 Science 309:741). The completely sequenced chromosomes 11 and 12 contain 289

disease resistance-like and 28 defense-response genes (BMC Biology 2005, 3:20). *O. sativa* cultivars die if completely submerged in water for two weeks. The *Sub1A* allele, near the centromere of chromosome 9, is an ethylene-response-factor-like gene and can convey tolerance to flooding and increases crop security (Xu K et al 2006 Nature [Lond] 442:705). ▶cytokinin, ▶gibberellins, ▶QTL, ▶candidate gene, ▶*Magnaporthe grisea*; Shimamoto K, Kyojuka J 2002 Annu Rev Plant Biol 53:399; Sasaki T et al 2002 Nature [Lond] 420:312; Feng Q et al 2002 Nature [Lond] 420:316; Kikuchi S et al 2003 Science 301:376; sequenced genome of the pathogen *Xanthomonas oryzae*: Lee B-M et al 2005 Nucleic Acids Res 33:577; Molecular Biological Encyclopedia: <http://cdna01.dna.affrc.go.jp/cDNA/>; <http://rgp.dna.affrc.go.jp/giot/INE.html>; <http://www.tigr.org/tdb/tgi/>; annotation database: <http://www.tigr.org/tdb/e2k1/osa1/>; reverse genetics: <http://orygenesdb.cirad.fr/>; annotations: <http://rapdb.lab.nig.ac.jp/>; mutants: <http://rmd.ncpgr.cn/>; annotation database: <http://rad.dna.affrc.go.jp/>; LTR retrotransposons: <http://www.retroryza.org/>; <http://rice.tigr.org>.

Richner-Hanhart Syndrome: ▶tyrosine aminotransferase

Ricin: An extremely toxic, ribosome-inactivating, dimeric toxin produced by the plant, castor bean (*Ricinus*). The estimated lethal dose is 1–10 µg/kg when delivered as an injection or aerosol to humans. It may be significant in cancer therapy research. The deglycosylated ricin toxin A chain (dgRTA)—when containing three-amino acid mutations (xAspyat, position 97) where x can be Leu, Ile, Gly or Val and y could be Val, Leu, Ser—causes practically no liver damage and shows much reduced vascular leak syndrome. Liver damage and vascular leakage in the lung would be the major obstacles requiring the therapeutic use of this toxin (Smallshaw JE et al 2003 Nature Biotechnol 21:387). Limited trials indicate that an effective and low-risk vaccine can be produced against ricin. By using recombinant DNA technology changes can be created at the ribotoxic A chain that can prevent vascular leak effects of ricin. Tests show that 100 µg of the modified antigen provided 100% protection when injected at monthly intervals into five human volunteers (Vitetta ES et al 2006 Proc Natl Acad Sci USA 103:2268). ▶magic bullet, ▶RIP, ▶biological weapons, ▶castor bean; Lord JM et al 1991 Semin Cell Biol 2:15; Day PJ et al 2001 J Biol Chem 276:7202.

Ricinosome: A protease precursor vesicle formed from the endoplasmic reticulum in senescing plant tissues. It contains large quantities of a 45 kDa cystin

endoprotease and other proteins required for apoptosis. ►**apoptosis**, ►**protease**; Schmid M et al 2001 Proc Natl Acad Sci USA 98:5353.

Rickets: Anomalies in bone development caused by defects of calcium and phosphorus absorption and/or vitamin D deficiency. Human autosomal recessive conditions may be caused by defects in the synthesis of calciferol (vitamin D) from sterols; in such cases vitamin D₃ can correct the dependency. In some forms the receptor is defective and vitamin D cannot alleviate the hereditary condition (12q12-q14). Deficiency of pseudovitamin D (25-hydroxycholecalciferol-1-hydroxylase) is also at about the same chromosomal area. Hypophosphatemia (Xp22.2-p22.1) may also cause vitamin D unresponsive rickets. Rickets may then have multiple phenotypic consequences such as alopecia, epilepsy, etc. ►**hypophosphatasia**, ►**hypophosphatemia**, ►**vitamin D**, ►**spermine**, ►**Dent disease**

Rickettsia: Small rod-shape or roundish, obligate intracellular, Gram-negative bacteria. They may carry typhus (typhoid fever, accompanied by eruptions, chills, headaches and high mortality) and spotted fever, a tick-borne disease of cerebrospinal meningitis (brain inflammation) from animals to humans by infected arthropods (ticks, lice, fleas). The mammalian receptor for *R. conorii* is Ku70 and the *Rickettsia* protein rOmpB is a ligand for the internalization process. Ubiquitin ligase c-Cbl is also recruited to the entry foci to block invasion by partial destruction of Ku70 (Martinez JJ et al 2005 Cell 123:1013). The genome of *Rickettsia prowazekii* contains 1,111,523 bp and it shows the closest similarity to mtDNA of eukaryotes (Andersson SG et al 1998 Nature [Lond] 396:109). ►**mtDNA**, ►**mitochondria**, ►**endosymbiont theory**, ►**Wolbachia**, ►**Ku70**, ►**OMP**, ►**ubiquitin**; Nature [Lond] 396:133 for complete physical map; ►**reductive evolution**, ►*Anaplasma marginale*; Ogata H et al 2001 Science 293:2093.

Rictor: A rapamycin-insensitive mTOR. ►**rapamycin**, ►**TOR**

RID (random insertion/deletion): A technique by which certain bases of the DNA can be deleted and/or replaced at various positions, thus generating mutations. ►**targeting genes**, ►**mutagenesis**; Murakami H et al 2002 Nature Biotechnol 20:76.

RIDGE (region of increased gene expression): The highly expressed genes appear to be clustered in the chromosome as detected by SAGE. These domains have high G-C content, high SINE and low LINE repeat density and shorter introns. Antiridge domains display opposite characteristics.

►**SAGE**, ►**clustering of genes**; Versteeg R et al. 2003 Genome Res 13:1998.

Rieger Syndrome: An autosomal dominant eye, tooth and umbilical hernia syndrome. Its chromosomal location (just as the Nazi discoverer of the disease) was controversial. Human chromosomes 21q22, 4q25, 13q14 and several others have been implicated. The basic cause is also unclear; epidermal growth factor, interleukin-2, alcohol dehydrogenase, fibroblast growth factor deficiencies appear to be involved in chromosome 4. The chromosome 4 gene (RIEG) has now been cloned and it encodes a transcription factor with similarities to the *bicoid* gene of *Drosophila*. Vertebrate homologs *Pitx*, *Potxlx* and *Apr-1* mediate the left-right development of visceral organs in concert with a number of other genes such as *Sonic hedgehog*, *Nodal*, etc. ►**eye diseases**, ►**tooth agenesis**, ►**morphogenesis in *Drosophila*** {8}, ►**left-right asymmetry**; Saadi I et al 2001 J Biol Chem 276:23034.

Rifampicin: An antibiotic that inhibits prokaryotic DNA-dependent RNA polymerase (but not the mammalian RNA polymerase) and inhibits replication in *E. coli* and other prokaryotes. Rifamycin has similar effects. The antibiotic effects of the different rifamycins may vary. ►**antibiotics**, ►**maytanisoids**; Campbell EA et al 2001 Cell 104:901.

Rifins (repetitive interspersed family): Rifins are *Plasmodium falciparum* proteins in high copy number, involving antigenic variation. They are instrumental in the infection by the parasite. ►*Plasmodium falciparum*, ►**antigenic variation**

Rigens: A translocation complex in *Oenothera muricata*. If during meiosis this complex goes to the top end of the megaspore tetrad, it may overcome its topological disadvantage and this megaspore may develop into an embryo sac because the other complex, *curvans*, is not functional in the megaspores. ►**megaspore competition**, ►*Oenothera*, ►**zygotec lethal**

RIG Oncogene: The RIG oncogene is probably required for all types of cellular growth and it is active in a very wide variety of cancers. The C-terminal domain of RIG-1 binds double-stranded RNA and thus senses infectious viruses. It also stimulates the expression of transcription factors such as NF-κB, IRF3, ATF2, and provides protection against virus infection. The overexpression of MAVS (mitochondrial antiviral signaling) boosts the protection by IFN-β stimulation. ►**oncogenes**, ►**NF-κB**, ►**IRF3**, ►**ATF2**; Seth RB et al 2005 Cell 122:669; McWhirter SM et al 2005 Cell 122:645; detection of viral RNA by RIG-1:

Hornung V et al 2006 Science 314:994; RIG-1 response to single-strand RNA: Pichlmair A et al 2006 Science 314:997.

RIGS (repeat-induced gene silencing): An apparently epigenetic phenomenon caused by the methylation of cytosine residues. An alternative process is that locally paired regions of homologous sequences are flanked by unpaired heterologous sequences in transgenic plants. Silencing and variegation occurs when transgenes are inserted either in trans or cis position to heterochromatin. The degree of silencing is proportional to the distance between the transgene and the heterochromatin. ▶methylation of DNA, ▶RIP, ▶silencing, ▶epigenesis, ▶co-suppression, ▶heterochromatin, ▶position effect; Selker EU 1999 Cell 97:157.

Riken (Genome Exploration Research Group, Genome Science Laboratory): Technologies, cDNA encyclopedias, etc. (<http://genome.gsc.riken.jp>).

Riley-Day Syndrome (dysautonomia): A human chromosome 9q31-q33 recessive neuropathy involving emotional instability, lack of tearing, feeding difficulties, unusual sweating, cold extremities, etc. The prevalence in Ashkenazic Jews is about $2-3 \times 10^{-4}$ but it is quite rare in other ethnic groups. Defects in the nerve growth factor receptor are suspected. ▶neuropathy, ▶nerve growth factor, ▶IkB, ▶pain-insensitivity; Slaugenhaupt SA et al 2001 Am J Hum Genet 68:598.

Ring Bivalent: A ring bivalent has terminalized chiasmata in both arms (see Fig. R81) and thus in early anaphase I the homologous chromosomes appear to be temporarily connected at the telomeric regions of the four chromatids (see Fig. R82). This, however, is not a ring chromosome. ▶translocation ring

Figure R81. Terminalization of ring bivalents

Figure R82. Ring and rod bivalents

Ring Canal: Ring canals are intercellular bridges during cytotblast differentiation (see Fig. R83). They

transport mRNA and proteins from nurse cells to the oocytes. They are composed of actin, the hts (hui-li tai shao), and the kelch proteins. ▶cytotblast, ▶maternal effect genes, ▶RNA localization

Figure R83. Ring chromosome

Ring Chromosome: A circular chromosome without free ends (o)—such as the bacterial chromosome—as the ring DNAs in mitochondria and plastids. Ring chromosomes may result by different types of chromosome breakage. Simultaneous breaks across the centromere and the chromosome ends (telomeres) may result in the fusion of the two broken termini generating one or two ring chromosomes. Also, crossing over between two ends of the same chromosome may give rise to a centric ring and acentric fragments. Sister chromatid exchange within a ring chromosome may result in a dicentric ring chromosome, which at anaphase separation may break at various points and generate unequal size ring chromosomes and genetic instability (see Fig. R84). ▶dicentric ring chromosome, ▶ring bivalent, ▶translocation ring, ▶sister strand exchange, photomicrograph by Dr. D. Gerstel.

Figure R84. Left: A simultaneous breakage at both the centromere and at the telomeres may result in fusion between the broken ends and the generation of ring chromosomes from both of the arms of the normal chromosome generating two new ring chromosomes. Right: Exchange between the two ends yields a ring chromosome and two acentric fragments. For the sake of simplicity the chromatids of the chromosomes are not represented in the diagrams

RING Finger: A cysteine-rich amino acid motif such as Cys-X2-Cys-X(9–27)-Cys-X(1–3)-His-X2-Cys-X2-Cys-X(4–48)-Cys-X2-Cys. X stands for any amino acids in the numbers shown in parenthesis. These are protein-protein, protein-membrane, protein-DNA interacting elements involved in the regulation of transcription, replication, recombination, restriction, development, cancerous growth, etc. The RING fingers may also bind Zinc and are thus related to Zinc fingers. The name comes from the human gene RING—carrying such a motif—located in the vicinity of HLA. ▶ [Zinc finger](#), ▶ [DNA-binding protein domains](#), ▶ [autoimmune disease](#); Saurin AJ et al 1996 Trends Biochem Sci 21:208.

Ring Species: Ring species are reproductively isolated, yet some connections exist between them (Irwin DE et al 2005 Science 307:414).

Ringer Solution: A ringer solution is prepared in somewhat different concentrations depending on type of tissues it is used for. It is used as a sterilized physiological salt solution, in 100 mL water mg salts: NaCl 860, KCl 30, CaCl₂ 33; some formulations also add NaHCO₃ 20, NaH₂PO₄ and glucose 200.

RIP: A term for “recombination induced premeiotically” and, alternatively, “repeat induced point mutation”. When repeated (generally longer than 400 bp) DNA is introduced into fungi (*Neurospora* and others) by transformation or by other means, and the replicated sequence may be lost premeiotically. Alternatively, the duplications are methylated to reduce recombination or mutations are induced. In *Ascobolus* and *Coprinus*, the repeats may be methylated without mutations to follow. The mutations are attributed to cytidylic acid methylation of 5'-CpG sequences as a defense against duplication introduced by transformation to silence the superfluous genetic material. The methylation results primarily in transition mutations, GC→AT. The distribution of the mutations in the DNA is not random but most commonly occurs 5' of adenine sites but somewhat less frequently take place 5' to thymine or guanine but rarely at site 5' to other cytosines. Generally, within the same chromosome, either C→T or G→A changes occur, but not both. The majority of the RIP mutations are missense or nonsense but occasionally functional alleles also arise. The RIP mutations are frequently unstable and the longer duplications revert at a frequency of about 10⁻⁴ in the vegetative cells. ▶ [co-suppression](#), ▶ [ripping](#), ▶ [RNAi](#), ▶ [RIGS](#), ▶ [methylation of DNA](#), ▶ [MIP](#), ▶ [position effect](#), ▶ [suppressor genes](#), ▶ [integration](#); Selker EU 1997 Trend Genet 13:296; Hsieh J, Fire A 2000 Annu Rev Genet 34:187; Miao VP et al 2000 J Mol Biol

300:249; Freitag M et al 2002 Proc Natl Acad Sci USA 99:8802.

RIP (ribosome-inactivating protein): Antiviral proteins in plants and animals with glycosylase activity. Thus, they may depurinate RNA of susceptible ribosomes and block protein synthesis. RIPs protect plants against pathogens. ▶ [depurination](#), ▶ [glycosylases](#), ▶ [saporins](#), ▶ [ricin](#), ▶ [abrin](#); Nielsen K, Boston RS 2001 Annu Rev Plant Physiol Plant Mol Biol 52:785.

RIP (RNAIII inactivating peptide): ▶ [RNAIII/rnaiii](#)

RIP (regulated intramembrane proteolysis): It may control cell differentiation, lipid metabolism and various proteins in prokaryotes and eukaryotes. The targets included are proteins of the endoplasmic reticulum, sterol regulatory element binding proteins (SREBP), and amyloid precursor protein (APP), Notch). ▶ [SREBP](#), ▶ [Alzheimer disease](#); Notch, Brown MS et al 2000 Cell 100:391.

Rip1: ▶ [RNA export](#)

Ripping: The process generated by RIP mutations. RIP may also generate point mutations primarily by G-C → A-T transitions. ▶ [RIP](#)

RISC (RNA-induced silencing complex): RISC is composed of siRNA as well as Argonaute 2, VIG, FXR and the Tudor-SN proteins. ▶ [RNAi](#), ▶ [named proteins](#), ▶ [miRNP](#), ▶ [P body](#); Caudy AA et al 2003 Nature [Lond] 425:411.

Rise: ▶ [one-step growth](#)

Risk: A combination of the degree of a hazard with its potential frequency of occurrence, e.g., if a recessive gene causes a particular malformation in 30% of the fetuses, the probability of its homozygosity among the progeny of heterozygous parents is 0.25. Thus, the risk of this malformation is $0.3 \times 0.25 \approx 0.075$, i.e., 7.5%. If an individual is known to be heterozygous for a recessive lethal gene and marries a first cousin, the risk of them having a stillborn child may be as high as $0.5 \times 0.25 = 0.125 = 1/8$. If, however, the carrier marries an unrelated person from the general population, where the frequency of this gene is only 0.005, the risk will be $0.5 \times 0.005 = 0.0025 = 1/400$. In some cases, the calculation of the genetic risk is not quite as simple. Let us assume that the penetrance of a dominant gene is 80% but non-transmissible factors (somatic mutation not included into the germline, environmental effects) may also evoke the same symptoms; in this case members of the family do not display the defect. For example, when new dominant germline mutations are responsible for 15% of the cases, in this instance the ancestors are not affected.

The offspring of such a mutant individual, however, has a 0.8 (penetrance) $\times 0.5$ (expected gametic transmission) = 0.4 chance of being affected. The risk of all their offspring not being affected is $1 - 0.15 = 0.85$, and if not inherited (0 inheritance), the chance is $0.85 \times 0 = 0$. The probability of inherited (0.15) \times penetrance (0.8) is $\cong 0.12$ (12%). Further considerations are necessary for proper genetic counseling if the proband has already normal, not-affected offspring. We designate the hereditary status of the proband, the probability of being a hereditary case: $P(H) = 0.15$, as specified above. The probability that the first child being normal (not affected), despite the defective parental gene is $P(N/H) = 1 - 0.4 = 0.6$. The probability that the proband does not have this defective gene in the germline is $P(H^-) = 0.85$. The conditional probability that an offspring would be normal is $P(N/H^-) \cong 1$. From Bayes' Theorem the probability that the first child inherited but did not express the trait is:

$$P(H/N) = \frac{P(H)P(N/H)}{P(H)P(N/H) + P(H^-)P(N/H^-)}$$

$$= \frac{[0.15][0.6]}{[0.15][0.6] + [0.85][1]} = \frac{0.09}{0.94} \cong 0.096$$

With two not-affected children $P(N/H) = 0.6^2 = 0.36$, and for n offspring 0.6^n is the probability of the parent being normal in phenotype although having the defective gene.

The second child being normal although carrying the defective gene is:

$P(N/H) = 0.096 \times 0.4 \cong 0.0384$ and after substitution into the Bayes' formula

$$P(H/N) = \frac{[0.15][0.0384]}{[0.15][0.0384] + [0.85][1]} = 0.0067$$

Attributable risk (AR) reveals the risk of genetically susceptible individuals relative to those who are not susceptible. It is estimated as $AR = \{P_{Aa}(1 - 2q[1 - P_{aa}])\} / (P_{Aa}[1 - 2q])$ where P is the frequency and A and a are the dominant and recessive alleles, respectively, at a locus. The relative risk can also be estimated by the contingency chi square using an association test. Absolute risk is the excess risk of an agent which causes a difference between exposed and unexposed populations. Background risk is the chance of being afflicted in a population with a certain frequency of disease-causing allele(s). Usually, confounding factors also influence the risk—age, sex, addictions, etc.—and when this is the case more elaborate statistical procedures are required. Life expectancy may be reduced by several factors in a complex manner (smoking a cigarette [10 min], accidents [95 days], obesity [by 20% or

2.7 years], 1 mrem of radiation [1.5 min], medical X-rays [6 days]).

It is of great recent interest to determine the risk of disease by genome-wide association studies (risk engine) (Editorial 2005 *Nature Genet.* 37:1153). RK: Rank of utility.

RK2 Plasmids: These plasmids represent a family of broad host-range plasmids (56.4 kb), resistant to tetracycline, kanamycin, and ampicillin. The size and selectability of other members of the family varies. (See Pogliano J et al 2001 *Proc Natl Acad Sci USA* 98:4486).

RKIP (Raf kinase inhibitor protein): [►RAF](#)

RLDB: [►reference library database](#)

RLGS (restriction landmark genomic scanning): The goal of the procedure is to determine the methylation status of genes that may have undergone epigenetic changes (such as oncogenic transformation) or are imprinted. It also detects tissue-specific methylation patterns in the genome. It is based on digestion of DNA by a rare-cutter restriction endonuclease such as *NotI*, which does not cleave methylated CpG islands. The fragments are then radioactively end-labeled at the *NotI* cut sites and further reduced in size by another restriction enzyme, e.g., *EcoRV* (GAT↓ATC). The fragments are then separated by agarose gel electrophoresis and further cleaved with a third restriction enzyme, e.g., *HinfI* (G↓ANTC) in the gel. The small fragments are then subjected to electrophoresis in a second dimension in an

acrylamide gel and the fragments containing the radioactive label are identified. The procedure thus identifies the difference between methylated and not methylated status at a specific site. The method holds promise for mass scanning potential cancer genes. It has also been used for determining allele-specific methylation of imprinted genes (Plass C et al 1996 *Nature Genet* 14:106). ▶[epigenesis](#), ▶[imprinting](#), ▶[electrophoresis](#), ▶[restriction enzymes](#), ▶[methylation of DNA](#); Costello JF et al 2000 *Nature Genet* 25:132; Costello JF et al 2002 *Methods* 27:144.

RMSA-1 (regulator of mitotic spindle assembly): A protein which is phosphorylated only during mitosis and is a substrate for CDK2 kinase; it is required for the assembly of the spindle. ▶[spindle](#), ▶[CDK](#); Yeo JP et al 1994 *J Cell Sci* 107:1845.

RNA: Ribonucleic acid is a polymer of ribonucleotides. There are three main classes of RNAs in the cell: the mRNA, which provides the instructions for protein synthesis, the various ribosomal RNAs, and the tRNAs. Other RNAs are involved in splicing, editing, post-transcriptional modification, ribonucleoproteins that insert proteins into membranes and mediate telomere synthesis, replication priming RNAs, inhibitory RNAs (RNAi), ribozymes, and the noncoding RNAs involved in dosage compensation and imprinting. Maps of nuclear and cytosolic polyadenylated [poly(A)⁺] RNAs longer than 200 nucleotides (nt) (long RNAs, lRNAs) and whole-cell RNAs less than 200 nt (short RNAs, sRNAs) are transcribed over the entire nonrepetitive portion of the human genome. The potential biological function of an appreciable portion of long unannotated transcripts is to serve as precursors for sRNAs. These maps reveal three classes of RNAs that have specific genomic localization at gene boundaries. The biological relevance of these classes of RNAs is supported by a strong correlation with the expression state of the genes they associate with, as well as their syntenic conservation between humans and mouse (Kapranov P et al 2007 *Science* 316:1484). ▶[RNA I](#), ▶[mRNA](#), ▶[tRNA](#), ▶[rRNA](#), ▶[rrn](#), ▶[nucleic acid chain growth](#), ▶[non-canonical bases](#), ▶[telomerase](#), ▶[RNA editing](#), ▶[replication](#), ▶[RNAi](#), ▶[microRNA](#), ▶[ribozymes](#),

RNA I: An untranslated bacterial RNA controlling the maturation of RNA II that serves as a primer for plasmid DNA synthesis. RNA I and RNA II are synthesized on opposite DNA strands. RNA I binds to RNA II and thereby prevents its folding into a cloverleaf that is necessary for the formation of a stable DNA:RNA hybrid between RNA II and the plasmid DNA. This binding is promoted by the Rop protein (63 amino acid residues) coded for by 400-base downstream from the origin of replication. A single G → A transition mutation in Rop or upstream from it may contribute to plasmid amplification (see Fig. R86). RNA I, RNA II, and Rop also control plasmid incompatibility. RNase H cuts off the pre-primer section and prepares the primer for the actual DNA synthesis. RNA I may be polyadenylated and then its decay hastened in a way similar to mRNA. RNA I and RNA II may interact initially by base pairing between their 7-nucleotide complementary loops. The Rom/Rop protein may also bind to the transient complex and assures a more stable duplex of the two RNAs causing failure of replication initiation. ►polyadenylation, ►plasmid, ►RNA polymerase, ►ROM; Mruk I et al 2001 Plasmid 46:128.

Figure R86. RNA I and RNA II synthesis

RNA II: ►RNA I

RNA Binding Proteins: These proteins modify the RNA structure locally or globally; they may affect RNA trafficking, mRNA biosynthesis, translation, splicing, polyadenylation, differentiation and diseases. They may be part of the combinatorial tagging of mRNA and may control the localization, translation, and decay of mRNA in the global expression program (Gerber AP et al 2004 PLoS Biol 2:342). The length and composition of the binding domains may vary. A human RNA-binding protein is encoded in chromosome 8p11-p12 (RBP-MS). ►DNA-binding protein domains, ►hnRNP; Burd CG, Dreyfuss G 1994

RNA Dependent RNA Polymerase (RdRP): This polymerase replicates the RNA genome of viruses. The RNA-directed RNA polymerase, primed by siRNA, amplifies the interference by RNAi. ►RNAi; Ahlquist P 2002 Science 296:1270; Ortin J, Parra F 2006 Annu Rev Microbiol 60:305.

RNA Display: A procedure for the enrichment of specific RNAs. In in vitro the translation system uses a synthetic mRNA, which carries the peptidyl acceptor antibiotic puromycin at the 3' end. The protein synthesis proceeds until the end of the open reading frame and the translation stalls at the RNA-DNA junction. The puromycin enters the A site of the ribosome and accepts the nascent peptide. Affinity chromatography and immunoprecipitation permit purification of the fused mRNA-peptide from the complex mixture. The RNA serves as a tag for specifying the peptide. ►protein synthesis, ►puromycin, ►affinity chromatography, ►immunoprecipitation, ►phage display; Roberts RW, Szostak JW 1997 Proc Natl Acad Sci USA 94:12297.

RNA, Double-Stranded: A double-stranded RNA is usually a minor fraction of the total cellular RNA (unlike to DNA). It appears that if double-stranded RNA, with sequences homologous to an open reading frame of a gene, is introduced into the cell, the antisense RNA more effectively blocks the function of that gene (in *Caenorhabditis*). It is a surprising fact that even at very low abundance this RNA is a highly effective inhibitor. A double-stranded RNA-binding protein is apparently required for gene activation in the mammalian germ cells. dsRNA is common in virus-infected cells and it is an inducer of interferon. It inhibits the transcription of about one-third of the genes and stimulates the rest to a variable degree.

A substantial fraction of the pairing of RNA molecules is not in compliance with the Watson-Crick model. Hoogsteen and "sugar edge" pairing also occur. The edge indicates the relative orientation of the glycosidic and hydrogen bases. The four RNA bases (A, C, G, U) may associate in 4² matrices.

These steric associations may be evolutionarily better preserved than the base positions themselves. They facilitate long-range RNA-RNA interactions and create binding sites for proteins and small ligands. ►antisense RNA, ►targeting genes, ►RNAi, ►Watson-Crick model, ►Hoogsteen pairing, ►RNA helicase; Geiss G et al 2001 J Biol Chem 276:30178; Leontis NB et al 2002 Nucleic Acids Res 30:3497.

RNA Driven Reaction: In a DNA-RNA hybridization experiment, the RNA is far in excess compared to single-stranded DNA. This assures that hybridization will take place at all potential annealing sites. ►DNA hybridization, ►nucleic acid hybridization

RNA Editing: A means of posttranscriptional or co-transcriptional altering of the RNA transcript (mRNA, tRNA, rRNA, 7 SLRNA). It is a very common process in the mitochondria of *Trypanosomes* (►*Trypanosoma brucei*). A separately transcribed 40–80-base “guide RNA” with homology to the 5′-end of the RNA to be modified pairs with the target. Then, uracil residues from the 3′-end tract of the guide are transferred into the target sequences. Two enzymes are primarily involved in the editing of exonuclease 1 (REX1) and (REL) RNA ligases (Kang X et al 2005 Proc Natl Acad Sci USA 102:1017). This editing thus changes the content of the message and the amino acids of the translated protein. In the mitochondria of this protozoan, thousands of U nucleotides may be inserted into different pre-mRNAs. Us may also be removed at a 10-fold lower frequency. It has been hypothesized that the U replacements are provided by the 3′-end of the gRNA, but recent experimental evidence indicates that they come from free UTPs. In the mitochondria of plants, in about 10% of the transcripts, U may replace C or C replaces U. The editing of four to 25 RNAs may take place in the chloroplasts. Transacting factors psbE and petB bind to five nucleotides cis upstream from the editing site (Miyamoto T et al 2004 Proc Natl Acad Sci USA 101:48). Although there is no conserved consensus around the edited sequences in plant chloroplasts, in tobacco a 27-nucleotide sequence at the RpoB-2C target plays a critical role (Hageman CE et al 2005 Nucleic Acids Res 33:1454). Editing appears to be rare but not limited to higher animals. One C residue deamination in the apolipoprotein-B results in a U replacement and the creation of a stop codon, and consequently a truncated protein. Another similar deamination in the middle of the transcripts alters the permeability of a Ca²⁺ channel. Thus editing produces two different mRNAs from one. Although C→U is the common change, U→C may also occur exceptionally. Simple deamination, addition

or co-transcriptional errors, such as stuttering of the polymerase may also bring about the changes. RNA editing also takes place in different RNA viruses. In HIV-1, G→A editing also occurs besides C→U. Mammalian nuclear RNA editing may involve the deamination of adenosine into inosine in the double-stranded pre-mRNA of the glutamate-receptor subunits. The enzyme responsible for the process is dsRAD (double-stranded RNA adenosine deaminase, also called DRADA or ADAR). The ADAR1 and ADAR2 proteins are associated with spliceosomal components of a 200 S large ribonucleoprotein complex (InRNP). The deficiency of ADAR in *Drosophila* results in behavioral anomalies during the advanced developmental stages. There are differences in editing among animals. Fruit flies, mosquitoes, and butterflies have similar editing sites within a single exon of the synaptotagmin genes. Honeybees, beetles and roaches, however, do not edit this synaptotagmin site. Comparative genomics of 34 species indicates that complex, multidomain, pre-mRNA structures (e.g., pseudoknots) determine the specificity of adenine editing in synaptotagmin (Reenan RA 2005 Nature [Lond] 434:409).

In the tRNA^{Asp} of marsupials, the GCC anticodon is found that can only recognize the glycine codon. In 50% of these tRNAs the middle base is edited to U, and thus the regular Asp anticodon is generated. The marsupial mitochondria also have the regular tRNA^{Gly} with anticodon GGN that recognizes all four glycine codons, but the edited codon can match up with only two of the glycine codons. Why among the only 22 tRNAs there are two for glycine (normal and edited) is a puzzling observation. RNA editing occurs through the plant kingdom (with few exceptions), in mitochondria as well as in chloroplasts, albeit at lower frequency in the latter. In the plastids there are about 25 editable sites, while in the mitochondria their number may exceed 1,000. RNA editing may generate new initiation and termination codons in plant organelles and thus new reading frames. No U→C editing was observed in the mitochondria or chloroplasts of gymnosperms or in the chloroplasts of angiosperms. The site of editing is apparently selected on the basis of the flanking sequences.

RNA editing also occurs in nuclear genes and contributes to the regulation at an additional level. It appears that the neurofibromas are determined by editing in the neurofibromatosis gene (NF1). Editing may also regulate the mRNA of the serotonin-2C receptor. In the immune system, T cell-independent B cells (B1) also diversify their surface receptors by RNA editing. Defects in RNA editing may potentiate tumorigenesis. ►mtDNA, ►apolipoproteins, ►kinetosome, ►gRNA, ►genetic code, ►stuttering, ►wobble, ►DRADA, ►ADAR, ►Z DNA,

RNA Enzyme: ►ribozyme

RNA Export: From the nucleus, mRNA requires the presence of the nuclear export factor NES and a cellular cofactor Rip1/Rab. The NES function is part of the Gle1 yeast protein (M_r 62K). Gle1 interacts with Rip1 and nucleoporin (Nup 100) in the nuclear pore. The Rev splicing factor can substitute the Gle1 function. Protein Aly of metazoans is involved in pre-mRNA slicing and mRNA export. The export of unspliced mRNA may be prevented by nuclear retention factors (RF), however some intron-less mRNAs can be exported and efficiently translated in the cytoplasm. The export of mRNA also requires PIP₂ and PIP₃. The abundant hnRNPs (hnRNP C and hnRNP K) have also been implicated in mediating RNA export. It seems, some TAP elements are also involved in the export. tRNA and U snRNA export may require members of the importin β family of proteins. The export of tRNAs may be mediated by the aminoacyl-tRNA synthetases after processing of transcripts. This involves the removal of the not needed 5' and 3' sequences, introns, addition to 3' end of the CCA sequence, and modification of some nucleotides. Some mRNA export protein factors coordinate the export of transcriptionally co-regulated functional classes of transcripts. Thus, the yeast export proteins, Yra1 and Mex67, bind 1,000 (20%) and 1,150 (36% of the total) mRNAs, respectively, and usually their specificity does not overlap (Hieronymus H, Silver PA 2003 *Nature Genet* 33:155). ►RNA transport, ►REV, ►nuclear pore, ►transport elements constitutive, ►export adaptors, ►nuclear export sequences, ►importin, ►TAP, ►aminoacyl-tRNA synthetase, ►Ipk1, ►cell-penetrating peptides; Michael WM 2000 *Trends Cell Biol* 10:46; Zenklusen D, Stutz F 2001 *FEBS Lett* 498:150; Sträßer K et al 2002 *Nature [Lond]* 417:304.

RNA Extraction: An essential requisite that RNase activity be eliminated or prevented during all operations. The glassware can be made RNase free by baking for 8 h or by chloroform washing. A 1% diethyl pyrocarbonate (DEPC [carcinogen!]) washing

(2 h, 37 °C) may also be useful. RNase activity in the extraction media can be inhibited by vanadium or by the clay, Macaloid. These are subsequently eliminated by water-saturated phenol extraction. RNases can also be blocked by 4 M guanidium thiocyanate and β -mercaptoethanol. RNA is extracted from the tissues in a buffer containing a detergent (0.5% Nonidet) and a reducing agent (dithiothreitol). Proteins may be removed by proteinase K digestion. RNase-free DNase removes DNA. Finally, chilling in cold ethanol (containing Na-acetate) precipitates RNA. The RNA is taken up in a TE, pH 7.6 buffer. Its quantity can be measured spectrophotometrically at 260 nm. Several variations of these general procedures are being used to isolate RNA. ►DNA extraction, ►RNase-free DNase, ►TE

RNA Factory: The complex associated with RNA polymerase II. It carries out transcription, splicing, and cleavage-polyadenylation of the mRNA precursor. ►mRNA; McCracken S et al 1997 *Nature [Lond]* 385:357.

RNA Finger: An RNA element (e.g., CCCH) binding to Zn-finger proteins. It controls various cellular processes. ►DNA binding protein domains

RNA Fingerprinting: The purpose is to identify the differential expression of the total array of genes that constitutes about 15% (or less) of all at a particular time in a mammalian genome. To attain this goal partial cDNAs are amplified by reverse transcription using PCR from a subset of mRNAs. The short sequences are then displayed on a sequencing gel (differential display). Pairs of primers are selected in such a way that each will amplify 50 to 100 mRNAs. One of the primers (5'-TCA) is anchored to the TG upstream of the poly(A) tail of the mRNA. This primer will recognize 1/12 (4!/2!) of the mRNAs with different combination of the last two 3' bases omitting T as the penultimate base. The primer will then only amplify this subpopulation. As 5' primers, 6–7 bp arbitrary sequences are used. Such a procedure can be used not just for molecular analysis of development. Eventually the genes producing the transcripts can be cloned. ►PCR, ►reverse transcription, ►DNA fingerprinting, ►fingerprinting of macromolecules, ►differential display, ►RDA, ►microarray hybridization, ►proteomics, ►SAGE, ►TOGA; Gill KS, Sandhu D 2001 *Genome* 44:633.

RNA Folding: There is a requirement for Mg²⁺ in maintaining the tRNA tertiary structure but other RNAs also need potassium or magnesium ions for folding. The ionic environment influences the folding of macromolecules and their function depends on the appropriately folded state. RNA folding proceeds through a number of intermediate states. For protein

synthesis on the ribosome in the cells the tRNA is aminoacylated in the tertiary fold (see Fig. R87). ▶aminoacyl-tRNA synthetase, ▶ribozyme, ▶RNA structural; Draper DE et al 2005 Annu Rev Biophys Biomol Struct 34:221; single RNA molecule folding: Zhuang X 2005 Annu Rev Biophys Biomol Struct 34:399; Pan T, Sosnick T 2006 Annu Rev Biophys Biomol Struct 35:161; detection of thermodynamically stable and evolutionarily conserved RNA secondary structures in multiple sequence alignments: <http://rna.tbi.univie.ac.at/cgi-bin/RNAz.cgi>.

Figure R87. RNA folding

RNA G8: RNA G8 contains about 300 nucleotides and it is associated with the ribosomes in *Tetrahymena thermophila*. It is transcribed by RNA polymerase III and conveys thermal tolerance to the cells. ▶thermal tolerance

RNA Helicases: RNA helicases unwind double-stranded RNAs to facilitate transcription. They have two double-stranded RNA domains and have a cis-acting transactivation response (TAR) element binding and a dsRNA activated protein kinase (PKR) domain. TAR enhances the transcription of HIV-1. It appears that the helicase activity resides within the ribosome and that the ribosomal proteins S3, S4 and S5 encircle the incoming RNA on the 30S ribosomal unit and play a role in processivity (Takayar S et al 2005 Cell 120:49). The NPH-II RNA helicase has specificity for the ribose moiety of the loading strand and for a section of the 3'-overhang. Yet, under less stringent conditions it also acts on DNA (Kawaoka J, Pyle AM 2005 Nucleic Acids Res 33:644). ▶eIF4A, ▶helicase, ▶DEAD-box, ▶breast cancer, ▶acquired immunodeficiency, ▶double-stranded RNA; Lüking A et al 1998 Crit Rev Biochem Mol Biol 33:259; Fujii R et al 2001 J Biol Chem 276:5445.

RNA, Heterogenous: ▶hnRNA

RNA Insertion Element: An RNA insertion element can be generated by in vitro combination of an endoribonuclease ribozyme with a R3C ribozyme with RNA ligation function. The conjoined bifunctional ribozymes can integrate into a target RNA. Several mutations had to be isolated and selected to generate an efficient modular system. Such structures may be useful for insertional mutagenesis of mRNA.

RNA Interference: In *Caenorhabditis* nematodes, fed on double-stranded RNA-containing bacteria, gene expression is transiently but specifically suppressed, as long as the dsRNA is available. The interfering dsRNA may be generated by inserting T7 phage RNA polymerase genes at the opposite ends of specific genes in a plasmid. Alternatively, a single copy of the polymerase may be used on inverted duplication of a specific gene. *Note:* some of the papers by Taira, K. had to be corrected (Nature [Lond] 431:211) and another (Nature 423:838) was retracted (Nature 426:100). ▶*Caenorhabditis*, ▶RNAi, ▶inhibition of transcription, ▶posttranscriptional gene silencing; Moss EG 2001 Curr Biol 11:R772.

RNA Ligase: An RNA ligase catalyzes the joining of RNA termini, such as generated during the processing of tRNA transcripts, in a phosphodiester bond and may need ATP for the reaction. It is an essential enzyme for RNA editing. ▶ligase DNA, ▶ligase RNA; Stage-Zimmermann TK, Uhlenbeck OC 2001 Nature Struct Biol 8:863; Ho KC, Shuman S 2002 Proc Natl Acad Sci USA 99:12709; deoxyribozyme RNA ligase: Prior TK et al 2004 Nucleic Acids Res 32:1075.

RNA Localization: Embryonic development is an asymmetric process and the local distribution and enrichment of special RNAs play decisive roles. The RNA transcribed from the bicoid locus of *Drosophila*, encoding a transcription factor, specifies anterior cell fates in the oocytes and embryos. The germcell-less nuclear pore associated factor participates in the definition of posterior development. The growth factor encoded by gurken affects anterior-dorsal differentiation whereas the prospero encoded transcription factor controls apical/basal development in the neuroblasts. In mammals, the transcript of the β -actin genes is involved in the definition of the cytoskeleton and it is localized primarily at the periphery of epithelial cells, fibroblasts, and myoblasts. The different RNAs appear at the predestined locations immediately following transcription. Some of the rather uniformly distributed RNAs are degraded, except at the locations where they exercise morphogenetic function(s). The localization seems to be mediated by signals (usually a few hundred bases or less), generally in the untranslated 3'-end (3'-UTR) of the mRNAs. The mRNAs are not translated until properly localized. Translation without prior localization might cause developmental anomalies. Besides the cis-acting element (e.g., 3'-UTR), trans-acting factors encoded by other genes may also affect

localization (e.g., influence the cytoskeletal motor proteins or RNA binding proteins). Localization of the RNA may also be assured by alternative splicing of the transcripts. The pattern of distribution may change as the microtubule-organizing center develops and motor proteins become available. At a later stage, before the nurse cells decay, they dump large amounts of RNA into the oocyte through the ring canals. Later, ooplasmic streaming somewhat mixes up the previously laid down distribution pattern. When the early syncytial blastoderm (~6,000 nuclei) is converted into a cellular blastoderm, the anterior-posterior and the dorsal ventral polarization begins, upon the expression of the genes, specifying the morphogenetic pattern. At this stage the control shifts toward the zygotic effect genes from the maternal effect ones. Another control involved the diffusion pattern of the morphogenetic gene products. ►*morphogenesis in Drosophila*, ►*maternal effect genes*, ►*MTOC*, ►*ring canal*, ►*METRO*, ►*motor proteins*; Bashirullah A et al 1998 *Annu Rev Biochem* 67:335; Palacios IM, St Johnston D 2001 *Annu Rev Cell Dev Biol* 17:569; Bullock SL, Ish-Horowicz D 2001 *Nature [Lond]* 414:611; Saxton WM 2001 *Cell* 107:707.

RNA Maturases: Ribosomal transcripts are processed to size by the U3, U8, U13 independently transcribed small RNAs (snoRNA, small nucleolar RNAs). The U13-U14 snoRNAs and E3 are encoded by the introns of protein-coding genes participating in the process of translation. They are co-transcribed with the pre-mRNA and removed during the processing of the genes. By the intron of the U22 host gene (UHG) seven U RNAs are transcribed. These U RNAs display 12–15 base complementary sequences to rRNAs. ►*splicing*, ►*introns*, ►*ribonuclease P*; Delahodde A et al 1989 *Cell* 56:431; Claros MG et al 1996 *Methods Enzymol* 264:389.

RNA, Micro (miRNA, mir): A 22-nucleotide inhibitory RNA. ►*RNAi*; Zeng Y et al 2002 *Mol Cell* 9:1327.

RNA, Noncoding (ncRNA): There are many mRNA-like-yet-not-translated molecules in the cell. They are polyadenylated and spliced but lack long open reading frames. They have regulatory or signal functions (Szymanski M, Barciszewski J 2003 *Int Rev Cytol* 231:197). A noncoding RNA transcribed

in an intergenic region upstream from the *SER3* gene of yeasts can interfere with the binding of activators to the *SER* promoter and thus regulates its transcription (Martens JA et al 2004 *Nature [Lond]* 429:571). Noncoding RNAs are the tRNAs, ribosomal RNAs, the snRNAs, microRNAs, and snoRNAs. In whole genome microarrays of *E. coli*, besides 4,052 coding transcripts, 1,102 apparently noncoding transcripts were found in the intergenic regions. In humans, about 98% of the transcripts are noncoding. There are also the tiny noncoding RNAs (tncRNA) that resemble microRNAs but are not transcribed as short hairpin RNA precursors and yet they play regulatory roles in development (Ambros V et al 2003 *Current Biol* 13:807). The development of the neural stem cells may be modulated by a small double-stranded RNA and protein interaction (Kuwabara T et al 2004 *Cell* 116:779). On the basis of secondary structure and thermostability, coding and noncoding RNAs can be rapidly identified by a computational procedure (Washietl S et al 2005 *Proc Natl Acad Sci USA* 102:2454). ►*microRNA*, ►*RNAi*, ►*antisense RNA*, ►*RNA regulatory*, ►*small RNA*, ►*Xist*, ►*Rfam*; Erdmann VA et al 2001 *Cell Mol Life Sci* 58:960; Eddy SR 1999 *Curr Opin Genet Dev* 9:695; Storz G 2002 *Science* 296:1260; Kiss T 2002 *Cell* 109:145; Fahey ME et al 2002 *Comp Funct Genomics* 3:244; Tjaden B et al 2002 *Nucleic Acids Res* 30:3732; Griffith-Jones S et al 2003 *Nucleic Acids Res* 31:439; <http://biobases.ibch.poznan.pl/ncRNA/>; <http://www.sanger.ac.uk/Software/Rfam/>; <http://rfam.wustl.edu/>; mammalian non-coding RNA: <http://research.imb.uq.edu.au/RNAdb>; <http://bioinfo.ibp.ac.cn/NPInter/>; plants: <http://www.prl.msu.edu/PLANTncRNAs/database.html>.

RNA Polymerases (RNAP): DNA-dependent RNA polymerases synthesize RNA on a DNA template. The T7 RNA polymerase is a relatively simple molecule (100 kDa). As a rule, this polymerase directs the incorporation of the first nucleotide in a template-directed manner with a single nucleotide primer. First, it produces several pieces of short RNAs and then these 10–12 nucleotide units polymerize into an elongation complex and exits from the promoter.

Between the DNA template and the 3'-proximal RNA transcript at least a 9-nucleotide long hybrid is formed for efficient processivity during the elongation of the RNA.

The RNA products then separate from the template and the duplex of the DNA is restored. The T7 phage promoter has a binding domain (−17 to −6) and an initiation domain (−6 to +6). After the binding domain of the polymerase recognizes the DNA, melting of the duplex takes place. During the elongation phase, about 200 nucleotides are added per second. The termination is rho independent in T7 and the end forms a stem-loop structure and a stretch of U bases. The termination seems to be a reverse process of the initiation, i.e., a stable isomerization is followed by an unstable sequence. In many respects, the phage enzyme despite its simple structure functions similarly to more complex polymerases. In prokaryotes a single polymerase synthesizes all cellular RNAs. The prokaryotic pol enzyme contains four subunits α , β , β' , and σ . The large β subunits are evolutionarily highly conserved and they are the main instruments of polymerization with the other subunits.

The prokaryotic RNA polymerases are of about 500 kDa in size whereas the T7 enzyme is only about 40 kDa. The *E. coli*, α subunits (36.5 kDa) recognize the promoter, the β' subunit (155.2 kDa) binds DNA, and the β (150.6 kDa) is active in RNA polymerization. The σ is essential to start transcription in a specific way by opening the double helix for the action of the RNA polymerization. The eukaryotic organelles contain prokaryotic type RNA polymerases. The eukaryotic RNA polymerase II—transcribing protein-encoding genes—has about 12 subunits and is somewhat larger but highly homologous across wide phylogenetic ranges. The two largest subunits are similar to the β' and β subunits of the prokaryotic enzyme. The carboxy-terminal domain (CTD) of the largest subunit of the eukaryotic RNAP II carries up to 52 amino acid repeats (YSPTSPS) which are liable to phosphorylation (Meinhart A, Cramer P 2004 Nature [Lond] 430:223). Only the CTD unphosphorylated form participates in a transcription initiation complex but it is phosphorylated when it begins to elongate the RNA transcript. After transcription, the CTD phosphates are removed by phosphatase Fcp1 (Kamenski T et al 2004 Mol Cell 15:399). The CTD repeat is not essential for transcription initiation by RNAP II but for the stability of the initiation complex (Lux C et al 2005 Nucleic Acids Res 33:5139). When transcription is arrested the carboxy-terminal domain of Pol II is ubiquitinated (Somesh BP et al 2007 Cell 129:57). The complex of transcription includes the Mediator

and a total of about 60 proteins with a combined mass of 3.5 MDa. In an *E. coli* cell there are about 2,000 core RNA polymerase molecules. The number of protein factors affecting transcription in *E. coli* is about 240–260.

In eukaryotes, there are three different DNA-dependent RNA polymerases (I, II, III) that display substantial homology. Polymerase IV of plants assists in the production of siRNA. It targets de novo methylation of cytosine and contributes to the formation of facultative heterochromatin (Onodera Y et al 2005 Cell 120:613). Besides RNA polymerase II, a single polypeptide nuclear RNA polymerase (spRNAP-IV) alternatively transcribed from the mammalian mitochondrial RNA polymerase gene (*POLRMT*) can also transcribe mRNA. This polymerase lacks terminal 262 amino acids in the nucleus (compared to the mitochondrially located form) and the mitochondrial targeting signal. It is resistant to α -amanitin but remains sensitive to *POLRMT*-specific RNAi. Its promoter is substantially different from that of Pol II and does not respond to transcriptional enhancers. It transcribes several nuclear genes (Kravchenko JE et al 2005 Nature [Lond] 436:735).

TRNA polymerases replicate the genome of the RNA viruses. Mammalian RNA polymerase II may also carry out RNA-dependent RNA synthesis by switching to the RNA genome of the hepatitis delta virus (Chang J, Taylor J 2002 EMBO J 21:157). The viral enzymes—in contrast to the DNA polymerases—lack a proofreading function and, consequently, their error rate may be within the 10^{-3} to 10^{-4} range per nucleotide leading to the extreme diversity of the RNA viruses. The prokaryotic RNA polymerase moves along the DNA at a speed exceeding 10 nucleotides/second. Termination is basically the reverse process of the transcription initiation. In the haploid yeast cell there are 2,000 to 4,000 RNA polymerase II molecules and about ten times more general transcription factor molecules. In 2006, Roger D. Kornberg received the Nobel Prize for his basic study of RNA polymerase structure and function. (See Figs. [R88](#), [R89](#), and [R90](#), [▶pol](#), [▶ \$\sigma\$](#) , [▶sigma factor](#), [▶promoter](#), [▶open promoter complex](#), [▶promoter melting](#), [▶transcription](#), [▶transcription factors](#), [▶transcription termination](#), [▶terminator](#), [▶antitermination](#), [▶error in replication](#), [▶error in transcription](#), [▶pausing transcriptional](#), [▶arrest transcriptional](#), [▶transcript cleavage](#), [▶transcription complex](#), [▶inchworm model](#), [▶nucleic acid chain growth](#), [▶processivity](#), [▶repression](#), [▶mediator complex](#), [▶SRB](#), [▶protein synthesis](#), [▶transcript elongation](#), [▶elongator](#), [▶RNA dependent RNA polymerase](#), [▶RNAi](#), [▶ \$\alpha\$ -amanitin](#),

Figure R88. Schematic drawing of the 10/12 subunits of the yeast RNA polymerase II. Subunits 1, 5 and 9 grip the DNA below the active center of the enzyme. Pores below the active center form the entry of the nucleotides and the exit of the polymerized RNA. (Redrawn after Cramer P et al 2000 *Science* 288:640)

Figure R89. Conceptualization of the general process of transcription of RNA on DNA template from ribonucleoside 5'-triphosphates. The first 5'-nucleotide retains the three phosphates; the following ones split off a pyrophosphate and are then hooked up to the 3'-OH ends. In this process a ternary complex involving DNA, RNA, and protein is involved. The RNA-protein has been located to about 9 bp from the DNA fork into the transcription bubble where the DNA template forms an approximate 8 bp heteroduplex (HBS, heteroduplex-binding site). The RBS (RNA-binding site) together with HBS extends to approximately 14–16 RNA nucleotides from the 3'-OH end. About 7–9 nucleotides further downstream, RBS, HBS, and DBS (DNA-binding site) are situated and stabilize transcription. The DNA entry and the RNA exit sites on the polymerase are in close vicinity to each other. This diagram does not show the general transcription factors and the numerous other proteins regulating the process. (Diagram is modified after Page DS, *Principles of Biological Chemistry*. Willard Grant, Boston MA; see also Nudler E, et al 1998. *Science* 281:424.) For the structure of initiation complex of the T7 enzyme at 2.4 Å resolution, see Cheetham GMT and Steitz TA 1999. *Science* 286:2305.

Figure R90. The structures of RNA polymerase II has been determined at 3.3 Å resolution. The schematic of the major functional elements is shown above. The enzyme enters DNA at right and holds onto it by the element designated as **JAW**. The **CLAMP** domain keeps the protein on the DNA. The **Switches** turn on the function. A large protein subunit, the **WALL** causes an approximately 90° turn of the DNA template. This then facilitates the addition of nucleotides to the RNA. The RNA building blocks, the nucleotide triphosphates, enter the complex through the **FUNNEL**, which ends in a **PORE**. Magnesium (or other metals) is required for the polymerization. The RNA chain is symbolized by a dotted line. The DNA and RNA from a 9-base duplex. The **RUDDER** (not shown here) prevents the extension of the DNA—RNA hybrid to go beyond the 9 base pairs and facilitates the separation of the duplex. The synthesized RNA exits under the **LID**. The **BRIDGE HELIX** under the coding strand of the DNA apparently promotes the addition of nucleotides. (Modified after Gnatt AL, et al 2001 *Science* 292:1876.)

R

RNA Polymerase Holoenzyme: A complex of RNA Pol II, transcription factors and other regulatory proteins including Srb. It is a general transcriptional regulator of eukaryotes. ▶transcription factors, ▶co-activators, ▶TBP, ▶TAF, ▶RNA polymerase

RNA Polymerase I: It generates ribosomal RNA. In yeast, the UAF includes histones H3 and H4 and four non-histone proteins as essential factors (Tangaonkar P et al 2005 *Proc Natl Acad Sci USA* 102:10129). ▶transcription factors

RNA Polymerase II: ▶RNA polymerases

RNA Polymerase III: RNA polymerase III mediates the transcription of tRNAs and other small RNAs. It has efficient proofreading ability and reduces transcriptional errors by 10^3 (Alic N et al 2007 *Proc Natl Acad Sci USA* 104:10400). This enzyme may be

suppressed by ARF (Morton JP et al 2007 *Nucleic Acids Res* 35:3046). ▶transcription factors, ▶ARF

RNA Polymerase IV (nuclear RNA polymerase D1A): A plant enzyme which, with RNA-dependent RNA polymerase 2, provides a substrate for Dicer-like 3 endoribonuclease in generating siRNA. It also mediates RNA-dependent methylation of DNA (Matzke M et al 2006 *Cold Spring Harbor Symp Quant Biol* 71:449). ▶Dicer, ▶RNA dependent RNA polymerase, ▶siRNA, ▶epigenesis; Zhang X et al 2007 *Proc Natl Acad Sci USA* 104:4536.

RNA Polymerizations: ▶pol

RNA Primer: ▶DNA replication

RNA Processing: Eukaryotic genes are “in pieces”, although the DNA is continuous, in between the protein-coding nucleotide sequences (exons), non-translated additional nucleotide sequences, introns occur. The long sequences are transcribed into a long RNA tract but the introns are removed and the exons are spliced to make the mRNA. Similar processing is carried also out with the rRNA and tRNA. The vast majority of prokaryotic genes do not require these processes. These cutoffs, the mRNA, and the primary transcripts constitute the pool of the hnRNA (heterogeneous nuclear RNA). The primary RNA transcripts are coated with different proteins and thus form hnRNP, i.e., hnRNA-protein particles. These particles are instrumental in cutting the transcripts and splicing the exons into mRNA. After the splicing is completed, the methylated guanylic cap and the polyA tail are added and then the mRNA exported into the cytosol. ▶introns, ▶hnRNA, ▶spliceosome, ▶post-transcriptional processing, ▶exosome; Varani G, Nagai K 1998 *Annu Rev Biophys Biomol Struct* 27:407.

RNA-Protein Interaction: A common phenomenon in the regulation of transcript elongation, attenuation, and in antitermination and several other functions in the cell. (See Nagai K, Mattaj IW 1994 *RNA-Protein interactions*, Oxford University Press; ▶antitermination; Xia T et al 2005 *Proc Natl Acad Sci USA* 102:13013).

RNA, Regulatory: See antisense RNA, B2 RNA, Csr, guide RNA, microRNA, noncoding RNA, noncoding sequences, plasmid maintenance, hok-sok-mok, RNAi, 6S RNA, shRNA, siRNA, signal sequence recognition particle, 7SK RNA, snoRNA, SRA RNA, telomerase, U RNA, Xist. (See Storz G et al 2005 *Annu Rev Biochem* 74:199).

RNA Repair: Among the ~62 naturally occurring RNA modification, 20 involves methylation. Modified RNAs play important roles in the control of gene

expression and RNA folding and RNA-Protein interactions, and may affect cellular defenses. The human demethylases AlkB (14q24) and an AlkB-like protein, ABH3 (encoded at 11q11), repair both RNA and DNA. ▶DNA repair, ▶methylation of DNA, ▶methylation of RNA, ▶ribozyme; Wei YE et al 1996 Nucleic Acids Res 24:931; Aas PA et al 2003 Nature [Lond] 421:859.

RNA Replication: Some bacteriophages (R17, MS2, fd2, f4, Q β , M12) and some animal viruses such as the polio virus, the vesicular stomatitis virus, rhinoviruses (influenza viruses) and the vast majority of the plant viruses have RNA genetic material. This RNA is either single- or double-stranded. One of the best known is the Q β replicase system. The tetramer (210 kDa) is encoded one viral (β subunit about 65 kDa) and three bacterial genes (translation factors). The replicase enzyme does not have an editing exonuclease function. These replicases do not replicate or transcribe host RNAs. The replication of the RNA is similar to the replication of DNA inasmuch as all nucleic acid strands are elongated at the 3'-OH ends. (The retrovirus replication is discussed under reverse transcription.) Most of the bacterial RNA viruses and many animal viruses have the same genetic material as their mRNA (+ strand viruses). They use a replicative intermediate (RI) for the synthesis of the first new (−) strand.

The (−) strand can then generate as many (+) strands as needed. Some viruses are, however (−) strand viruses because their genetic material is not identical to the mRNA but complementary to it. The polio virus (+) strand is the genetic material that is associated with a protein at the 5'-end through a phosphodiester linkage to a tyrosine residue. The (−) strand lacks this feature. Apparently, the OH group of the tyrosine primes the synthesis of the (+) strand but the (−) strand can get by without it. The reoviruses of vertebrates contain 8–10 short double-stranded RNA molecules. When the virus enters the host cell the coat protein is shed and its RNA polymerase is activated and works conservatively and asymmetrically. A virion enzyme copies the (−) strand and a new (+) is released. The original RNA duplex is conserved. On the new (+) strand a (−) strand is made and the double-stranded RNA is reconstituted. ▶DNA replication, ▶RNA dependent RNA replication, ▶replicase, ▶replicative intermediate, ▶plus strand, ▶retroviruses; Tang H et al 1999 Annu Rev Genet 33:133; Knipe DM, Howley PM (Eds.) 2001 Fundamental Virology, Lippincott Williams & Wilkins, Philadelphia, Pennsylvania.

RNA Restriction Enzyme: In ribozymes restriction functions may exist. ▶restriction enzyme, ▶ribozyme

RNA Rewriting: ▶RNA editing

RNA, Ribosomal: ▶ribosomes

RNA, 4.5S: A bacterial RNA of 114 nucleotides. It targets signal peptide-equipped proteins to the secretory apparatus where it forms the signal-recognition particle with protein Ffh. It also binds to the translation elongation factor G. It is homologous to the eukaryotic 7S RNA. ▶Ffh, ▶secretion system, ▶RNA 7S, ▶elongation factors; Nakamura K et al 2001 J Biol Chem 276:22844.

RNA, 5S; RNA, 5.8S: ▶ribosomes; <http://biobases.ibch.poznan.pl/5SData/>.

RNA 6S: A regulator of the RNA polymerase of *E. coli*. (See Wassarman KM, Storz G 2000 Cell 101:613).

RNA, 7S: A cytoplasmic class of RNA of ~300 nucleotides, present in prokaryotes and eukaryotes. It participates in the function of RNA polymerase III and in the sequence signal recognition particle to direct proteins to the endoplasmic reticulum. The 7S RNA, which is part of the eukaryotic 35S pre-rRNA, is also a precursor of the 5.8S ribosomal RNA and the small GTPase RAN processes it. ▶RAN, ▶DNA 7S, ▶signal sequence recognition particle; Luehrsen KR et al 1985 Curr Microbiol 12:69; Suzuki N et al 2001 Genetics 158:613.

RNA, 10Sa (SsrA/tmRNA): When an mRNA is truncated at the 3'-end and has no stop codon, the ribosome may switch from one RNA to another to terminate the translation. The switching results in the generation of an 11-amino residue at the carboxyl end that destines the protein for degradation. The last 10 amino acids are translated from a stable so-called 10Sa RNA (363 nucleotides). So far, these 10 amino acids were found on murine interleukin-6 translated in *E. coli*, λ phage *cI*, cytochrome b-562, and polyphenylalanine translated on polyU. The 10Sa RNA is similar to a tRNA and it is charged with alanine. This alanine is found as the first amino acid of the tag. This saves the ribosome from the “unfinished” mRNA and permits its quasi-normal operation. The mechanism carries out the same task as ubiquitin does in eukaryotes. ▶translation non-contiguous, ▶ubiquitin, ▶lambda phage, ▶tmRNA; Gillet R, Felden B 2001 EMBO J 20:2966; Zwieb C, Wower J 2000 Nucleic Acids Res 28:169; <http://www.indiana.edu/~tmrna>.

RNA, 20S: A naked, single-stranded RNA phage-like replicon of about 2,500 nucleotides in yeast, encoding a 95 kDa RNA polymerase-like protein. Its termini are 5'-GGGGC and GCCCC-3' and therefore may circularize. (See Rodriguez-Cusino N et al 1998 J Biol Chem 273:20363).

RNA Sequencing: RNA sequencing can be done by digesting RNAs with different ribonuclease enzymes that cut the phosphodiester linkages at the specific nucleotides and then separate the fragments by gel electrophoresis (ca. 20% polyacrylamide) in one or in two dimensions. The RNA is generally labeled by ^{32}P in order to autoradiograph the dried gels. T_1 ribonuclease (from *Aspergillus oryzae*) generates fragments with 3' guanosine monophosphate ends. U_2 ribonuclease (from *Ustilago sphaerogena*) cleaves at purine residues (intermediates 2',3'-cyclicphosphates). RNase CL 3 (from chicken liver) has about 16-fold higher activity for cytidylic than uridylic linkages. RNase B (from *Bacillus cereus*) cuts Up↓N and Ap↓N bonds. RNase Phy M (from *Physarum polycephalum*) has the specificity Ap↓N and Up↓N. When several of these enzymes are employed, from the separate electrophoretic patterns, the sequences from the positions of the fragments with different termini can be deduced. In many ways the sequencing of RNAs with the aid of enzymatic breakage is very similar in principle to the Maxam and Gilbert method of DNA sequencing. Recently, RNA was sequenced by first converting it using reverse transcriptase into cDNA and then using the much easier DNA sequencing methods to determine the RNA nucleotide sequences. ▶DNA sequencing, ▶ribonucleases; Gilham PT 1970 Annu Rev Biochem 39: 227; Bachellerie J-P, Qu L-H 1993 Methods Enzymol 224:349; Kuchino Y, Nishimura S 1989 Methods Enzymol 180:154; Lane DJ et al 1988 Methods Enzymol 167:138; sequences and motifs: <http://uther.otago.ac.nz/Transterm.html>.

RNA Silencing: ▶RNAi, ▶microRNA

RNA 7SL: An approximately 300-base long molecule forming the signal recognition particle (SRP) with six proteins of 10 to 75 kDa size. (See Müller J, Benecke BJ 1999 Biochem Cell Biol 77:431).

RNA, Small: ▶snRNA

RNA Splicing: The primary RNA transcript is much larger than required for particular functions and is, therefore, cut up during processing and the transcripts corresponding to introns removed. The remaining pieces are then reattached (spliced together) to form the mature RNA molecule. ▶introns, ▶RNA processing; Weg-Remers S et al 2001 EMBO J 20:4194.

RNA, Structural: Structural RNA may have a noncoding, regulatory function in the genome (Washietel S et al 2007 Genome Res 17:852). Several computational methods are available for their analysis. ▶AlifoldZ, ▶EvoFold, ▶RNAz, ▶RNA folding

RNA Structure (SCOR): See Noller HF 2005 Science 309:1508; ▶MS2 phage; structural classification:

RNA Surveillance: RNA surveillance monitors for the presence of RNAs that have stop codon mutations, which might lead to the synthesis of truncated proteins. The nonsense mRNA is directed to P bodies for degradation by the NMD (nonsense-mediated decay) pathway (Sheth U, Parker R 2006 Cell 125:1095). In yeast, the NMD process begins by recruiting the Upf1 protein to the ribosomes. Ubf1p can bind ATP. It can also bind nucleic acids without ATP and can hydrolyze ATP in a nucleic-acid-dependent manner. Ubf1p is also an ATP-dependent 5'→3' RNA/DNA helicase. Upf32p is probably a signal transducer from Ubf1 to Ubf3, and the latter then enlists the nonsense mRNA to the NMD complex. Ubf3p is located mainly in the cytoplasm but it can shuttle between the nucleus and the cytoplasm. In yeast proteins eRF1 and eRF3, termination factors are also required for the abortion of translation. The complex also mediates the decay of the defective polypeptide if any is made. NMD systems operate in a wide range of eukaryotes and may have roles to play in some cancers and hereditary diseases of humans. ▶Pab1p, ▶Xrn1p, ▶exosome, ▶degradosome, ▶SMG, ▶SR motif, ▶P body; Culbertson MR 1999 Trends Genet 15:74; Maquat LE, Carmichael GG 2001 Cell 104:173; Ishigaki Y et al 2001 Cell 106:607; Frischmeyer PA et al 2002 Science 295:2258; Lewis BP et al 2003 Proc Natl Acad Sci USA 100:189; Chang Y-F et al 2007 Annu Rev Biochem 76:51.

RNA, Therapeutic: Therapeutic RNAs may be used in medicine as a gene function inhibitory means such as in antisense technologies and RNAi. Ribozymes may cleave pathogenic RNA molecules of infectious agents (e.g., HIV). Trans-splicing of transcripts may correct defective functions (e.g., sickle-cell disease, tumor suppressor transcripts). RNA may be used to prevent the binding of pathogenesis proteins to target (e.g., HIV-1 TAR, REV). Transfection of dendritic, antigen-presenting cells with DNA that generate mRNA for tumor antigens may boost the effectiveness of cytotoxic T lymphocytes. ▶decoy RNA, ▶RNAi, ▶aptamer, ▶ribozyme, ▶acquired immuno deficiency, ▶transsplicing, ▶CTL, ▶antigen presenting cell, ▶tumor antigen, ▶tumor suppressor; Sullenger BA, Gilboa E 2002 Nature [Lond]: 418:252.

RNA Transcript: An RNA copy of a segment of DNA.

RNA Transport: mRNA, snRNA, U3 RNA, and ribosomal RNA (but not tRNA) are exported from the nucleus by RCC1 (yeast homolog is PRP20/MTR1). This nuclear protein is a guanine nucleotide exchange factor for the RAS-like guanosine triphosphatase (GTPase). Some plant virus RNAs spread through plasmodesmata to a distance from the site of infection with the aid of protein transporters. Plants can move their own mRNAs through the phloem cells at great distances. ►**RAN**, ►**RCC1**, ►**nuclear pore**, ►**plasmodesma**, ►**phloem**, ►**transport elements constitutive**, ►**TAP**, ►**RNA export**, ►**export adaptors**; Yang J et al 2001 Mol Cell 8:397.

RNA Trap (RNA tagging and recovery of associated proteins): The purpose of the procedure is to test the mechanism of action on gene expression exerted by enhancers, which are distant from a genic site. To this goal, the unprocessed RNA transcript of a specific locus with labeled oligonucleotides is hybridized to isolated cell nuclei. Horseradish peroxidase-conjugated antibodies are localized to the oligonucleotide probe. Peroxidase-activated biotinyl-tyramide covalently labels the electron-rich protein moieties by biotin in this region. From the sonicated cell fragments the biotin-conjugated chromatin is isolated by affinity to a streptavidin column. The specific sequences are then enriched by quantitative PCR. Enrichment of the locus control region—specifically the DNase hypersensitive sites—indicated by immunofluorescence analysis that one of the hypersensitive sites becomes physically associated with the gene transcribed. This technology thus supports the role of DNA looping in gene function. ►**biotin**, ►**enhancer**, ►**LCR**, ►**PCR**, ►**regulation of gene activity**, ►**streptavidin**, ►**DNA looping**; Carter D et al 2002 Nature Genet 32:623.

RNA Trimming: ►**trimming**

RNA World: RNA world existed in the pre-biotic era when RNA carried out auto- and heterocatalysis without DNA. There is evidence now that ribozymes can even catalyze nucleotide synthesis giving further support to the RNA world concept. In addition, evidence shows that RNA is involved in the catalysis of protein synthesis: (i) by encoding amino acid sequence in protein; (ii) activation of amino acids; (iii) synthesis of aminoacyl-tRNA by a reaction analogous to the aminoacyl-tRNA synthetases; and (iv) formation of peptide bonds. Highly reactive aminoacyl phosphate oligonucleotide adaptors and

RNA guides facilitate di- and tripeptide synthesis in a single guide sequence-dependent manner without ribosomes or ribozymes (Tamura K, Schimmel P 2003 Proc Natl Acad Sci USA 100:8666). ►**origin of life**, ►**ribozyme**, ►**autocatalytic function**, ►**heterocatalysis**, ►**peptide nucleic acid**, ►**protein synthesis**; Kumar RK, Yarus M 2001 Biochemistry 40:6998; Joyce GF 2002 Nature [Lond] 418:214; Szabó P et al 2002 Nature [Lond] 420:340; Yarus M 2002 Annu Rev Genet 36:125; Spirin AS 2002 FEBS Lett 539:4; Gilbert W 1986 Nature [Lond] 319:P618.

RNA-Dependent RNA Polymerase: ►**RNA-dependent RNA polymerase**

RNA-Directed DNA Methylation (RdMD): A sequence-specific silencing of DNA. The methylation may be limited to as short as 30-base sequences but it extends generally to longer stretches (Pélissier T, Wassenegger M 2000 RNA 6:55). Argonaute 4 plays both catalytic and non-catalytic roles in DNA methylation through the RNAi pathway (Qi Y et al 2006 Nature [Lond] 443:1008). Transcriptional silencing via RNA-directed DNA methylation and chromatin modification involves two forms of nuclear RNA polymerase IV (Pol IVa and Pol IVb), RNA-dependent RNA polymerase 2 (RDR2), DICER-LIKE3 (DCL3), ARGONAUTE4 (AGO4), the chromatin remodeler, DRD1, and the de novo cytosine methyltransferase, DRM2 (Pikaard CS 2006 Cold Spring Harbor Symp Quant Biol 71:473). ►**methylation of DNA**, ►**epigenetics**, ►**argonaute**, ►**RNAi**; Wassenegger M et al 1994 Cell 76:567; Mette MF et al 2000 EMBO J 19:5194.

RNAi (RNA-mediated genetic interference): Single or double-stranded RNA, formed or introduced into the cell, may interfere with the translation of the endogenous genes of *Caenorhabditis* or plants, *Drosophila* or mammals. Apparently, *Saccharomyces cerevisiae* lacks miRNA and RNAi capabilities. The miRNAs (~22 nucleotides) are very similar to RNAi but they are produced from foldback DNA. They can cleave hundreds of mRNAs or repress their translation and thereby regulate the function of genes involved in the regulation of plant and animal development (Bartel DP 2004 Cell 116:281). Short synthetic RNAs may also evoke interference. The double-stranded RNA is at least an order of magnitude more potent. In the nematode, the most effective exogenous delivery, to any part of the body, is through the intestines. The effective pre-RNAi length is 2,000—1,000 nucleotides. RNAi is ATP-dependent, but it is not linked to mRNA translation. There is now evidence that the effect of RNAi is enzymatic (RNAi nuclease) and involves the degradation of the mRNA rather than some kind of antisense mechanism. The nascent dsRNA, generated

by RNA-dependent RNA polymerase, is degraded to eliminate the incorporated mRNA and new cycles of dsRNAs are produced that yield new siRNAs (short interfering RNAs), and secondary siRNAs (Lipardi C et al 2001 Cell 107:297). The secondary siRNAs are the products of the action of RNA-directed RNA polymerase versus the primary siRNAs, which are the products of the action of Dicer nuclease. The secondary siRNAs, in contrast to the primary siRNAs, do not have mismatches to their target (Sijen T et al 2007 Science 315:244). The siRNA (21–22 nucleotides) combines with proteins (RISC [RNA-induced silencing complex]) that degrade the RNAs recognized by siRNA (Martinez J et al 2002 Cell 110:563). siRNA is also involved in chromatin remodeling by the nucleolar RNA processing center (localized in the Cajal bodies) involving RNA-dependent RNA polymerase, DICER-LIKE3, ARGONAUTE4 and the largest subunit RNA polymerase IV b (Pontes O et al 2006 Cell 126:79; Li CF et al 2006 Cell 126:93). RNA silencing by siRNA in both plants and animals may be mediated by the methylation of DNA and histone H3 lysine⁹ (Kawasaki H, Taira K 2004 Nature [Lond] 431:211).

For high effectiveness of RNAi in the mammalian system the antisense strand should have A/U at the 5' end and the 5' end should have a 7-base pair AU-rich sequence. At the 5' end of the single-strand there should be G/C. There should be no more than a 9 bp long GC stretch present (Ui-Tei K et al 2004 Nucleic Acids Res 32:936). The secondary siRNA may spread 5' to the original target sequence of the mRNA and this new RNA has been called transitive RNAi. This phenomenon may lead to the silencing of many genes with each siRNA and provide a means for revealing their function (Chi J-T et al 2003 Proc Natl Acad Sci USA 100:6343). Genome-wide analysis of growth and viability of *Drosophila* cells using high throughput RNAi screen with 19,470 double-stranded RNAs identified ~91% of the genes involved in these functions. Many of these genes had no known mutant alleles before (Boutros M et al 2004 Science 303:832).

Theoretically, siRNA appear ideal for therapeutic purposes but their practical application faces several hurdles. Although invertebrate cells readily take up siRNA, the majority of cells of vertebrates do not absorb it efficiently enough to bring about gene silencing (see Fig. R91). Direct injection or delivery

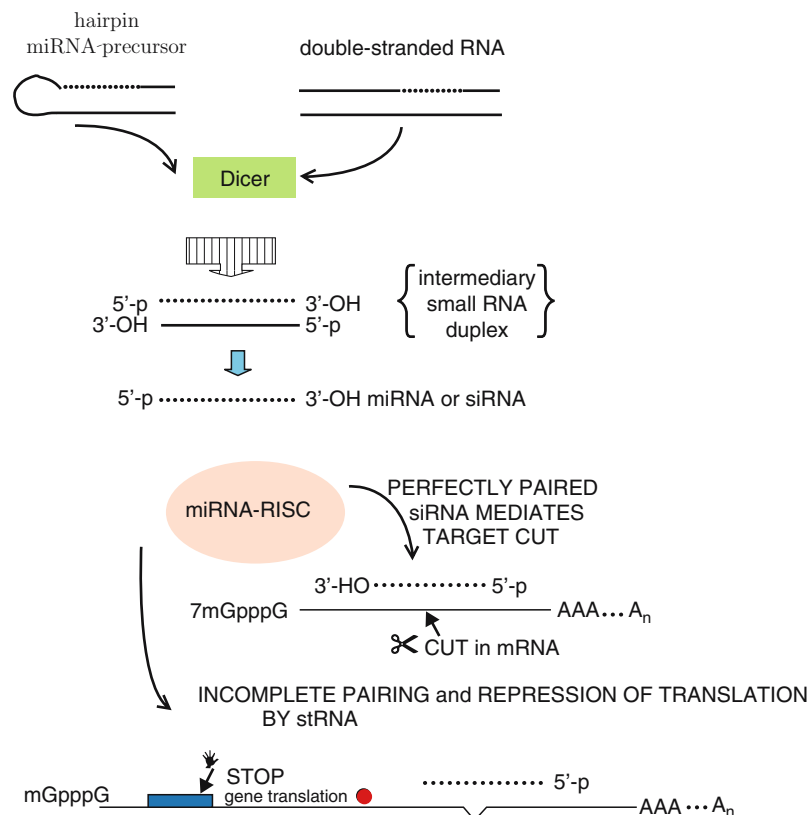

Figure R91. A model of the roles in gene silencing by miRNA, stRNA and RNAi (Modified after Hutvagner G and Zamore PD 2002 Science 297:2056)

by cationic lipids into the retina or into the genital tract seems to be more successful and may provide help in age-related macular degeneration or in viral infections, e.g., corona virus (SARS) in the lung. There are promises for treatment of local inflammatory lesions. New vehicles of delivery to internal organs are under exploration; these include liposomes or nanoparticles. siRNA-binding antibody fragments with fusion proteins may target special cells (tumors, HIV-infected lymphocytes). The free siRNA has a very short half-life in the body but once it is incorporated into the RISC complex it may survive for weeks. Unintended targets may be adversely silenced by siRNA. Chemical modification of the second residue in the active siRNA strand may prevent off-target problems. Other problems may involve triggering inflammatory, immune or interferon reactions by the body to the siRNA resembling viral RNA. The cells may become resistant to siRNA if the viral or cancer targets undergo mutational changes. siRNA may also adversely affect endogenous microRNAs (see, for excellent reviews, Dykxhoorn DM, Lieberman J 2006 Cell 126:231; Kim DH, Ross JJ 2007 Nature Rev Genet 8:173)

An shRNA/siRNA library targeting 9,610 human and 5,563 mouse genes is also available (Paddison PJ et al 2004 Nature [Lond] 428:427; see also Berns K et al 2004 *ibid*:431). In organisms, which have not been sequenced or annotated there are, in some cases, difficulties with the use of the RNAi technology. To overcome these problems, siRNA libraries were constructed containing all possible permutations. These were obtained by the use of a plasmid vector containing two convergent RNA III polymerase promoters. This procedure facilitated the construction of 5×10^7 siRNA-encoding plasmids in a single vessel. Such a library permitted genome-wide screening on the basis of phenotype (Chen M et al 2005 Proc Natl Acad Sci USA 102:2356). RNA polymerase II can synthesize a short hairpin RNA with a special green fluorescent protein coupled marker and good function (Zhu H et al 2005 Nucleic Acids Res 33(6):262). A pDECAP vector, expressing double-stranded RNA from an RNA polymerase II promoter that lacks the 5'-cap and the 3'-polyA tail transcript is not exported to the cytoplasm where it would encounter interferons, which would destroy it. The induction of an interferon response may cause general rather than specific silencing. The introduction of double-strand RNAs activates protein kinase PKR in the animal cell which phosphorylates and inactivates the eukaryotic translation initiation factor eIF2a. This causes general inactivation of many genes in the same way as an antiviral response. By keeping it within the animal nucleus it can be used to knock down specific genes by the double-stranded

RNA transcript of a transcriptional corepressor gene (Shinagawa T, Ishii S 2003 Genes Dev 17:1340). In cases when RNAi inactivates more than the target gene, the rescue of the critical gene is feasible by transforming the cell with the aid of a bacterial artificial chromosome carrying an RNAi-resistant transgene from a related species (Kittler R et al 2005 Proc Natl Acad Sci USA 102:2396). If a gene-specific siRNA sequence is inserted between two opposing promoters such as the mouse U6 and human H1, sense and antisense strands of the same template results in the mammalian cell after transfection. The construction of siRNA expression cassettes can be used in a high-throughput manner to scan targets genome-wide (Zheng L et al 2004 Proc Natl Acad Sci USA 101:135). siRNAs can be generated efficiently by restriction enzymes (Sen G et al 2004 Nature Genet 35:183; Shirane D et al 2004 Nature Genet 36:189). In *Caenorhabditis* genes, *rde-1*, *-2*, *-3*, *-4* control this interference. RDE-1 and RDE-4 proteins seem to practice surveillance for the presence of double-stranded RNA, and transposons and RDE-2 and RDE-3 (and MUT-7) degrade these RNA molecules as a defense mechanism. The mut-7 gene controls RNA interference and transposon silencing in *Caenorhabditis*. The two strands of the targeted double-stranded RNA are cleaved into 21–23- (or 25-) nucleotide long segments (siRNAs [short interfering RNAs] and stRNA [small temporal RNA]). The siRNA degrades its target whereas the regulatory stRNA represses translation of its target mRNA. There appear to be two RNase III motif enzymes involved in their processing from precursors RNAs. One, the initiator enzyme, Dicer, generates a ~22 nucleotide guide that marks the mRNA for further degradation by the RISC (RNA-induced silencing complex), an effector ribonuclease complex. Dicer-1 has specificity for single-stranded RNA and Dicer-2 (R2D2) cuts double-stranded RNA. R2D2 also selects the proper strand for association with the Argonaute component of RISC (Tomari Y et al 2004 Science 306:1377). The silencing is highly specific and yet the interference may affect related genes too; the effect may vary in degree in the various tissues. The dsRNA precursor of RNAi is transported within the body by the transmembrane protein SID-1 (Feinberg EH, Hunter CP 2003 Science 301:1545). The interference can also be transmitted to the progeny although, most probably, posttranslational events are involved. The protein product of the gene is homologous with the 3'-5' exonuclease domains of RNaseD and the Werner syndrome protein. By establishing a library of DNA clones in a bacterium, which produces double-stranded RNA (RNAi/shRNA) and fed to post-embryonic *Caenorhabditis*, the function of a large number of hitherto unknown

ORF could be identified by the silenced phenotype. Or, in case of genes controlling cell division by the use of in vivo, time-lapse differential interference contrast microscopy. The *eri-1* mutants of *Caenorhabditis* encode an evolutionarily conserved protein domain, homologous to nucleic acid-binding and exonuclease proteins. The *ERI-1* gene product (and its human homolog) degrades siRNA and thus negatively regulates RNAi (Kennedy S et al 2004 Nature [Lond] 427:645). A genome-wide study of *Caenorhabditis* revealed 90 proteins, including Piwi/PAZ, DEAH helicases, DNA binding/processing factors, chromatin-associated factors, DNA recombination proteins, nuclear export/import factors and 11 known components of the RNAi machinery within the interference pathway (Kim JK et al 2005 Science 308:1164). A genome-wide library of *Drosophila melanogaster* RNAi transgenes, extending to 88% of the genome, enables the conditional inactivation of gene function in specific tissues of the intact organism (Dietzl G et al 2007 Nature [Lond] 448:151).

In plants, the same mechanism can account for co-suppression and VIGS. In plants, two types of mechanism account for viral RNA silencing: (i) The helper component-proteinase (HC-Pro) derived from the potyviruses, which is very efficient and can silence a broad range of plant viruses and transgene-induced as well as VIGS silencing; (ii) The potato virus X (PVX) p25, which is much less effective and its action targets systemic silencing. *Arabidopsis* has four Dicer enzymes. The Dicer-like 4 (DCL4) complex confers antiviral immunity but it can be suppressed by a viral factor. Both DCL4 and DCL2 have to be suppressed for a suppressor-deficient virus to achieve systemic infection and cause bleaching (see Fig. R92) (Deleris A et al 2006 Science 313:68).

Figure R92. Photobleaching

These small RNAs may fight (HIV, Hepatitis viruses, cancer) and suppress transposons. The viral suppression of miRNAs may be responsible for some

of the disease symptoms (Kasschau KD et al 2003 Dev Cell 4:205). Some endogenous proteins can also mediate gene silencing in plants and in *Caenorhabditis* or *Drosophila*. RNAi technology may also be applied to human pathogenic viruses such as HIV (Jacque J-M et al 2002 Nature [Lond] 418:435). The therapeutic application of RNAi technology appears promising. Systemic delivery of siRNA in liposomes by intravenous injection into nonhuman primates seems very effective. Within 24–48 h after injection it showed precise targeting of apolipoprotein B and the biological effect lasted for 11 days at the highest dose (Zimmermann TS et al 2006 Nature [Lond] 441:111). Interfering RNAs have sequence-specificity for silencing but the specificity is not absolute. The siRNA technology combined with targeting specific dominant disease alleles (Machado-Joseph/spinocerebellar ataxia type 3 or Pick disease/tau) can specifically inhibit a disease symptom in a highly discriminating manner (Miller VM et al 2003 Proc Natl Acad Sci USA 100:7195). RNAi can specifically eliminate new single nucleotide mutations in the SOD1, amyotrophic lateral sclerosis alleles (Ding HG et al 2003 Aging Cell 2:209).

siRNA microbicides targeted to the Herpes simplex virus 2 envelope glycoprotein and DNA-binding protein. siRNA microbicides targeted to Herpes simplex virus 2 envelope glycoprotein and DNA-binding protein and thymidine kinase provided effective protection by vaginal application against the lethal effects of Herpes in mice. The treatment protected the animals even if applied one day after the infection and provided protection for several days. No adverse interferon effects occurred. This approach appears promising in the fight against sexually transmitted diseases (Palliser D et al 2006 Nature [Lond] 439:89). Although targeting of siRNAs to the proper disease sites and their maintenance in the cells is difficult, chemical modifications substantially improve their therapeutic potential (Soutschek J et al 2004 Nature [Lond] 432:173). Recently, reservations emerged concerning the specificity of siRNAs for effective medical treatment because the RNA molecules also hit unintended targets in some studies (Jackson & Linsley 2004 Trends Genet. 20:521). Certain mismatches between siRNA and the target abolish silencing effects. This may be due either to the failure of accessing the RISC complex or the inability of base recognition in the target. A study of the 57 all possible single-nucleotide mutations in the CD46 siRNA (siCD46) revealed that in this case mismatches between A and C bases as well in the G:U wobble pair were well tolerated, but alterations at other sites involved degradation of the target mRNA (Du Q et al 2005 Nucleic Acids Res 33:1671). The RNAi-induced silencing may be transmitted to

several generations of *Caenorhabditis* although the penetrance may not be more than 30% and the expressivity may vary (Vastenhouw NL et al 2006 Nature [Lond] 442:882).

The average silencing activity of randomly selected siRNAs is as low as 62%. Applying more than five different siRNAs may lead to saturation of the RNA-induced silencing complex (RISC) and to the degradation of untargeted genes. Therefore, selecting a small number of highly active siRNAs is critical for maximizing knockdown and minimizing off-target effects. To satisfy these needs, a publicly available and transparent machine learning tool is available that ranks all possible siRNAs for each targeted gene. Support vector machines (SVMs) with polynomial kernels and constrained optimization models select and utilize the most predictive effective combinations, thermodynamic, accessibility and self-hairpin features. This tool reaches an accuracy of 92.3% in cross-validation experiments (Ladunga I 2007 Nucleic Acids Res 35:433; <http://optirna.unl.edu/>).

Curiously, 21-nt dsRNAs targeted to selected promoter regions of human genes of E-cadherin, p21, and VEGF boost the expression of the genes rather than dampen it. The dsRNA mutation at the 5' end of the antisense strand, or "seed" sequence, is critical for activity. Mechanistically, the dsRNA-induced gene activation requires the Argonaute 2 (Ago2) protein and is associated with a loss of lysine-9 methylation on histone 3 at dsRNA-target sites (Li LC et al 2006 Proc. Natl. Acad. Sci. USA 103:17337). Multiple duplex RNAs complementary to the progesterone receptor (PR) promoter increase the expression of both PR protein and RNA after transfection into cultured human breast cancer cells. Upregulation of PR protein reduced the expression of the downstream gene encoding cyclooxygenase 2 but did not change concentrations of the estrogen receptor. This demonstrates that activating RNAs can predictably manipulate physiologically relevant cellular pathways. Activation decreased over time and was sequence specific. Chromatin immunoprecipitation assays indicated that activation is accompanied by reduced acetylation at histones H3K9 and H3K14 and by increased di- and trimethylation at histone H3K4 (Janowski BA et al 2007 Nature Chem Biol 3:166).

RNAIII/rnaiii: A bacterial virulence-controlling molecule. It is induced by the RNAIII activating protein (RAP). The RIP protein produced in non-pathogenic strains competes for activation of rnaIII and the production of *Staphylococcus aureus* toxin. ▶RAP; Balaban N et al 2001 J Biol Chem 276:2658.

RNA-IN: The leftward transcript of the bacterial transposase gene in transposable elements, transcribed from the pIN promoter. ▶RNA-OUT, ▶Pin

RNA Interference: ▶RNAi

RNA-Mediated Gene Activation: ▶RNAi

RNA-Mediated Recombination: RNA-mediated recombination is thought to be involved in the exchange between the reverse transcript and the corresponding cellular allele. The Ty element-mediated recombination is supposed to involve RNA. ▶Ty; Derr LK et al 1991 Cell 67:355.

RNA-OUT: A transcript originating from the strong pOUT promoter of bacterial transposable elements. It opposes pIN and it directs transcription toward the outside end of the IS10 element. ▶RNA-IN, ▶pIn, ▶pOUT, ▶Tn10

RNAP: RNA polymerases; in prokaryotes there is only one DNA-dependent RNA polymerase whereas in eukaryotes RNA Pol I, Pol II, and Pol III are found. ▶RNA polymerases

RNA-PCR: A polymerase chain reaction may amplify rare RNAs after the RNA is reverse-transcribed into DNA. ▶polymerase chain reaction, ▶reverse transcripts

RNA-Peptide Fusions: Synthetic mRNAs can be fused to their encoded polypeptides when the mRNA carries puromycin, a peptidyl acceptor antibiotic at the 3'-end. After in vitro enrichment, proteins can be selected in a directed manner. ▶directed mutation, ▶evolution; Roberts RW, Szostak J 1997 Proc Natl Acad Sci USA 94:12297.

RNA-Protein Interactions: RNA-protein interactions are ubiquitous in all cells in the formation of ribosomes, spliceosomes, in several ribozymes, in posttranscriptional regulation, in translation machinery (in tRNAs, elongation factors), and viral coat proteins. (See Jones S et al 2001 Nucleic Acids Res 29:943).

RNase: ▶ribonucleases

RNase-free DNase: Heat, at 100 °C for 15 min, 10 mg RNase A per mL and 0.01 M Na-acetate (pH 5.2). Then cool and adjust pH to 7.4 (1 M Tris-HCl) and store at -20 °C. ▶DNase free of RNase

RNase MRP: A ribonuclease that cleaves rRNA transcripts upstream of the 5.8 rRNA. In the mitochondria it cleaves the primers of DNA replication. ▶U RNPs, ▶cartilage hair dysplasia; Ridanpää M et al 2001 Cell 98:195.

RNASIN: A ribonuclease inhibitor.

RNAz: A computer program which combines comparative sequence analysis and structure prediction for noncoding RNAs. The measure for RNA secondary structure conservation is based on computing a consensus secondary structure and a measure for thermodynamic stability, which, in the spirit of a z score, is normalized with respect to both sequence length and base composition but can be calculated

without sampling from shuffled sequences (Washietl S et al 2005 Proc Natl Acad Sci USA 102: 2454; <http://www.tbi.univie.ac.at/~wash/RNAz>). ▶AlifoldZ, ▶EvoFold, ▶Z score

RNKP-1: A homolog of ICE and fragmentin-2. ▶apoptosis, ▶ICE, ▶fragmentin-2

RNP: A ribonucleoprotein; any type of RNA associated with a protein particle as in the hnRNA or in the ribosomes. Proteins bind only single-stranded sequences of RNA. In the recognition of the bases, the shape and charge distribution of the RNA are also important. ▶RNA, ▶hnRNA, ▶ribosomes

RNR: ▶ribonucleotide reductase

RNS (reactive nitrogen species): ▶nitric oxide, ▶ROS

Roadmap: A project of the National Institute of Health. It was initiated in 2002 for the purpose of promoting medical research and its application for the benefit of public health. It provides technical information, support for high-risk research, and other funding (<http://nihroadmap.nih.gov>).

ROAM Mutation (regulated overproducing alleles under mating signals): Activates yeast Ty elements through the influence of the MAT gene locus. Such a system may operate if the Ty insertion takes place at the promoter of a gene and then the Ty enhancer may be required for the expression of that gene. These genes are expressed only in the *a* or *a* mating type cells but not in the diploid *a/a* cells. ▶Ty, ▶mating type determination in yeast; Rathjen PD et al 1987 Nucleic Acids Res 15:7309.

Roan: A fur color (cattle, horse) with predominantly brown-red hairs interspersed with white ones. It is common sign of heterozygosity for the *R* and *r* alleles of a gene locus. ▶co-dominance

Roberts Syndrome: The Roberts syndrome actually overlaps with the *SC phocomelia* (= absence or extreme reduction of the bones of extremities located proximal to the trunk of the body; see Fig. R93) and with the TAR syndrome involving thrombocytopenia (reduction in the number of blood platelets), mental retardation, cleft palate, etc. These three syndromes are all autosomal recessive and seem to be basically the same. They are caused by chromosomal instability. Although linkage to chromosomes 1q, 4q and 8p has been detected, the strongest linkage (lod score 13.4) pointed to 8p12-p21.2. In this tract, gene ESCO2 controls sister chromatid cohesion and the protein supposedly expresses acetyltransferase activity (Vega H et al 2005 Nature Genet 37:468). ▶chromosome breakage, ▶thrombocytopenia, ▶Holt-Oram syndrome, ▶Wiskott-Aldrich syndrome, ▶mental retardation

Figure R93. Roberts syndrome

Robertsonian Translocation (Robertsonian change):

Two nonhomologous telocentric chromosomes fused at the centromere. Or, more likely, the translocation between two nonhomologous acrocentric chromosomes. The outcome is a replacement of two telo- or acrocentric chromosomes with one clearly bi-armed chromosome. These translocated chromosomes may have preserved the centromeres of both acrocentrics and remain cytologically stable because one of the centromeres is inactivated. Robertsonian translocations are very common in mouse cell cultures but they also occur in wild natural populations, resulting in an apparent change in chromosome morphology and numbers. The telomeric region of different mouse chromosomes include a contiguous linear order of T₂AG₃ repeats that share considerable identity in the centromeric minor satellite DNA, ranging from 1.8 to 11 kb (see Fig. R94). This telomeric domain shows the same polarity and more than 99% identity

Figure R94. Late diakinesis/early metaphase I in the mouse, heterozygous for different Robertsonian translocations; 15 metacentrics in a superchain, 1 Trivalent, 2 Bivalents. The sex chromosomes are not involved in Robertsonian changes. (Courtesy Capanna E et al 1976 Chromosoma 58:341)

between nonhomologous chromosomes and may explain both the maintenance of the telomeric state and Robertsonian translocations (see Fig. R95) (Kalitsis P et al 2006 Proc Natl Acad Sci USA 103:8786). If this translocation occurs, generally a minute piece of the acrocentric chromosome is lost, but being genetically inert, it has no consequence for fitness. Robertsonian translocation may affect 1/843 human neonates. ▶translocations, ▶acrocentric, ▶telocentric, ▶fitness, ▶dicentric chromosome; Pardo-Manuel de Villena F, Sapienza C 2001 Cytogenet Cell Genet 92:342; Bandyopadhyay R et al 2002 Am J Hum Genet 71:1456.

Figure R95. Robertsonian translocation

Robinow Syndrome (RRS): A rare autosomal dominant phenotype involving, usually but not always, short stature, normal virilization but micropenis, hypertelorism of the face, etc. In the Robinow-Sorauf syndrome the main characteristic is the flattened and almost doubled big toe. An autosomal recessive Robinow syndrome included the same facial and genital features but, in addition, multiple ribs and abnormal vertebrae were present. The basic defect of the recessive RRS (9q22) is due to premature chain termination in an orphan receptor tyrosine kinase (ROR2). It is allelic to brachydactyly type B. ▶limb defects, ▶Chotzen syndrome, ▶limb defects, ▶stature in humans, ▶brachydactyly, ▶micropenis

Robo (roundabout): A *Drosophila* gene determining the straight movement of axons along the embryonal axis and preventing crossing back over the midline once a cross-over is made. Homologs exist in other eukaryotes. ▶axon, ▶slit; Simpson JH et al 2000 Cell 103:1019.

Robot Scientist: Implementing the technology of artificial intelligence makes it possible to originate hypothesis, devise experiments for their testing, carry out physical experiments in the laboratory, interpret the results, and falsify hypotheses inconsistent with test. Upon actual trials involving genes, proteins, and metabolites in the aromatic amino acid pathway of yeast, the system appeared competitive with the human performance and proved a cost decrease three-fold to 100-fold. ▶artificial intelligence; King RD et al 2004 Nature [Lond] 427:247.

Robotic Technologies: Machine operations for the performance of routine tasks in order to carry out analytical methods on a large scale and in a precise manner. For example, the robotic spotting of

thousands of nanoliter or picoliter volumes on microscope slides to an area of 1 cm². DNA that can be structurally programmed can be inserted within a two-dimensional crystalline DNA array and facilitates the construction of a nanorobotic system. Atomic force microscopy demonstrated that a rotary device was fully functional after insertion (Ding B, Seeman NC 2006 *Science* 314:1583). ▶ [atomic force microscope](#)

Robustness: A statistical concept that indicates the justification of an assumption concerning the procedures applicable to the data at hand (e.g., normal distribution). A robust statistical method is less liable to violations of the assertion. Usually, but not necessarily, the parametric methods are more robust than the nonparametric ones (because of, e.g., subjective scales). Robustness is also used in physiology to characterize the stability of the steady state under variable conditions; robustness is invariance of the phenotype despite perturbations. Robustness is inherent in all evolvable biological systems (Kitano H 2004 *Nature Rev Genet* 5:826). Genetic robustness can be associated with redundancy, epistasis, and with the function of genetic networks. The “ordered systems” of the cell are very resistant to perturbations whereas the “chaotic” systems are very susceptible to perturbations (Shumulevich I et al 2005 *Proc Natl Acad Sci USA* 102:13439). Robustness against mutation can be explained by multiple solutions to specific biological problems. Mutations can be neutral in a “neutral space” where alternative configurations can solve the same biological need. ▶ [parametric methods in statistics](#), ▶ [non-parametric methods](#), ▶ [epistasis](#), ▶ [redundancy](#), ▶ [genetic networks](#), ▶ [canalization](#); Albert R et al 2000 *Nature [Lond]* 406:378; Stelling J et al 2004 *Cell* 118:675; Wagner A 2005 *Robustness and Evolvability in Living Systems*. Princeton University Press, Princeton, New Jersey.

Rock: An RHO-associated protein serine/threonine kinase involved with microtubules of nuclear division. It induces the phosphorylation of cofilin by LIM-kinase. Caspase-3 removes an inhibitory domain of Rock 1 and that then phosphorylates the light chain of myosin. This is the main cause of the blebs on cells undergoing apoptosis. ▶ [RHO](#), ▶ [microtubules](#), ▶ [ROK](#), ▶ [LIM](#), ▶ [citron](#), ▶ [cofilin](#), ▶ [myosin](#), ▶ [apoptosis](#), ▶ [immunological surveillance for blebs](#); Sebbagh M et al 2001 *Nature Cell Biol* 3:346.

Rock-Paper-Scissors Model: An ecological dispersal, movement and interaction model based on a children's game by the same name. A rock crushes the scissors, the scissors cut paper, and the paper covers the rock. There is a complex facultative interaction here

that determines the survival of colicin-producing, colicin-sensitive and colicin-resistant strains of *E. coli* bacterium. ▶ [E. coli](#), ▶ [colicin](#); Kerr B et al 2002 *Nature [Lond]* 418:171.

Rocks: ▶ [scaffolds in genome sequencing](#)

Rocket Electrophoresis: A type of immunoelectrophoresis where antigens are partitioned against antisera. ▶ [immunoelectrophoresis](#), ▶ [antigen](#), ▶ [anti-serum](#), ▶ [electrophoresis](#); Hansen SA 1988 *Electrophoresis* 9:101.

Rodents (order *Rodentia*): A large number of species (mouse, rat, hamsters, rabbit) that have been extensively used for genetic research because of the small size of these multiparous mammals and short generation time. Mice and rats reach their sexual maturity in 1 or 2 months, and their gestation period is 19 and 21 days, respectively. They have been exploited as laboratory models for the study of cancer, antibodies, population genetics, behavior genetics, radiation and mutational responses, etc. Rodents are carriers of several human pathogens (bubonic plague [*Pasteurella pestis*], tularemia [*Pasteurella tularensis*], etc.). Several inbred strains of mice have contributed very significantly to the understanding of immunogenetics. ▶ [animal models](#), ▶ [mouse](#), ▶ [rat](#); <http://www.niehs.nih.gov/crg/cprc.htm>.

Roentgen (röntgen): A unit of ionizing radiation (X-rays). ▶ [R unit](#), ▶ [Röntgen machine](#)

Rogers Syndrome (TRMA): ▶ [megaloblastic anemia](#) (human chromosome 1q23)

Rogue: An off-type of unknown (genetic) determination.

ROI (reactive oxygen intermediates): ROI are by-products of oxidative metabolism of mitochondria, peroxisomes, and may be formed by ionizing radiation. ▶ [ROS](#); Ono E et al 2001 *Proc Natl Acad Sci USA* 98:759.

ROK: One of the multiple RHO-associated protein kinases regulating the microtubules of the spindle. ▶ [RHO](#), ▶ [spindle](#), ▶ [ROCK](#), ▶ [citron](#)

Rolling Circle: Replication is common among circular DNAs (such as conjugative plasmids [e.g., the F plasmid], double-stranded [λ phage] and single-strand phages [M13, ϕ X174], amplified rDNA minichromosomes in the amphibian oocytes). A protein nicks one of the DNA strands and remains attached to the 5'-end. The free 3'-OH terminus serves as the point of extension by DNA polymerase in such a way that the opened old strand is displaced from the circular DNA while the new strand is formed and is immediately hydrogen bonded to the old template strand (see Fig. [R96](#)). Thus, the rolling circle remains

intact and may generate new single-stranded DNAs that may be doubled later. The displaced single strand may be formed in just a single unit length of the original duplex circle or it may become a single- or double-stranded concatamer. It may also circularize in a single- or double-stranded form with the assistance of a DNA ligase to join the open ends.

Figure R96. Rolling circle replication. The (-) strand is the template for the (+) strand. The → indicates the direction of growth. The 5' end of the (+) strand attaches to the membrane (□5'). (Diagram is courtesy Gilbert W, Dressler D 1968 Cold Spring Harbor Symp Quant Biol 33:473. Electronmicrograph is the courtesy of Dr. Nigel Godson)

Rolling circle mechanisms have been identified in the transposition of bacterial insertion elements but they are more common in eukaryotes. The transposons of eukaryotes that utilize rolling circle transposition are called Helitrons. These elements may be quite abundant in eukaryotes but are hard to detect by the common computer programs because they do not generate target site duplications like the majority of transposable elements. Many of them are non-autonomous in transposition. Helitrons do not have inverted terminal repeats. Their 5' end begins with TC nucleotides and the 3' end is CTRR [R stands for purine]. Near the 3' end they have a characteristic 16—20-nucleotide palindrome, which does not have a conserved sequence. Helitrons can pick up several genes and transpose them to other locations and thus gene collinearity is altered within the same species (Lal SK, Hannah C 2005 Proc Natl Acad Sci USA 102:9993). The *Arabidopsis*, rice, and *Caenorhabditis* Helitrons may encode about 1,500 amino acids that embed a 5' → 3' helicase-like protein and a replication A protein besides some other gene products. For transposition several host proteins are also required. Evolutionarily Helitrons may have originated from geminiviruses. (See Fig. R97) ▶conjugation, ▶conjugation mapping, ▶concatamer, ▶padlock probe, ▶insertion element, ▶palindrome, ▶replication protein A, ▶geminivirus;

del Pilar Garcillan-Barcia M et al 2001 Mol Microbiol 39:494; Kapitonov VV, Jurka J 2001 Proc Natl Acad Sci USA 98:8714; Feschotte C, Wessler SR 2001 Proc Natl Acad Sci USA 98:8923.

Figure R97. Rolling circle (see Figure R96 for explanation)

Rolling Circle Amplification (RCA): A short DNA primer, which is complementary to a segment of a circular DNA, and an enzyme generate many single-stranded, concatameric copies of DNA in the presence of deoxyribonucleotide (see Fig. R98). It can produce sufficient material for microarray analysis from specific locations and can detect single-nucleotide differences. ▶microarray hybridization, ▶concatamer; Nallur G et al 2001 Nucleic Acids Res 2001 29[23]:e118.

Figure R98. Rolling circle amplification

ROM (RNA-one-Modulator): A protein of 63-amino acid residues which affects the inhibitory activity of an antisense-RNA. A transacting inhibitor of plasmid replication is also named Rop/Rom. ▶RNA I, ▶antisense technology, ▶Fanconi's anemia; Lin-Chao S et al 1992 Mol Microbiol 6:3385.

ROMA: Representational oligonucleotides microarray analysis. ▶RDA

ROMA (Romani): ▶gypsy

Roman and Arabic Numerals: See Fig. R99.

I = 1, II = 2, III = 3, IV = 4, V = 5, VI = 6, VII = 7, VIII = 8, IX = 9, X = 10, XX = 20, XXX = 30, XL = 40, L = 50, LX = 60, LXX = 70, LXXX = 80, XC = 90, C = 100, CC = 200, CCC = 300, CD = 400, D = 500, DC = 600, DCC = 700, DCCC = 800, CM = 900, M = 1000

Figure R99. Roman and Arabic numerals

Romanovs: The last Tsar of Russia, Nicholas II, and his wife and three children were executed and buried near Ekaterinburg, Russia, on 16 July 1918 after the

Bolshevik take-over of power. Seventy-five years later the bodies were exhumed and from the bone tissues, the identities of the remains were determined on the basis of mitochondrial and nuclear DNAs. Tsarina Alexandra was granddaughter and Prince Philip (husband of the present Queen of England, Elizabeth) the great grandson of Queen Victoria. Their mitochondrial DNA should be identical, as well as those of the three daughters of Alexandra. Forensic DNA analysis confirmed the expectation. Sex was determined from the bone samples by identifying the X-chromosomal amelogenin gene that is expressed in the enamel of the teeth. It is rich in GC (51%) and codes for a proline-rich protein (24%). The nuclear DNA samples confirmed the identity. The Tsar and his paternity and his mtDNA tied him to his brother (by the exhumed remains of Grand Duke Georgij) on the basis of heteroplasmy. The four other skeletons did not belong to royal family members but were of the physician and other people of the court. The two youngest children, Anastasia and Alexis, were not found in the grave. The purported identity of Anastasia with Anna Anderson was not confirmed by DNA analysis. The results of these studies have been questioned (Stone R 2004 Science 303:753), and the controversy regarding the identity of the skeletal remains continues (Science 306:407 [2004]).
 ▶DNA finger-printing, ▶heteroplasmy, ▶Tsarevitch Alexis, ▶Queen Victoria; Gill P et al 1994 Nature Genet 6:130.

ROMK: A potassium ion channel family member; it is encoded in human chromosome 11 and alternative splicing generates its isoforms. ▶ion channels, ▶isoform, ▶splicing, ▶Bartter syndrome

Ron: A cell-membrane tyrosine kinase and receptor of the macrophage stimulating protein. Both are located in human chromosome 3p21. ▶macrophage-stimulating protein, ▶HGF

Röntgen Machine: An X-ray machine (invented by WK Röntgen), producing ionizing radiation (used for induction of mutation, mainly deletions) and medical examination of the body. The dose delivered is measured by R, Rad, Rem, rep, Sv, Gy. ▶R, ▶roentgen, ▶radiation hazard, ▶radiation effects, ▶radiation threshold, ▶radiation protection, ▶radiation measurement

RO[•], ROO[•]: Reactive oxygen, hydroperoxide radical. ▶ROS

roo: ▶copia

Roof Plate: An organizing center for dorsal neural development in the embryo. ▶floor plate, ▶organizer

Root: Refer a segment of the transverse cross section in Figure R100. Roots secrete a great variety of

chemicals through their roots and transgenic plants may eventually be used to manufacture, in hydroponic cultures, various needed chemicals (see Fig. R101). The advantage of the hydroponic cultures is that the purification of the secreted substances is easier. The Rho GTPase GDP dissociation inhibitor, RhoGDI, regulates root hair development at special sites (Carol RJ et al. 2005 Nature [Lond] 438:1013). Root regeneration is mediated by auxin distribution and the expression pattern of three transcription factors (Xu J et al 2006 Science 311:385). ▶quiescent zone, ▶seed germination, ▶hydroponic culture, ▶transgenic, ▶trichostatin, ▶rho; Ryan PR, Delhaize E 2001 Annu Rev Plant Physiol Plant Mol Biol 52:527; Xie Q et al 2002 Nature [Lond] 419:1676.

Figure R100. Root cross section segment

Figure R101. Root cross section segment

Root Cap: A thin membrane-like protective shield at the tip of the roots. Genetic ablation with the aid of transformation by diphtheria-toxin transgene, driven by a root cap-specific promoter showed that transgenic plants are viable without several root tip cell layers and develop more lateral roots.

Root Nodule: ▶nitrogen fixation

Root Pressure: The guttation of a wounded stem caused by osmosis in the roots of plants.

Rooted Evolutionary Tree: The evolutionary tree indicates the origin of the initial split of divergence. ▶evolutionary tree, ▶unrooted evolutionary tree

Rop Protein: ▶RNA I

ROP (RhoGEF GTP-binding protein): ROP increases nucleotide dissociation (1,000 x) from Rop (RAS-related GTP binding protein) and associates tightly with nucleotide-free Rop. It functions as a molecular

switch in plant growth and development (Berken A et al 2005 Nature [Lond] 436:1176). ►RAS, ►GEF

ROR (retinoid-related orphan receptor): RORs are animal hormone receptors regulating *Bcl* and thus the survival of lymphocytes. They are, however, involved in the regulation of several other developmental processes too. The ROR response elements (RORE) have the AGGTCA consensus, preceded by a 5 bp A/T-rich sequence. ►*Bcl*, ►survival factors, ►IL-17; Jetten AM et al 2001 Progr Nucleic Acid Res Mol Biol 69:205.

RoRNP: A ribonucleoprotein involving the so-called Y RNA (transcript of RNA polymerase III), the 60 kDa Ro60 protein and, in some cases, also the La protein (regulator of pol III). RoRNP has been identified in all eukaryotes examined and it appears to be the target of the autoimmune diseases of lupus erythematosus and Sjögren syndrome. ►autoimmune disease; Labbe JC et al 1999 Genetics 151:143.

ROS: The reactive oxygen species that may play a detrimental role in radiation damage, modification of DNA, degenerative human diseases, plant disease, etc. Mitochondrial oxidative phosphorylation, lipid peroxidation, and induced nitric acid synthase (NOS) may produce large amounts of reactive NO (nitric oxide) and thus generate ROS. NO is a known deaminating mutagen. The production of antioxidants (vitamin C, vitamin E, glutathione, ferritin, β carotene) is the defense against ROS damage. A PPAR γ coactivator (PGC-1 α) is required for the induction of several ROS-detoxifying enzymes (such as GPx1, SOD2); it protects against neurodegeneration by ROS (St-Pierre J et al 2006 Cell 127:397). The cells may also use SOD, catalases, and peroxidases to degrade ROS. Reactive oxygen may be responsible for half of the human cancer cases. Also, deficiency of ROS (by supplying 2-methoxyestradiol) may trigger the demise of leukemia cells because cancer cells have increased aerobic metabolism. The redox enzyme p66^{Shc} generates mitochondrial hydrogen peroxide and is a signal to apoptosis. Electron transfer between cytochrome c and p66^{Shc} contributes to ROS formation, apoptosis, and aging (Giorgio M et al 2005 Cell 122:221). ►SOD, ►hydrogen peroxide, ►PPAR, ►hydroxyl radical, ►RO $^{\bullet}$, ►ROO $^{\bullet}$, ►oxidative DNA damage, ►nitric oxide, ►Fenton reaction, ►oxidative deamination, ►aging, ►host-pathogen relationship, ►photodynamic effect, ►singlet oxygen, ►ROI, ►apoptosis, ►aging; Möller IM 2001 Annu Rev Plant Physiol Plant Mol Biol 52:561; Lee D-H et al 2002 Nucleic Acids Res 30:3566.

ROS oncogene: The ROS oncogene is in human chromosome 6q22 and it is the c-homolog of the

viral v-ros. It appears to be the same as MCF. ►oncogenes

Rosa spp: Ornamentals with $2n = 14, 21, 28$. ►*Rosa canina*

Rosa canina (dog rose): A pentaploid species with 35 somatic chromosomes (see Fig. R102). Unlike other pentaploids it is fertile. In meiosis, the plants produce seven bivalents and 21 univalents. The univalents are lost at gametogenesis in the male and so the sperms contain only seven chromosomes, derived from the seven bivalents. During formation of the megaspore all the 21 univalents and the seven chromosomes from the seven bivalents are incorporated into the embryo sac. The addition of the seven male and the 28 female chromosomes to the zygote restores the 35 somatic chromosome number. The female contributes more chromosomes to the offspring; it is therefore matroclinous. Recombination is limited to the seven bivalents. Its breeding system is a unique mixture of generative and apomictic reproduction. ►pentaploids, ►apomixis, ►matroclinous, ►univalent; Gustafson Å 1944 Hereditas 30:405.

Figure R102. *Rosa canina*

Rosacea: A skin disease caused by inflammation due to persistent reddening of the skin (erythema). The antimicrobial peptides cathelicidine and serine protease levels seem to be elevated, which are involved in innate immunity, dilation of the blood vessels, leukocyte migration and wound healing responses. It may be due to candidiasis, Sjögren syndrome and other causes (Bevins, Yamasaki K et al 2007 Nature Med 13:975). ►candidiasis, ►Sjögren syndrome

Rosetta Stone Sequences: Rosetta stone sequences aid in deciphering the function of simple polypeptide sequences. Prokaryotic proteins frequently carry out the same functions as the corresponding eukaryotic ones. In eukaryotes, the homologous proteins are

frequently fused with other proteins that are required for their function whereas in prokaryotes they may appear separately as single proteins. Once the function of the fused eukaryotic proteins is known, the function of both the prokaryotic counterparts can also be inferred. For example, in *E. coli*, gyrase A and B are encoded separately but in yeast they have homology to different domains of topoisomerase II. In a sequential manner, then, functional connections can be revealed to other proteins too. ▶[phylogenetic profile method](#), ▶[gene neighbor method](#); Marcotte EM et al 1999 Science 285: 751.

Rosette: Plant shoots with greatly reduced internodes commonly found in dicots before the stem bolts after induction of flowering; any anatomical structure in animals arranged in a form resembling the petals of a rose (see Fig. [R103](#)).

Figure R103. Leaf rosette

ROSI: Also called the round spermatid injection or round spermatid nucleus injection (ROSNI). This and the elongated spermatid injection (ELSI) involve injection of haploid germ cells retrieved from testicular biopsies into recipient oocytes. These procedures help overcome male infertility when the spermatozoon is unable to penetrate the egg (Jurisikova A et al 1999 Mol Hum Reprod 5:323). ▶[ART](#)

Rossellini-Guienetti Syndrome: ▶[ectodermal dysplasia](#)

Rossmann Fold: An NAD(P)-binding domain (Gly-XXXGlyXGly) near the N-terminus, encoded by a large number of eukaryote and prokaryote genes. ▶[NADP⁺](#)

Rostral: In the direction of the beak, mouth or nose rather than toward the hind position.

***r*₀t:** In a RNA-driven DNA-RNA hybridization reaction, it is the concentration of RNA × the time of the reaction (analogous to *c*₀t in reassociation kinetic

studies with DNA). *r*₀t sheds information on the RNA complexity of different cells during development. ▶[c₀t](#), ▶[RNA driven reaction](#)

Rotamase: A group of enzymes catalyzing cis-trans isomerization. ▶[cyclophilin](#), ▶[immunophilins](#)

Rotamer: A rotational isomer involving a side chain, i.e., not the backbone of the molecule. The place of atoms is altered by rotation around single bonds.

Rotational Diffusion: A process wherein membrane proteins travel within the membranes by rotation perpendicular to the plane of the lipid bilayer. ▶[cell membrane](#)

Rotaviruses (*Reoviridae*): Their genomes consist of 10–12 double-stranded RNA and each particle carries a single copy of this genome (see Fig. [R104](#)). The terminal sequences control replication and packaging. Through internal deletions the RNAs may become aberrant, called DI RNA (defective interfering), resulting in lower infectious capacity. The rotaviruses may cause gastroenteritis (stomach and intestinal inflammation) and diarrhea in human babies and animals. The introduction of recombinant vaccinia virus T7 RNA polymerase into rotavirus generates artificial viral mRNA and can induce mutation (Komoto S et al 2006 Proc Natl Acad Sci USA 103:4646). ▶[reovirus](#), ▶[vaccinia](#)

Figure R104. Rotavirus

Rothmund-Thomson Syndrome: An autosomal recessive human disorder involving dermal (skin) lesions (see Fig. [R105](#)), dark pigmentation, light-sensitivity, early cataracts, bone and hair problems, and premature aging. It may lead to squamous (scaly) carcinomas. Autosomal dominant genes determine some similar types of diseases. One form is assigned to human chromosome 8q24.3 and another to 17q25. Both genes encode helicases; the homologs of what control recombination in yeast. ▶[cancer](#), ▶[light-sensitivity diseases](#); helicase: Sangrithi MN et al 2005 Cell 121:887).

Figure R105. Rothmund syndrome skin lesions. (From Bergsma D (Ed.) 1973 Birth Defects. Atlas and Compendium. By permission of the March of Dimes Foundation)

Rotor Syndrome: ▶Dubin-Johnson syndrome

Rough Draft of the Syndrome: A not complete sequence of a genome and yet it displays the sequences of about 90% of the euchromatic parts, containing the coding units. ▶human genome, ▶genome projects

Rough ER: ▶endoplasmic reticulum rough, ▶RER

Round of Matings: After bacteriophages have been replicated within the host cell, the newly formed molecules of “vegetative DNAs” may recombine with each other several times. Because of the multiple exchanges (in agreement with the Poisson distribution expectations), it appears that the maximal recombination between markers cannot exceed 30–40%. ▶mapping function, ▶negative interference, ▶coefficient of coincidence; Visconti N, Delbrück M 1953 Genetics 38:5.

Rous Sarcoma: Rous sarcoma was originally detected as a viral RNA cancer in chickens. The protooncogene homolog was detected in rats and other mammals. ▶RAS and homologs, ▶oncogenes, ▶TV/RCAS

Rowley-Rosenberg Syndrome: An autosomal recessive growth retardation, different from dwarfism, and characterized by aminoacidurias. ▶dwarfism, ▶aminoacidurias

RPA: A single-strand DNA-binding protein (of subunits of 70, 34 and 14 kDa) participating in replication, nucleotide excision repair, repair of double-strand breaks by recombination. ▶replication protein A, ▶DNA replication eukaryotes, ▶NER, ▶BER, ▶UNG2; Davis AP, Symington LS 2001 Genetics 159:515.

RPB: Subunits (differently numbered, each) of RNA polymerase II. ▶RNA polymerase

RPD3/Sin3: A histone deacetylase and a component of the Mad/N-CoR/Sin3/RPD transcriptional protein repressor complex. It may also block the position effect exerted by centromeric and telomeric heterochromatin. ▶position effect, ▶PEV, ▶histone, ▶histone deacetylase, ▶Mad, ▶N-CoR, ▶signal transduction, ▶repression, ▶transcription, ▶Sin3; Fazio TG et al 2001 Mol Cell Biol 2001 21:6450.

R-Phycocerythrin: A phycobiliprotein fluorochrome isolated from algae. Maximal excitation is at 545 and 565 nm but it is also excited at 480 nm. Maximal emission is at 580 nm and hence the red color.

rpo: RNA polymerases such as A, B, C₁, C₂ in (organelles) plastids and mitochondria and resembles bacterial RNA polymerases. ▶RNA polymerase, ▶σ

RPPA: ▶reverse-phase protein array

r-Proteins: Ribosomal proteins. ▶ribosome

RPTK (ROS receptor protein tyrosine kinase): A sperm receptor protein tyrosine kinase that may bind to the ZP3 (zona pellucida) protein of the egg matrix. These proteins, in various stages of cooperation, affect several cellular processes. ▶sperm, ▶egg, ▶fertilization; Zeng L et al 2000 Mol Cell Biol 20:9212.

RRAS: ▶RAS oncogene

RRE (Rev response element): An RNA export adaptor promoting the export of the HIV-1 transcripts from the nucleus. If an RRE is inserted into an intron (which normally retained within the nucleus), even that could be exported to the cytoplasm. ▶export adaptors, ▶acquired immunodeficiency; Zhang Q et al 2001 Chem Biol 8:511.

rrn: In *E. coli* there are seven ribosomal transcription units, *rrn-A*, *-B*, *-C*, *-D*, *F*, *-G*, *-H* including the 16S-23S-5S RNAs, spacers and intercalated tRNA genes within the spacers. Maturation involves trimming of the co-transcript (cleavage by RNase III) and processing by other RNases, RNases P and D (See Fig. R106). The number of rRNA genes in eukaryotes is very variable and subject to amplification. At the developmental stages of very active protein synthesis the number of ribosomal genes may be amplified to several thousands, and, e.g., in the amphibian oocytes may be sequestered into mini-nuclei. Eukaryotic rRNA genes are transcribed in a ca. 45S precursor RNA, containing the 18S-5.8S-28S (in this order) and

Figure R106. Segment of a eukaryotic rRNA gene cluster in transcription. (Courtesy Spring H et al 1976 J Microsc Biol Cell 25:107)

Figure R107. The DNA region of the rRNA and tRNA gene cluster (*rrn*) in *E. coli* is transcribed into longer than 30S primary transcripts, interrupted by spacers. The ribosomal and transfer RNA genes are clustered and co-transcribed in the order 5' - 26S-23S-5S-3' and within the intergenic spacers the tRNA genes are situated. RNase III at the duplex stems trims the individual gene transcripts. The different loops contain ca. 1,600, 2,900 and 120 nucleotides, corresponding to the 16S, 23S and 5S ribosomal RNAs, respectively. (The 1,600 and the 2,900 base sequences are also called p16 and p22, respectively). RNase P further trims each of these rRNA precursors and the tRNA precursors are processed by RNase P at the 5' and by RNase D at the 3' end

spacer sequences. The pathway of trimming may vary among the different species. The 18S rRNA is immediately methylated at about 40 sites and a few more methyl groups are added in the cytoplasm after maturation. The 28S rRNA is methylated immediately after transcription at over 70 sites and these methylated sites are saved during the process of maturation. The cleavage takes place at the 5' side of the genes and between the spacers. The 5.8S rRNA eventually associates with the 28S rRNA by base pairing. (See Fig. R107, ►ribosomal RNA, ►ribosomal proteins, ►ribosomes, ►stringent response, ►stringent control, ►RNA maturases; Hirvonen CA et al 2001 J Bacteriol 183:6305).

rRNA: Ribosomal RNA; a structural component of the ribosomes. rRNAs may be preferentially amplified in the oocytes of amphibians and other organisms. ►ribosome, ►ribosomal RNA

RRS (reduced representation shotgun): A method for mapping single nucleotide polymorphism in a genome. ►SNIPS; Altshuler D et al 2000 Nature [Lond] 407:513.

RS Domain: The RS domain is rich in arginine (R) and serine (S); RS proteins are parts of the spliceosomes. ►spliceosome

RSC (remodel structure of chromatin): ►chromatin remodeling

r-Scan Statistics: Detects anomalous spacing of oligonucleotides and peptides. (Jeff AR et al 2001 Genes, Chromosomes Cancer 32:144).

RSF: ►hybrid dysgenesis I-R system

RSF: A 400–500 kDa protein complex of a 325 kDa protein and the 135 kDa hSNF2h/ISWI. ►chromatin

remodeling, ►SNF2; Labourier E et al 1999 Genes Dev 13:740.

RSK (ribosomal protein S6 kinase, RSK-3 at Xp22.2-p22.1, RSK-2 at 6q27, RSK-1 in human chromosome 3, there is also an RSK-4): An epidermal growth factor-regulated protein kinase phosphorylating histone 3; RSK-3 defect is involved in the Coffin-Lowry syndrome. MAPK-phosphorylated RSK prevents parthenogenetic development of unfertilized eggs. RSK integrates MAPK and PDK1 signaling pathways. ►Coffin-Lowry syndrome, ►EGF, ►histones, ►MAPK, ►PDK, ►S6 kinase, ►chromatin remodeling

R-Spondin: A family of proteins binding Wnt ligands to the Frizzled (Fzd) receptor and the low-density lipoprotein-related receptor (LRP) 5 or LRP6 coreceptor. They initiate downstream signaling events leading to gene activation by β -catenin and the T-cell factor (TCF)-lymphoid enhancer factor (LEF) family transcription factor complex (Nam J-S et al 2006 J Biol Chem 281:13247). ►Wingless, ►lipoprotein, ►T cell receptor, ►T cells, ►LEF, ►catenins

RSR: The relative survival rate.

RSS (recombinational signal sequence): V(J)D recombinase mediates recombination only in gene segments flanked by tripartite recombination signal sequences consisting of a highly conserved heptamer (7mer), an AT-rich nonamer (9mer), and 12 or 23 base-long intervening nucleotides. ►immunoglobulin, ►V(J)D recombinase, ►RAG

Rst (*R-st*): The stippled, paramutable allele of *R* locus of maize in the long arm of chromosome 10. ►paramutation, ►R locus. (See Fig. R108).

Figure R108. Rst Kernel

R_{ST}: The same as F_{ST} but it is based on variation in microsatellites. ▶F_{ST}, ▶microsatellite

r₀t Value: The measure of RNA-DNA or RNA-RNA hybridization; the product of the concentration of single-stranded RNA and the time elapsed since the beginning of the reaction. ▶c₀t value

RTF (resistance transfer factor): Bacterial plasmids carrying various antibiotic and other resistance genes. ▶resistance transfer factors, ▶conjugation in bacteria, ▶plasmid mobilization

Rth: ▶Rad 27

RTK: ▶receptor tyrosine kinase

RTP (replication termination protein): The RTP is functionally, but not structurally, similar to Tus. ▶replication bidirectional, ▶Tus gene product; Gautam A et al 2001 J Biol Chem 276:23471.

RT-PCR: A reverse transcription-polymerase chain reaction. The purpose of the procedure is similar to the PCR in general. In this instance it amplifies the small amounts of RNA transcripts as cDNA. The reaction requires reverse transcriptase, mRNA, deoxyribonucleotides and primers that can be random DNA sequences, oligodeoxythymidine or antisense sequences. The method is very sensitive and the RNA of a single cell can be amplified and thus localized gene expression studied. Under well-controlled conditions it can be semi-quantitative. It is now used for clinical diagnostic purposes too. ▶RNA fingerprinting, ▶PCR, ▶in situ PCR, Barlič – Maganja D, Grom J 2001 J Virol Methods 95:101; <http://web.ncicrf.gov/rtp/gel/primerdb/>.

rtTA (reverse transactivator tetracycline): Basically a tTA system containing a nuclear localization signal at the 5'-end. It binds efficiently the *tetO* operator—but only in the presence of tetracycline derivatives such as doxycycline or anhydrotetracycline. ▶tTA, ▶tetracycline; Pacheco TR et al 1999 Gene 229:125.

rtTA-nls: The same as rtTA.

RU486 (mifepristone/mifeprex): A pregnancy prevention drug. It chemically induces abortion. Recently, a small number of women developed excessive bleeding and ectopic pregnancies after its use. Misopristol, the most common vaginally administered drug, in rare cases lead to deadly infection by *Clostridium sordelli* bacteria by weakening the immune system. These drugs are in wide use in Europe. RU486 has been approved in the USA since 2000. ▶hormone receptors; Mahajan DK et al 1997 Fertil Steril 68:967; DeHart RM, Morehead MS 2001 Ann Pharmacother 35:707; Schulz M et al 2002 J Biol Chem 277:26238.

RU Maize: RU maize carry plasmid-like elements in their mitochondria and yet they are not male sterile. ▶cytoplasmic male sterility, ▶mtDNA

Rubella Virus (a toga virus): The Rubella virus causes the disease of German measles. Infection during early pregnancy may cause intrauterine death of the human embryo and/or developmental anomalies in the newborn. ▶teratogenesis

Rubinstein Syndrome (Rubinstein-Taybi syndrome, RSTS, 16p13.3): The Rubinstein syndrome is characterized by dominant defects in the heart valve of the pulmonary aorta, collagen scars on skin wounds, an enlarged passageway between the skull and the vertebral column, mental retardation, and broad thumbs (see Fig. R109).

Figure R109. Rubinstein Syndrome

This condition has very low recurrence risk (1%) and about 0.2–0.3% of the inmates of mental asylums are afflicted by it. Haplo-insufficiency for the CBP transcription factor seems to be involved in the abnormal differentiation. Many afflicted individuals have break points at chromosome 16p13.3, and this is the site of the human cyclic AMP response element-binding protein (CBP/CREB). The syndrome may also be elicited by a continued requirement for CREB co-activation and histone acetylation of the CREB-binding protein (Alarcón JM et al 2004 Neuron 42:947). In addition, the p300 protein encoded by the EP300 gene (22q132) is also similar in structure to CBP and can be responsible for RSTS (Roelfsema JH et al 2005 Am J Hum Genet 76:572). ▶mental retardation, ▶CREB, ▶CBP, ▶GLI3 oncogene, ▶epigenesis; Murata T et al 2001 Hum Mol Genet 10:1071.

Rubisco: Ribulose biphosphate carboxylase-oxygenase (M_r 550,000), a chloroplast enzyme.

The eight large subunits (each M_r 56,000) are coded for by chloroplast DNA and the small subunits (each M_r 14,000) are under nuclear control (see Fig. R110). The carboxylase function catalyzes the covalent attachment of carbon-dioxide to ribulose-1,5-bisphosphate and then splits into two molecules of 3-phosphoglycerate. The oxygenase function mediates the incorporation of O_2 into ribulose-1,5-bisphosphate and the resulting phosphoglycolate re-enters the Calvin cycle. ▶chloroplast, ▶chloroplast genetics, ▶photosynthesis, ▶ribulose biphosphate carboxylase; Douce R, Neuberger M 1999 Curr Opin Plant Biol 2:214; Spreitzer R, Salvucci ME 2002 Annu Rev Plant Biol 53:449.

Figure R110. Genetic and electrophoretic evidence that the large subunits of RUBISCO are maternally inherited, whereas the small subunit is transmitted biparentally. Molecular studies mapped the large subunits in the chloroplast DNA. (After Chen K, Gray JC, and Wildman SG. See also 1975. *Science* 190:1304.)

Rudiment: Either the beginning stage of a developing structure or the remains of a decayed or reduced one.

Rule 12/23: ▶immunoglobulins, ▶V(D)J, ▶RAG

Rumex hastatulus: A North-American herbaceous plant which has variable chromosomal sex determination. The plants found in North Carolina have three pairs of autosomes, one X and two Y chromosomes. The form prevalent in Texas has four pairs of autosomes and one X and one Y chromosome. The middle line connects the positions of the centromeres. ▶sex determination, ▶chromosomal sex determination, see Fig. R111.

Figure R111. (Redrawn after Smith BW 1964. *Evolution* 18:93.)

Runaway Plasmids: At lower temperature (30 °C) runaway plasmids are present in relatively low copy number and do not interfere with the growth of the host cell. At above 35 °C their copy number rises substantially and so does the DNA they contain. Only after about 2 h (by the time they account for 50% of the DNA of the cell) do they suppress cellular growth. ▶vectors, ▶copy-up mutation; Uhlin BE et al 1983 Gene 22:255.

Runaway replication: The replication is not restricted to the normal manner. (See Chao YP et al 2001 Biotechnol Progr 17:203).

Run-off Transcription: The inducer of gene activity (e.g., light signal) is withdrawn and the tapering off of transcription is monitored by incorporation of labeled nucleotides. (See Delany AM 2001 Methods Mol Biol 151:321).

Run-on Transcription: Once the transcription is turned on in isolated nuclei it proceeds without further need for enhancers as measured by the incorporation of labeled nucleotides into mRNA. ▶transcription, ▶regulation of gene activity; Hu ZW, Hoffman BB 2001 Methods Mol Biol 126:169.

Run1 (run, 1–65): A *Drosophila* pair-rule gene encoding a DNA-binding protein/transcription factor with homologies to, e.g., CBFA1, -2, -3 core-binding factor subunits of human and mouse genes. ▶leukemia, ▶pair rule genes, ▶tandem repeats

Runx: Transcription factors, which may either activate or suppress tumorigenesis. *Runx3* may also aid the proliferation of B lymphocytes and autoimmune disease. The mouse *Shox2* gene upstream of *Runx2* is a key regulator of chondrogenesis and long-bone development (Cobb J et al 2006 Proc Natl Acad Sci USA 103:4511). In hematopoietic stem cells, Smad6, an inhibitor of Bmp4 signaling, binds and inhibits Runx1 activity, whereas Smad1, a positive mediator of Bmp4 signaling, transactivates the *Runx1* promoter. Three key determinants of HSC development are the Scl (small cell lung) transcriptional network, Runx1 activity, and the Bmp4/Smad signaling pathway (Pimanda JE et al 2007 Proc Natl Acad Sci USA 104:840). Runx2 is also involved in the control of RNA polymerase I promoter and associated proteins (Young DW et al 2007 Nature [Lond] 445:442). During mitosis, when transcription is shut down, Runx2 selectively occupies target gene promoters, and Runx2 deficiency alters mitotic histone modifications (Young DW et al 2007 Proc Natl Acad Sci USA 104:3189). ▶lymphocytes, ▶mesenchyma, ▶osteoblast, ▶Smad, ▶Bmp, ▶small cell lung carcinoma; Spender LC et al 2005 Oncogene 24:1873; Sato T et al 2005 Immunity 22:317.

Rupert: The hemophiliac grandson of Leopold of Albany (a hemophiliac himself), son of Queen Victoria. ▶[hemophilias](#), ▶[Queen Victoria](#)

Russell-Silver Syndrome (RSS): Most commonly autosomal recessive (7p11.2-p13, 17q23-24, 15q26.1-qter, 11p15), but X-linked or sporadic cases with low birth-weight dwarfism, frequently with asymmetric body and limbs, deformed fingers, relatively large skull and mental retardation are common. The 7p site is closely associated with the location of the genes encoding growth factor receptor-binding protein 10 and the insulin-like growth factor-binding proteins 1 and 3. Maternal disomy, at least for a 35 Mb sequence, appears to account for the symptoms. ▶[dwarfism](#), ▶[stature in humans](#), ▶[imprinting](#), ▶[uniparental disomy](#); Hannula K et al 2001 *Amer J Hum Genet* 68:247; Nakabayashi K et al 2002 *Hum Mol Genet* 11:1743.

Rust: Disease of grasses (cereals) caused by *Puccinia graminis*. *Puccinia* fungi display rust color pustules (see Fig. R112). Resistance in barley is based on a receptor-like serine/threonine kinase protein (Nirmala J et al 2006 *Proc Natl Acad Sci USA* 103:7518). New aggressive variants of *Puccinia graminis* are threatening existing resistant wheat varieties. ▶[host-pathogen relations](#); Staples RC 2000 *Annu Rev Phytopath* 38:49.

Figure R112. *Puccinia trititica* (Courtesy of Dr ER Sears)

Rut: ▶[oestrus](#)

RuvABC: A protein complex operating in the Holliday structure of recombination. The RuvAB helicase/ATPase and motor protein complex mediates branch migration (also through nucleosomes in eukaryotes) and replication. RuvC is an endonuclease. ▶[branch migration](#), ▶[Holliday juncture](#), ▶[recombination molecular mechanisms in prokaryotes](#), ▶[recA](#), ▶[endonuclease](#), ▶[AAA proteins](#); West SC 1997 *Annu Rev Genet* 31:213; Constantinou A et al 2001 *Cell* 104:259; Yamada K et al 2001 *Proc Natl Acad Sci USA* 98:1442.

RVs: ▶[BIN](#)

RXR: ▶[RAR](#)

Ryanodine (ryanodol 3-[1H-pyrrole-2-carboxylate]): A toxic extract (insecticide) from the new world tropical shrub *Ryania speciosa*. It regulates calcium ion channels in muscles. The mutation of deletion of the ryanodine receptor gene (RYR1, 19q13.1) may lead to malignant hyperthermia. ▶[ion channels](#),

▶[central core disease](#), ▶[hyperthermia](#); Zalk R et al 2007 *Annu Rev Biochem* 76:367.

Rye (*Secale cereale*): $2n = 2x = 14$ is an outbreeding crop plant used for the production of bread, biscuits, starch, and alcohol.

Its taxonomy is somewhat controversial. Rye can be crossed with a number of other cereals; among them the allopolyploid *Triticale* (wheat \times rye hybrids, $2n = 42$ and $2n = 56$) are most notable. Addition lines and transfer lines carrying rye chromosomes or chromosomal segments have been made. Rye belongs to those exceptional grain crops where autotetraploid varieties have agronomic value. Trisomic lines are known. Some varieties harbor a variable number of B chromosomes (see Fig. R113). Rather unusually, some of the plastids are also transmitted through the pollen. ▶[chromosome banding](#), ▶[Triticale](#), ▶[alien addition](#), ▶[chromosome substitution](#), ▶[alien substitution](#), ▶[transfer lines](#), ▶[holocentric](#), ▶[ergot](#); <http://www.tigr.org/tdb/tgi.shtml>.

Figure R113. Giemsa-stained rye karyotype displaying an isochromosome (⇔) and the corresponding arm in a normal chromosome (→). (Courtesy Dr. Gordon Kimber)

Ryegrass: *Lolium multiflorum* and *L. perenne*, both $2n = 14$ (see Figs. R114 and R115).

Figure R114. Rye ear

Figure R115. Ryegrass ear

Historical vignettes

George W. Beadle recollections (Stadler Genetics Symp. 2:114) about Archibald E. Garrod discoveries of inborn errors of metabolism beginning in 1899 and Richard Goldschmidt's classical book of *Physiologische Theorie der Vererbung* 1927 (Springer, Berlin).

"I recall giving a lecture at the University of California, Berkeley, in the mid-forties in which I recounted this remarkable story of the neglect of GARROD's work. RICHARD GOLDSCHMIDT, then on the faculty of that university was in the audience. He told me after the lecture that he could not understand how he had omitted mention of GARROD's work in his well-known book *Physiological Genetics* and that he had indeed been well aware of it, but had forgotten about it when he wrote the book. That seems to me a pretty good indication that he had not really appreciated its significance, much as de VRIES had not properly assessed the work of MENDEL when he first read about it."

At the January 6-8, 1909 meeting of the American Breeder's Association the above paper was presented in Columbia, Missouri.

AMERICAN BREEDERS' ASSOCIATION. 365

WHAT ARE "FACTORS" IN MENDELIAN EXPLANATIONS?

BY PROF. TH MORGAN.

Columbia University, New York, N. Y.

In the modern interpretation of Mendelism, facts are being transformed into factors at a rapid rate. If one factor will not explain the facts, then two are invoked; if two prove insufficient, three will sometimes work out. The superior jugglery sometimes necessary to account for the results may blind us, if taken too naively, to the common-place that the results are often so excellently "explained" because the explanation was invented to explain them. We work backwards from the facts to the factors, and then, presto! explain the facts by the very factors that we invented to account for them. I am not unappreciative of the distinct advantages that this method has in handling the facts. I realize how valuable it has been to us to be able to marshal our results under a few simple assumptions, yet I cannot but fear that we are rapidly developing a sort of Mendelian ritual by which to explain the extraordinary facts of alternative inheritance. So long as we do not lose sight of the purely arbitrary and formal nature of our formulae, little harm will be done; and it is only fair to state that those who are doing the actual work of progress along Mendelian lines are aware of the hypothetical nature of the factor-assumption. But those who know the results at second hand and hear the explanations given almost invariably in terms of factors, are likely to exaggerate the importance of the interpretations and to minimize the importance of the facts.

S

S (such as in 5S RNA): ►sedimentation coefficient

s: ►selection coefficient

s: Standard deviation of a set of experimental observations. ► σ parametric

σ : The measure of superhelical density of DNA.

σ : A subunit of prokaryotic RNA polymerase enzyme, essential to start transcription in a specific way. This factor opens the double helix for the action of the RNA polymerase. Also, the σ^{70} is involved in pausing of transcription. The σ^{70} recognition sites consist of two hexamers located at -10 and -35 positions from the transcription start point. The sigma factor can melt promoter independently from the RNAP (polymerase) protein (Hsu H-H et al 2006 Cell 2006 127:317). The σ^{70} s are in excess of the polymerase enzyme and there is a competition for the enzyme molecules among the σ^{70} units (Grigorova I et al 2006 Proc Natl Acad Sci USA 103:5332). The σ^{38} subunits are used at the stationary phase of growth. σ^{28} is a minor subunit transcribing only less than two dozen genes. σ^{54} , another minor subunit binds to the promoter even in the absence of the core polymerase. In the synthesis of stress proteins σ^{32} and σ^{24} are used. Usually the σ^{70} is released from the polymerase (RNAP) at the beginning of the elongation of the transcript or shortly afterwards. However, some of them stay on throughout elongation and regulate gene expression depending on the cellular circumstances. The σ elements are complexed with anti- σ proteins when not in use. In some algae the protein present in the chloroplast is encoded by the nucleus. In several plant species, the same polypeptide is coded for by the chloroplast DNA. ►RNA polymerase, ►open promoter complex, ►sigma factor, ►chloroplast, ►chloroplast genetics, ►rpo, ►Pribnow box, ►transcription factors, ►UP elements, ►DnaJ; Dartigalongue C et al 2001 J Biol Chem 276:20866; Marr MT et al 2001 Proc Natl Acad Sci USA 98:8972; Bar-Nahum G, Nudler E 2001 Cell 106:443; Kuznedelov K et al 2002 Science 295:855; Mekler V et al 2002 Cell 108:599; Nickels BE et al 2005 Proc Natl Acad Sci USA 102:4488; review: Mooney RA et al 2005 Mol Cell 20:335; anatomy of *E. coli* σ^{70} : Shultzaberger RK et al 2007 Nucleic Acids Res 35:771.

σ : The parametric designation of standard deviation. ►standard deviation, ►standard error

σ : Yeast transposable element. ►Ty

σ : A viral infectious hereditary agent of *Drosophila*. ►CO₂ sensitivity, ►infectious heredity

σ : 387 bp region intercalated between the two S elements in opposite orientation of the complex R locus of maize. ►paramutation, ►tissue specificity, ►R locus of maize

S8: A ribosomal protein with binding site at the 597–599/640–643 at the hairpin of the 16S rRNA and it is required for the assembly of the 30S small ribosomal subunit (see Fig. S1). ►ribosomes

Figure S1. Hairpin

S-9: ►microsomes, ►Ames test

S³⁵ or ³⁵S: Sulfur isotope. ►isotopes

S49: A mouse lymphoma cell line.

S Alleles: Control self-sterility in plants. ►self-incompatibility, ►incompatibility alleles

S Cytoplasm: Present in some cytoplasmically male sterile lines. ►cms

S Factor: A mitochondrial plasmid-like element in male sterile plants. ►cms

S6 Kinase (RSK, S6K): The collective name for the cytosolic p70^{S6K} and the nuclear p85^{S6K} kinases that phosphorylate the S6 ribosomal protein before the initiation of translation. The supply of amino acids affects the process. Mutation in the genes results in reduced cell and body size. Mice deficient for S6K are glucose intolerant and hypoinsulinemic. S6K is an effector of mammalian TOR. The carboxyl end of S6 and the phosphorylation sites within are highly conserved from *Drosophila* to humans. ►translation initiation, ►platelet-derived growth factor, ►phosphatidylinositol, ►S6 ribosomal protein, ►5'-TOP, ►cell size, ►insulin, ►TOR; Duffer A, Thomas G 1999 Exp Cell Res 253:100; Um SH et al 2004 Nature [Lond] 431:200.

S Locus: ►selfsterility alleles

S1 Mapping: When genomic DNA is hybridized with the corresponding cDNA or mRNA the non-homologous sequences cannot find partners to anneal with, and the single-stranded loops can be digested with S1 nuclease (see Fig. S2). The remaining DNAs that formed double-stranded structure can then be isolated by gel electrophoresis or their position and length can be

determined by autoradiography if appropriately labeled material was used. Thus, intron positions are revealed. ►introns, ►S₁ nuclease, ►DNA hybridization, ►genomic DNA; Favaloro J et al 1980 Methods Enzymol 65:718; Dziembowski A, Stepien PP 2001 Anal Biochem 294:87.

Figure S2. S₁ mapping

S₁ Nuclease: S₁ Nuclease from *Aspergillus oryzae* cleaves single-stranded DNA (preferentially), and single-stranded RNA. Double-stranded molecules and DNA–RNA hybrids are quite resistant to it unless used in very large excess. The enzyme produces 5′-phosphoryl mono- and oligonucleotides. S₁ has many applications in molecular biology: mapping of transcripts, removal of single-stranded overhangs from double-stranded molecules, analysis of the pairing of DNA–RNA hybrids, opening up “hairpin” structures. Its pH optimum is 4.5 and this may cause unwanted depurination. ►nucleases, ►S₁ mapping, see figure of hairpin structure; Kormanec J 2001 Methods Mol Biol 160:481.

S Phase: S phase of the cell cycle when regular DNA synthesis takes place. ►cell cycle

S Protein: ►vitronectin

S1 Ribosomal Protein: Binds to U-rich sequences upstream of the Shine-Dalgarno sequence and may promote translation. ►Shine-Dalgarno sequence, ►translation; Boni IV et al 2001 EMBO J 20:4222.

S6 Ribosomal Protein: Phosphorylated at about 5 serine residues near its C terminus, and the phosphorylated state is correlated with the activation of protein synthesis on the ribosomes; the phosphorylation is stimulated by mitogens and growth factors. ►ribosome; Recht MI, Williamson JR 2001 J Mol Biol 313:35.

5S RNA: ►ribosomal RNA, ►ribosomes; Artavanis-Tsakonas S et al 1977 Cell 12:1057.

6S RNA: Binds σ^{70} RNA polymerase in response to limited nutrient supply of bacteria and represses its transcriptional activity (Wassarman KM, Storz G 2000 Cell 101:613) and assures cell survival (Trotochaud AE, Wassarman KM 2004 J Bacteriol 186:4978). ►B2 RNA, ►7SK RNA, ►SRA RNA, ►RNA regulatory

7S RNA: ►RNA 7S

SAA: Serum amyloid A. ►amyloidosis

SABE (serial analysis of binding elements): A method for identification of DNA-binding transcription factors. ►SAGE; Chen J, Sadowski I 2005 Proc Natl Acad Sci USA 102:4813.

S-Adenosylmethionine (SAM): A methyl donor for restriction-modification methylase enzymes, and general methylation of DNA; synonymous with Adomet. Folic acid and other compound contribute indirectly to SAM synthesis and methylation. ►methylation of DNA

S-Adenosylmethionine Decarboxylase (AdoMetDC): An enzyme involved in the biosynthesis of spermidine and spermine. For its activity, it is essential to contain a covalently bound pyruvoyl end group to the α -subunit of the dimeric enzyme (see Fig. S3). This enzyme is found in both prokaryotes and eukaryotes. ►spermidine, ►spermine; Li Y-F et al 2001 Proc Natl Acad Sci USA 98:10578.

Figure S3. Pyruvoyl

SAC: A regulator of nuclear export and the cell cycle. ►nuclear pore, ►nuclear export factors

Saccades: Abrupt changes in the fixation of the eyes during scanning objects directed by the reflex center of the brain (superior colliculus).

Saccharin: A non-caloric sweetener; hundreds of times sweeter than sucrose. Oral LDLo for humans is 5 g/kg; it has been a suspected carcinogen and mutagen but later studies did not confirm its classification as a carcinogen. ►LDLo, ►aspartame, ►fructose

Saccharomyces cerevisiae: The eukaryotic budding yeast has chromosome number $n = 16$, its genome sizes is about 1.2×10^7 bp, approximately three times that of the prokaryotic *E. coli*. Recent sequencing and knockout information contradicted earlier estimates that less than 10% of its genome would be repetitive. A newer study estimates gene duplication (concerted evolution) and gene conversion rate to be about 25 million years and about 28 times of the mutation rate (Gao L-Z, Innan H 2004 Science 306:1367). In chromosome III of 55 open reading frames only 3 appeared indispensable for growth on a rich nutrient medium. Of 42 other genes, only 21 displayed

a phenotype. This information points to redundancy even in this small genome. This conclusion may be misleading, however, because some genes are called to duty only under specific circumstances. Its entire genome was sequenced by 1996. The 5885 open reading frames are encoded by 12,068 kb. About 140 genes code for rRNA, 40 for snRNA and for 270 tRNA. About 11% of the total protein produced by the yeast cells (proteome) has metabolic function, 3% is involved in DNA replication and energy production, respectively; 7% is dedicated to transcription, 6% to translation and 3% (ca. 200) are different transcription factors. About 7% is concerned with transporting molecules. About 4% are structural proteins. The original gene number estimate has been since reduced to 6128 or fewer, and some studies consider the number only 5726 (Kellis M et al 2003 Nature [Lond] 423:241). Promoters, terminators, regulatory sequences and intergenic sequences with unknown functions occupy about 22% of the genome. The majority of yeast genes are not absolutely essential for survival or function (Giaever G et al 2002 Nature [Lond] 418:387). Many proteins are involved with membranes. In rich nutrient media its doubling time is about one and half-hour. The organism has regular meiosis and mitosis. The vegetative multiplication is by budding (budding yeast), i.e., the new (daughter) cell is formed as a small protrusion (bud) on the surface of the mother cell. Haploid cells may fuse to generate diploidy and the diploid cells may undergo meiosis (sporulation), and the four haploid products are retained in an ascus as an unordered tetrad. The haploid cells may have α or a mating type. Although budding yeast is eukaryotic it can be cultured much like prokaryotes, and thus it combines many of the advantages of both groups of organisms.

The yeast cell can be spherical (oblong) as represented in Figure S4 or they may become pseudohyphal (filament-like) in appearance. MAPK,

PKA and AMPK proteins mediate this switch of growth type. Approximately 25–30% of the human genes have significant homology with a yeast gene. The present genome might have evolved through extensive duplications. Baker's yeast is not a pathogen but may be harmful for immune-compromised individuals (Wheeler RT et al 2003 Proc Natl Acad Sci USA 100:2766) and it is considered to be an opportunistic pathogen. ►mating type determination in yeast, ►fungal life cycles, ►mtDNA, ►tetrad analysis, ►YAC, ►duplication, ►yeast vectors, ►yeast transformation, ►yeast transposable elements, ►gene replacement, ►synthetic genetic array, ►synthetic lethal, ►transcript mapping, ►*Schizosaccharomyces*, ►databases, ►MAPK, ►PKA, ►AMPK; sequencing: <ftp://ftp.ebi.ac.uk/pub/databases/yeast>; protein coding sequences: <ftp://ftp.ebi.ac.uk/pub/databases/lista>; <http://genome-www.stanford.edu/Saccharomyces>; <http://www.yeastgenome.org/>; <http://mips.gsf.de/genre/proj/yeast/>; yeast introns: http://www.cse.ucsc.edu/research/compbio/yeast_introns.html; Triples: <http://bioinfo.mbb.yale.edu/e-print/genome-transposon-nature/text.htm>; phenome: <http://prophecy.lundberg.gu.se>; transcriptional regulation: <http://www.yeasttract.com>; protein–protein interaction: <http://mips.gsf.de/genre/proj/impact>; proteomics, fluorescence microscopy: <http://www.yeastrc.org/pdr/>; Dwight SS et al 2001 Nucleic Acids Res 30:69; Barnett JA, Robinow CF 2002 Yeast 19:151 and 745; Mackiewicz P et al 2002 Yeast 19:619; 4000 interactions among 1000 genes: Tong AHY et al 2004 Science 303:808.

SACO (serial analysis of chromatin occupancy): Detects the binding sites of proteins along the chromosome. (See Impey S et al 2004 Cell 119:1041).

Sacral Agensis (Currarino triad): A malformation of the caudal (tail) end of the notochord. Genes at human chromosomes 7q36 and 1q41-q42 may affect its rare dominant expression. ►Currarino triad, ►notochord

Figure S4. Life cycle of budding yeast

SAD Mouse: An animal model for human sickle cell anemia. It produces polymerized hemoglobin due to mutations in β globin, Hb^{SAD}. ▶[sickle cell anemia](#); Martinez-Ruiz R et al 2001 *Anesthesiology* 94:1113.

SADDAN (severe achondroplasia with delayed development and acanthosis nigricans): ▶[achondroplasia](#), ▶[acanthosis nigricans](#)

SADR (serious adverse drug reaction): Considered the fourth leading cause of human death, it claims 100,000 fatalities and affects about 2,000,000 persons each year in the USA due to marketed medicine. Individual reaction to specific drugs varies and certain ethnic groups include more vulnerable genotypes than others. Besides beneficial effect, many drugs have unknown side effects. It is highly desirable to develop test that would predict the genetic bases of SADR. With the progress of genomic information there are potentials for clinical application of such tests. The European pharmacogenomics project EUDRAGENE, the Canadian Genotypic Adjustment of Therapy in Childhood (GATC) and various programs of the US National Institute of Health (Pharmacogenetics Research Network) are seeking solutions for the problems. ▶[drug development](#), ▶[metabonomics](#), ▶[genetic medicine](#), ▶[pharmacogenetics](#), ▶[pharmacogenomics](#); Giacomini KM et al 2007 *Nature [Lond]* 446:975.

Saethre-Chotzen Syndrome: ▶[Chotzen syndrome](#)

SAF: SKP-associated factors, F-box proteins. ▶[SKP](#), ▶[F-box](#)

Safety: ▶[laboratory safety](#), ▶[chemicals hazardous](#), ▶[recombinant DNA and biohazards](#), ▶[radiation hazard assessment](#), ▶[cosmic radiation](#), ▶[gloves](#), ▶[environmental mutagens](#). (See Fleming DO, Hunt DL (Eds.) 2000 *Biological Safety. Principles and Practices*, ASM Press, Washington DC).

Safflower (*Carthamus tinctorius*): An oil crop of warmer climates, $2n = 24$; other related species have $2n = 20$ or $2n = 44$ chromosomes.

SAGA: A histone acetyltransferase complex of about 20 different proteins that interact with TBP (TFIID) and with gene-specific transcriptional activators. In yeast SAGA, SLIK and TFIID complexes appear to have some redundant functions. The Chd1 (chromo-ATPase/helicase-DNA binding domain) links histone (H3, H2B) methylation with SAGA and SLIK-dependent acetylation (Pray-Grant MG et al 2005 *Nature [Lond]* 433:434). ▶[histone acetyltransferase](#), ▶[histones](#), ▶[TBP](#), ▶[bromo-domain](#), ▶[transcription](#), ▶[transcription factors](#), ▶[chromatin](#)

[remodeling](#), ▶[SNF/SWI](#); Sterner DE et al 1999 *Mol Cell Biol* 19:86.

SAGE (Serial Analysis of Gene Expression): A procedure that permits the analysis of the function of many genes by a sweeping procedure. The first step is to isolate all the mRNAs that are produced in a single organ, at a particular developmental stage. By reverse transcription they are converted into cDNA. The 3' ends are then tagged by biotin. The cDNAs are digested by a restriction enzyme and the end fragments are trapped on streptavidin beads. After that, a second restriction enzyme is applied which cuts at least 9 bp from the fragments. In a following step, each short (9 bp or longer) tag is amplified by PCR and the tagged pieces are linked into a single DNA molecule. Then each tag is sequenced by an automatic sequencer and the tags are counted. In this sweeping manner 20,000 genes can be monitored in a month. The same effort would require years if it would be conducted on separate genes. This procedure reveals not just the number of expressed genes in that organ but reveals also the level of their activity. Some may be expressed in a single copy, others may be very active and are represented by multiple copies. Long SAGE is a variant of the SAGE procedure (Saha H et al 2002 *Nature Biotechnol* 20:508). ▶[genome project](#), ▶[genomics](#), ▶[biotin](#), ▶[streptavidin](#), ▶[DNA sequencing automated](#), ▶[electrospray MS](#), ▶[laser desorption MS](#), ▶[DNA chips](#), ▶[expressed-sequence tag](#), ▶[microarray hybridization](#), ▶[microarray analysis](#), ▶[SABE](#), ▶[RIDGE](#); Lash AE et al 2000 *Genome Res* 10:1051; Polyak K, Riggins GJ 2001 *J Clin Oncol* 19:2948; review: Wang CM 2007 *Trends Genet* 23:42; <http://www.sagenet.org>; 5' end SAGE tags: <http://5sage.gi.k.u-tokyo.ac.jp>; DEGSAGE, accurate mapping of SAGE tags: <http://dna.bio.puc.cl/SAGEExplore.html>.

SAGE Genie: An innovative new bioinformatics tool based on SAGE but providing a single platform for acquiring, annotating and interpreting large sets of gene expression data. The new technology measures gene expression by the frequency of 3' signature SAGE tags of 10 bases specific and unique to each transcript. The method permits the analysis of gene expression that are up- or down-regulated and allows automatic matching of SAGE tags to known transcripts. The incorrectly linked or those occurring only once or obtained by sequencing errors are filtered out from millions of tags. Then *confident SAGE tags* (CST) are obtained. The SAGE Genie permits *horizontal comparisons* (e.g., normal versus cancerous expression) and in addition *vertical comparisons* (e.g., expression profiles in different tissues or organs) under any desired conditions. This technology appears simpler and has far greater specificity than microarrays. The SAGE Genie

provides an automatic link between gene names and SAGE transcript levels accessible by the Internet: <http://cgap.nci.nih.gov/SAGE>. ► **SAGE**, ► **microarray hybridization**; Boon K et al 2002 Proc Natl Acad Sci USA 99:11287.

Sagittal (adjective): In the anterior-posterior body plan.

Saguenay—Lac-Saint-Jean Syndrome (2p16): A rare, recessive, morbid cytochrome oxidase deficiency with symptoms similar to Leigh disease. ► **Leigh's encephalopathy**

SAHA (suberoylanilide hydroxamic acid): An inhibitor of histone deacetylase.

Saimiri (squirrel monkey): ► **Cebidae**

Sainfoin (*Onobrychis viciifolia*): A leguminous forage plant; $2n = 14$ or 28 (see Fig. S5).

Figure S5. Onobrychist

Sal I: Restriction endonuclease with recognition site $G\downarrow TCGAC$.

Salamander: *Salamandra salamandra*, $2n = 24$, *Ambystoma mexicanum*, *A. tigrinum tigrinum* ($n = 14$). The estimated genome size of the ambystomas is 7291 map units, the largest known. (See Voss SR et al 2001 Genetics 158:735).

Salicylic Acid (*O*-hydroxybenzoic acid): A painkiller, keratolytic and fungicidal agent; it also mediates the expression of disease defense-related responses in plants (see Fig. S6). Its methylsalicylate derivative, a volatile compound, may carry out airborne signaling after infection of plants by pathogens. The PAD genes

Figure S6. Salicylic acid

encode lipase-like molecules involved in salicylic signaling. Salicylic acid activity may be modulated by desaturation. ► **host-pathogen relation**, ► **hypersensitivity reaction**, ► **desaturase**, ► **aspirin**; Dempsey DM et al 1999 Crit Rev Plant Sci 18:547; Wildermuth MC et al 2001 Nature [Lond] 414:562.

Saline: The water solution of NaCl; the “physiological saline” is 0.9% salt solution for humans.

Salivary Gland Chromosomes: These are polytenic and because of their large size and clear landmarks, have been used extensively for cytogenetic analyses of *Drosophila* and other flies. The cultures to be used for this type of studies should be less crowded and moist. Third instar larvae can be used as they crawl out of the medium before the cuticle hardens. The larvae are placed in aceto-orcein or into 7% aqueous NaCl on microscope slides. A needle is used to hold the larva in place, and with a second needle placed behind the mouth parts the larva is decapitated and the salivary gland is pulled out. In aceto-orcein on a clean slide, the nuclei are stained in 5 to 10 min. The chromosomes may be spread by gentle pressure on the cover slide and after sealing the edge with wax, they can be examined under a light microscope. ► **polytenic chromosomes**, ► *Drosophila*, see Fig. S7; Lifschytz E 1983 J Mol Biol 164:17; Cold Spring Harb Symp Quant Biol 38 1974.

Figure S7. Salivary gland chromosomes of *Drosophila* (Courtesy of Dr. HK Mitchell). Upper right (circled) a regular mitotic set of chromosomes at about the same scale. (Redrawn after Painter TS 1934 J Hered 25:465)

Salivary Gland Chromosomes and Mapping: Since the salivary chromosomes display clear topological markers (bands), they can be used to locate deletions, duplications, inversions, translocations and can be used to associate mutant phenotypes with physical alterations. The genetic and cytological maps are collinear yet they are not exactly proportional by distance. ►coefficient of crossing over, ►*Drosophila*; Painter TS 1943 J Hered 25:465; Bridges CB 1935 J Hered 26:60.

Salla Disease: ►sialic acid, ►sialuria

Salmon: *Salmo gairdneri*, $2n = 58-65$. A transgenic Atlantic salmon strain carrying the growth hormone of the Pacific chinook salmon (*Oncorhynchus tshawytscha*) and the promoter of the eel-like ocean pout (*Macrozoarces americanus*), for an antifreeze protein grows twice as fast as its normal counterpart and actually thrives on less food. Some other transgenic strains do not perform as well (see Fig. S8). ►animal hormones, ►antifreeze protein; <http://pewagbiotech.org/research/fish>.

Figure S8. Coho Salmon (*Oncorhynchus kisutch*)

Salmonella: A member of the enteric Gram-negative bacteria and as such related to *E. coli*, and its handling ease is similar to it. It is a human pathogen and even in the laboratory it requires some caution when manipulated. Several of the related species contaminate food and feed supplies and create health hazards. F⁺, F' and Hfr strains are available. Its best known transducing phage is P22. The 4,809,037 bp genome of *Salmonella enterica* CT18 and two plasmids, pHCM1 (multiple-drug-resistance incH 218,159 bp) and the cryptic plasmid pHCM2 (106,516 bp) have been sequenced. It includes >200 pseudogenes and hundreds of insertions and deletions. *Salmonella enterica* serovar Typhimurium LT2 contains 4857 kb chromosome and a 94 kb virulence plasmid. *Salmonella cholerae suis* genome of 4.7 Mb has been sequenced. This bacterium primarily infects swine but is also pathogenic to humans (Chiu C-H et al 2005 Nucleic Acids Res 33:1690). ►histidine operon, ►Ames test, ►phase variation; Parkhill J et al 2001 Nature [Lond] 413:848; McClelland M et al 2001 Nature [Lond] 413:852; Edwards RA et al 2002 Trends Microbiol 10:94; <http://www.salmonella.org>.

Salpiglossis variabilis (Solanaceae): A plant species with the rather unusual characteristics where the four pollen grains, product of a single meiosis, stick together and, therefore can be used for tetrad analysis and gene conversion in higher plants. ►tetrad analysis, ►gene conversion

Salpingectomy: The sterilization of mammals by removal of the Fallopian tube (salpinx) leading to the uterus. ►sterilization humans, ►vasectomy, ►tubal ligation, ►birth control, ►uterus

Salt Bridges: Non-covalent ionic bonds in multimeric proteins.

Saltation: The unproven evolutionary proposition that species (and even higher taxonomic categories) arise by non-Darwinian sudden, major alterations. ►hopeful monster

Saltatory Replication: The sudden amplification of DNA segments during evolution.

Salt-Tolerance: Salt-tolerance of plants is regulated by the HKT1 (high affinity potassium [K⁺] transporter). This protein is actually a Na⁺ and K⁺ cotransporter and at high K⁺ level results in low level of Na⁺ uptake thus conveying some salt tolerance. Ca²⁺ is beneficial for salt tolerance supposedly under the control of a protein sensor displaying about 50% similarity to calcineurin and neuronal calcium sensors. The Na⁺/H⁺ antiport protein (NHX) mediates another salt control. Low proline content in the cells causes high salt-sensitivity whereas an increase in the level of sugar alcohols favors salt tolerance. Another potential mechanism for salt tolerance would be the improved elimination of the salt from the cells. *Arabidopsis* plants carrying a mutant NHX1 gene displayed higher tolerance for sodium and, in addition, because of the accumulation of NaCl in the vacuoles acquired better exploitation of the soil moisture through osmosis. Having salt tolerant crops may extend the usage of alkaline soils and may make it possible to use seawater for irrigation. Increased glyoxylase activity improves salt tolerance (Singla-Pareek SL et al 2003 Proc Natl Acad Sci USA 100:14672). Tobacco plant transgenic for the pea DNA helicase 45 (a homolog of the translation initiation factor eIF-4A) increased salt tolerance without reducing yield (Sanan-Misra N et al 2005 Proc Natl Acad Sci USA 102:509). The overlapping gene pair of *Arabidopsis* encoding Δ^1 -pyrroline-5-carboxylate dehydrogenase (*P5CDH*) and *SRO5* of unknown function can generate a 21-nucleotide siRNA that can increase salt tolerance (Borsani O et al 2005 Cell 123:1279). ►ion channels, ►calcium signaling, ►calcineurin, ►glyoxylate cycle, ►eIF-4a,

► *Priformospora indica*, ► overlapping genes, ► RNAi; Zhang H-X, Blumwald E 2001 Nature Biotechnol 19:765; Zhu J-K 2002 Annu Rev Plant Biol 53:247; Shi H et al 2003 Nature Biotechnol 21:81.

Salvage Pathway: A recycling pathway, in contrast to the de novo pathway, e.g., nucleotide synthesis from nucleosides after removal of the pentose followed by phosphoryborylation. ► phosphoribosyl transferase, ► HGPRT, ► HAT medium

SAM (significance analysis of microarrays): Permits statistical distinction between microarray signals. ► microarray hybridization; Tusher VG et al 2001 Proc Natl Acad Sci USA 98:5116.

SAM: ► S-adenosyl-L-methionine, ► substrate adhesion molecules

SAM68 (SRC-associated in mitosis): A phosphoprotein and a target of SRC, FYN and ITK kinases during mitosis. It also binds to the SH domains of the Grb adaptor protein of the cytoplasm and NCK in the nucleus. When SAM68 is tyrosine dephosphorylated, it binds RNA. A homolog of SAM68 is ÉTOILE. ► STAR, ► signal transduction, ► Src

SAM (system for assembling markers): <http://www.sanger.ac.uk/Software/sam/>.

Sampling Distribution: The probability distribution of a statistic estimated from a random sample and a certain size. The sampling distribution is somewhat different from the normal distribution that is characterized by the mean (μ) and the standard deviation (σ) inasmuch as mean (M) has a standard deviation of σ/\sqrt{n} .

Sampling Error: Can occur when the population is too small or when few individuals are sampled. The proper sample size n can be statistically estimated as shown in the formula. $n = \frac{2(z_\alpha - z_\beta)^2 \sigma^2}{(\mu_1 - \mu_2)^2}$ where z_α is the normal deviate for a level of significance α , and z_β is the normal deviate for β and $1 - \beta$ is the power required, σ^2 is the variance of each population with means μ_1 and μ_2 chosen or whenever the selection is not random. ► drift genetic, ► genetic drift, ► effective population size, ► founder principle, ► normal deviate, ► normal deviation, ► Z distribution

Sancho: A non-viral retrotransposable element. ► transposable elements

Sandhoff's Disease: Characterized either by the absence of both β -hexosaminidase α and β activity or by β -hexosaminidase β subunit only. This autosomal recessive hereditary defect has very similar symptoms to those of the Tay-Sachs disease that is caused by β -hexosaminidase α subunit deficiency.

β -Hexosaminidase β subunit defect blocks the degradation of β -galactosyl-*N*-acetyl-(1→3)-galactose-galactose-glucose-ceramide to β -(1→4)-galactosyl-galactose-glucose-ceramide and hexosaminidase α normally converts GM₂ ganglioside (neuraminic-*N*-acetyl-galactose-4-galactosyl-*N*-acetyl-glucose-ceramide) into GM₃ ganglioside (neuraminic-*N*-acetyl-galactose-glucose) ceramide. The genes for β -hexosaminidase α and β are in human chromosomes 15q23-q24 and 5q13, respectively. Their structural similarity indicates evolution by duplication. ► sphingolipidoses, ► sphingolipids, ► gangliosides, ► Tay-Sachs disease

Sandwich-Like Protein: Two β -sheets of 3–5 β -strands packed face-to-face.

Sanfilippo Syndrome: ► mucopolysaccharidosis

Sanger Method of DNA Sequencing: ► DNA sequencing

SANT (SWI3, ADA-2, N-COR, TFIIB): The chromatin remodeling complex sharing among them an ATPase and transcription and chromatin remodeling domains. ► chromatin remodeling, ► SWI, ► ADA, ► N-COR, ► TFIIB

Santa Gertrudis Cattle: Originated by a cross between the exotic-looking Brahman x shorthorn breeds (*Bos taurus*). The Brahman cattle descended from *Bos indicus*. ► cattle

SAP-1 (stress activated protein): SAP-1 is involved in the activation of MAP kinases in binding to their serum response factor (SRF). SAP is required for the activation of SLAM. ► MADS box, ► MAP, ► SRF, ► Epstein-Barr virus, ► SLAM, ► Elk, ► lymphoproliferative diseases X-linked, ► XPL; Latour S et al 2001 Nature Immunol 2:681; Cannons JL et al 2004 Immunity 21:693.

SAPK: A stress-activated protein kinase of the ERK family. SAPK can be activated by SEK a protein kinase, related to MAP kinase kinases. The signaling cascade involved is targeted to JUN. ► signal transduction, ► ERK, ► MAPKK, ► MEKK, ► JUN, ► JNK, ► Ire

Saponification: Alkaline hydrolysis of triacylglycerols to yield fatty acids. ► triacylglyceride, ► fatty acids

Saponins: Glycosylated triterpenoid or steroidal alkaloids in plants where they may be protective against fungal pathogens. Some fungal pathogens detoxify this defense molecule in a two-step process. ► host-pathogen relation; Bourab K et al 2002 Nature [Lond]: 418:889.

Saporins: Plant glycosidases, which remove adenine residues from RNA and DNA but not from ATP or dATP. ▶RIP

Saposins (10q22.1): Glycoproteins involved in the activation of galactosylceramidase. Pro-saponins are precursors of the endosomal lipid transfer proteins, which in association with CD1 present lipid antigens to the natural killer lymphocytes (NKT). ▶leukodystrophy, ▶shingolipids, ▶killer cell, ▶CD1; Qi X, Grabowski GA 2001 J Biol Chem 276:27010.

Saprophytic: Lives on non-living organic material. ▶biotrophic

SAR (structure-activity relationship): A field of study in carcinogen, mutagen and drug research. Structural modifications may or may not affect activity and it would be important to know what are the decisive factors and how to design more effective drugs. The biological assays of inhibition not only permit classification of the compounds (potential drugs) but also provide information on the structure of the proteins they interact with (Fliri AF et al 2005 Proc Natl Acad Sci USA 102:261). ▶TD₅₀, ▶CASE, ▶MULTICASE, ▶biophore

SAR (systemic acquired resistance): SAR may be induced in plants by pathogens, salicylic acid, ethephon, a compound releasing ethylene. The SAR-related genes may be members of regulons under common promoters binding specific transcription factors. Inactivation of MAP kinase 4 by the maize *Ds* transposon increased SAR and salicylic acid level and boosted the expression of pathogenesis-related proteins in *Arabidopsis*, although it reduced the size of the plants. In *Arabidopsis* for the expression of SAR a protein secretory pathway, including many genes, requires activation (Wang D et al 2005 Science 308:1036). Salicylic acid binding protein (SABP2) can convert methylsalicylic acid to salicylic acid and activates SAR (Forouhar F et al 2005 Proc Natl Acad Sci USA 102:1773). ▶host-pathogen relationship, ▶ethylene, ▶salicylic acid, ▶MAPK, ▶desaturase; Maleck K et al 2000 Nature Genet 26:403; Petersen M et al 2000 Cell 103:1111; Maleck K et al 2000 Nature Genet 26:403.

SAR: ▶scaffold

SAR1: A low activity GTPase, related to Arf. It regulates the traffic between the endoplasmic reticulum and the Golgi apparatus. ▶endoplasmic reticulum, ▶Golgi, ▶GTPase, ▶Arf, ▶GTPase; Takai Y et al 2001 Physiol Rev 81:153.

SAR by NMR (structure-activity relationship by nuclear magnetic resonance-based methods): An essential and sophisticated method to synthetic drug design. Natural or synthetic molecules are screened and

optimized analogs are synthesized to identify high-affinity ligands to develop effectively targetable drugs. ▶SAR, ▶NMR

SARA (Smad anchor for receptor activation): Recruits SMADs to the TGF- β receptor and thus regulates TGF signaling. ▶SMAD, ▶TGF

SarA: A pleiotropic staphylococcal accessory regulator of virulence. It binds to multiple AT-rich sequences. (See Schumacher MA et al 2001 Nature 409:215).

Saran Wrap: A thin sheet of plastic that clings well to most any surface and suitable for covering laboratory dishes, gels, etc.

Sarcoglycans (SGCA, 17q12-q21.33; SBCB, 4q12): A part of the dystrophin—glyco-protein complex in the sarcolemma. The complex protects the muscles and connects the cytoskeleton and the extracellular matrix. Sarcoglycan mutations may cause dystonia and myoclonous. ▶dystroglycan, ▶muscular dystrophy, ▶dystonia, ▶myoclonous; Zimprich A et al 2001 Nature Genet 29:66.

Sarcoidosis (susceptibility locus at 6p21.3, HLA-DRB1, BTNL2 [butyrophilin-like 2], Löfgren syndrome): A polygenic disorder of the immune system affecting lung, lymph nodes and eyes. Prevalence is $\sim 1.2 \times 10^{-4}$ among the majority of people of European extraction, except Swedes whose risk is about 5 times larger. The relative risk of first-degree relative is 2.8 to 18. ▶HLA; Valentonyte R et al 2005 Nature Genet 37:357.

Sarcolemma: Membranes covering the striated muscle fibers. ▶caveolin, ▶dystrophin

Sarcoma: A solid tumor tissue with tightly packed cells embedded in a fibrous or homogeneous substance; sarcomas are frequently malignant. Sticker sarcoma is canine transmissible venereal tumor. ▶Rous sarcoma, ▶RAS, ▶oncogenes; Bonnicelli JL, Barr FG 2002 Curr Opin Oncol 14:412.

Sarcomere: Muscle units of thick myosin, thin actin filaments between two plate-like Z discs. These units are repetitive. ▶titin, ▶nebulin, ▶myosin

Sarcoplasmic Reticulum: The membrane network in the cytoplasm of muscle cells containing high concentration of calcium, which is released when the muscle is excited.

Sarcosinemia: Sarcosine (methylglycine, CH₃NHCH₂-COOH) is normally converted to glycine (NH₂CH₂-COOH) by the enzyme sarcosine dehydrogenase. A defect at this step increases the level of sarcosine in the blood and in the urine (hypersarcosinemia), and may result in neurological anomalies but it may have almost no effect at all. Glutaric aciduria and defects in folic acid metabolism may also cause hypersarcosinemia. ▶glycine, ▶folic acid

Sarin: A nerve gas, which inhibits acetylcholinesterase.
 ►organophosphates

Sarkosyl (*N*-lauroylsarcosine): A detergent for solubilizing membranes and is used for extraction of tissues.

SARS (severe acute respiratory syndrome): The disease symptoms resembling flu develop by exposure to a corona virus of about 30,000-nucleotide, positive single-stranded RNA genome (see Fig. S9) (Marra MA et al 2003 Science 300:1399). The genome displays regional variations at several sites. The different strains show essential variations in the proteins decorating the capsid that determine virulence. During the first week high fever occurs without much additional symptoms. During the following four days, pneumonia develops in the lung that subsequently may become destructive to this organ. Protection is prevention, hygiene, avoiding breathing the airborne particles but no effective drug therapy exists. It is a zoonosis. Apparently the Himalayan palm civet (*Paguma larvata*) and the raccoon dog (*Nyctereutes procyonoides*) transmitted the virus to humans. In these animals the genomic sequence of the virus is 99.8% identical to that found in human (Song H-D et al 2005 Proc Natl Acad Sci USA 102:2430). Mortality rate is 5 to 15%. In mice DNA vaccine is effective (Yang Z-y et al 2004 Nature [Lond] 428:561). Angiotensin-2 converting enzyme (ACE2) is the only known receptor for this virus. L-SIGN is similar to SIGN/DC-SIGNR (dendritic cell specific ICAM-3 grabbing non-integrin) is expressed in the lymph nodes and placenta is encoded by *CLEC4M* gene in mouse. L-SIGN and DC-SIGN bind to high-mannose oligosaccharides of viruses including the SARS virus. Human individuals heterozygous for the *CLEC4M* tandem repeats are less susceptible to SARS. L-SIGN homozygotes bind even better the virus and degrade it and show lower capacity for trans infection (Chan VSF et al 2006 Nature Genet 38:38; the conclusions of this paper were questioned by Teng NL-S et al 2007 Nature Genet 39:691; Zhi L et al 2007 Nature Genet 39:692; Chang KVK et al 2007 Nature Genet 39:694 did not concede). The coronavirus variants SARS-CoV and other coronaviruses encode two RNA-dependent replicases, a specific spike protein, a small envelope protein, a membrane protein, a nucleocapsid protein and nine unidentified other proteins. Diagnostic approaches involve RT-PCR, ELISA and an IIFT kit for the detection of IgG antibody response and all of them display some advantage and shortcomings for diagnosis. A microarray-based technology appears rapid, sensitive and accurate and it is adaptable to other viral infections (Zhu H et al 2006 Proc Natl Acad Sci USA 103:4011). ►zoonosis, ►immunization

genetic, ►plant vaccine, ►angiotensin, ►ICAM, ►dendritic cell, ►RT-PCR, ►ELISA, ►immunoglobulins, ►Newcastle disease; Navas-Martin S, Weiss SR 2003 Viral Immunol 16(4):451; Webby RJ, Webster RG 2003 Science 302:1519; antiviral drugs: Wu C-Y et al 2004 Proc Natl Acad Sci USA 101:10012.

Figure S9. Corona virus

SAS (statistical analysis system): A computer software for the many types of data analyses.

SAS (switch-activating site): ►*Schizosaccharomyces pombe*

SAT: ►satellited chromosome

SATB1 (special AT-rich sequence binding protein 1): Regulates chromatin folding and anchors special DNA sequences (ATC) into its network. It facilitates histone acetylation at many specific loci and it controls tissue-specific gene expression. ►tissue-specificity, ►chromatin remodeling; Cai S et al 2003 Nature Genet 34:42; controlling cytokine gene expression: Cai S et al 2006 Nature Genet 38:1288.

SAT-DAC (satellite-DNA-based artificial chromosome): SAT-DAC of mammals is expected to replicate independently from the genome and to express its gene content as a huge vector. It may serve also for transferring any gene into mammals (humans) without the risk of disruption resident genes. SAT-DACs composed mainly of AT sequences may be readily isolated from the rest of the genome. Such a structure was stably inherited in mice. (See Hadlaczky G 2001 Curr Opin Mol Ther 3:125).

Satellite Cells: Surround each myofiber beneath the basal lamina and are precursors of muscle growth and repair. As few as seven satellite cells, associated with myofibers, are sufficient sources of muscle regeneration (Collins CA et al 2005 Cell 122:289; Montarras D et al 2005 Science 309:2064). ►basement membrane, ►myofibril, ►stem cells

Satellite DNA: DNA fraction with higher or lower density (during ultracentrifugal preparations) than the bulk DNA (see Fig. S10). Generally, it contains substantial repetitive DNA (in up to 5 Mb tracts). These satellite sequences generally pose problems

in genome sequencing because of their instability in the cloning vectors. Very little information is available regarding the function of SAT DNA. Dimeric oligopyrroles-imidazoles target adenine-thymine-rich satellite sequences and the scaffold-associated region (SAR) of *Drosophila*. Unexpectedly these polyamides induce gain- or loss-of-function phenotypes. It is assumed that these chemicals facilitate accessibility to chromatin. ▶repetitious DNA, ▶ultracentrifugation, ▶heterochromatin, ▶α-satellite, ▶polyamides, ▶satellite, ▶pyrrole, ▶imidazole; Janssen S et al 2000 Mol Cell 6:999; Janssen S et al 2000 Mol Cell 6:1013.

Figure S10. Satellite DNAs are identified by ultracentrifugation on the basis of their densities in CsCl

Satellite RNA: The transcript of satellite DNA: ▶satellite DNA

Satellite Virus: A defective virus co-existing with another (helper) virus to correct for its insufficiency. The unrelated helper is required for infection.

S

Satellited Chromosome: Carries an appendage to one arm by a constriction (see Fig. S11). The bridge between the main body of the chromosome and appendage is the site of the nucleolar organizer. It was named originally SAT as an abbreviation for *sine acido thymonucleinico*, i.e., a place where there was, then, no detectable DNA (= thymonucleic acid, as it was called in the 1930s) in that part of the chromosome. The appendages were also called trantabs.

Figure S11. Satellited chromosome

Satsuma Mandarin: A pollen sterile citrus variety that, if no foreign pollen can reach the flowers, produces seedless oranges. This is the characteristic also for navel oranges although some navel oranges have many seeds because in those the abnormal carpel development may interfere with pollination but they are not basically self-sterile. ▶seedless fruits

Saturated Fatty Acids: All their chemical affinities satisfied, have higher energy content than the unsaturated fatty acids that contain one or more double bonds. ▶fatty acids, ▶cholesterols, ▶omega-3 fatty acids

Saturation Density: of a mammalian cell culture before contact inhibition takes place. ▶cancer, ▶malignant growth, ▶contact inhibition

Saturation Hybridization: One component in the nucleic acid annealing reaction mixture has excessive concentration to allow finding all possible sites of homology and hybridization. ▶nucleic acid hybridization

Saturation Mutagenesis: Induce mutations at all available sites to reveal the relative importance of these sites. ▶mutagenesis, ▶localized mutagenesis, ▶linker scanning, ▶GAMBIT

Saturation of Molecules: The carbon-carbon attachments of single covalent bonds (no double bonds when entirely saturated). ▶saturated fatty acids

Sau 3A: Restriction endonuclease with recognition sequence ↓GATC; *Sau* 96 I: G↓GNCC.

SAUR (small auxin-up RNA): RNAs encoded by several genes that are induced by auxins. ▶auxins; Guilfoyle TJ 1995 ASGSB Bull 8:39.

SBD: Single-strand DNA binding domains of ~120 amino acids in the large subunits (and possibly in the small) of the RPA protein of eukaryotes. ▶DNA replication in eukaryotes, ▶RPA

SBF (Saccharomyces binding factor): Composed of Swi4 and Swi6 along with MBF (composed of Swi4 and Mbp1) initiate the transcription of genes cyclin 1 (*CLN1*) and cyclin 2 (*CLN2*) required for activation of Cdc28 enabling the progress of the cell cycle from G1 to S phase. ▶cell cycle, ▶cyclin, ▶Cdc28, ▶Swi, ▶MBF

Sbf1 (SET-binding factor 1): A myotubularin-like protein (but without phosphatase activity) binding to SET domains. ▶SET, ▶myopathy

SBMA: ▶Kennedy disease

sc: Indicating *Saccharomyces cerevisiae* (budding yeast) DNA, RNA or protein as a prefix.

SC1: An immunoglobulin superfamily cell adhesion molecule, it is transiently expressed during avian embryogenesis by a variety of cell types.

SC Phocomelia: ▶ [Roberts syndrome](#)

SC35: An SR protein. ▶ [SR motif](#)

SCA: ▶ [spinocerebellar ataxia](#), ▶ [ataxin](#), ▶ [ataxia](#)

SCA (statistical coupling analysis): Maps energetic interactions in proteins and measures the statistical interactions between amino acid positions in order to shed light on folding patterns (Lockless SW, Ranganathan R 1999 Science 286:295). ▶ [protein folding](#)

Scaffold: The cytoskeleton of the cell or residual protein fibers left in the chromosome after the removal of histones. The bulk of the scaffold is of two proteins, Sc1 (a topoisomerase II) and Sc2. The scaffold is attached to SAR (scaffold attaching regions) of the chromatin. Cytoskeletal scaffolds facilitate the transport of various molecules along its network and secure them at the proper cellular positions. Scaffold proteins—in connection with other molecules—can also fine tune quantitatively input-output properties (Bhattacharyya RP et al 2006 Science 311:822). Artificial polymer scaffolds have been constructed and used as an alternative to viral vectors to deliver therapeutic proteins or gene constructs to cells with defective or deleted genes and release their cargo in their target environment. In animal models, implanted platelet-derived growth factor greatly enhanced vascularization. ▶ [cytoskeleton](#), ▶ [topoisomerase](#), ▶ [loop domains model](#), ▶ [genetic engineering](#), ▶ [MAR](#), ▶ [WGS](#); Dietzel S, Belmont AS 2001 Nature Cell Biol 3:767.

Scaffold Protein: A platform that accepts, assembles and delivers cofactors to biological targets.

Scaffolds in Genome Sequencing: A set of ordered, oriented contigs, assembled relative to each other

by mate pairs in adjacent contigs. For assembling the over 99% accurate sequences of the *Drosophila* genome, Celera group used 8 Compaq Alpha ES40 computers with 32 gigabyte memory. In the assembly, the repetitive sequences pose real challenges because the overlaps can be *true overlaps* that belong together or the overlaps are parts of repeated sequences that may occur multiple times and being scattered in the genomes and therefore, do not belong together. A collection of fragments whose arrangement is uncontested by overlaps from other fragments are *unitigs*. The unitigs that represent unique (non-repetitive) sequences—although some extending into repeats—are called *U-unitigs*. In Figure S12 X' and X'' represent repeated sequences and in the box, they are “overcollapsed” in a unitig because they consistently subassemble as the interior of the repeats. In the repeat boundary box, A and B or B and C do not overlap and they are computationally resolved and help in extending of the assembly of the U-unitigs into scaffolds (see Fig. S13).

If mate pairs and overlaps consistently appear in bundles, the ordering of the non-repetitive euchromatic segments is facilitated. Usually gaps appear between the U-unitigs and scaffolds. Smaller fragments called *rocks*, *stones* and *pebbles* fill in these gaps. The shorter unitigs still have two or one mate links. The correct *tiling path* (a minimally overlapping DNA fragment map spanning that length of the genome) is also verified by statistics. The *reads* (base sequences) are verified also by multiple *base-calls* (identifying the correct nucleotide in a sequence) and the sets are evaluated by Bayesian statistics.

The *Drosophila* genome was sequenced and assembled in 838 *firm scaffolds* (containing at least one U-unitig). As of 2000, the WGS still has 1887 gaps with a total length of 2322 Mbp varying in size up to 150 Mbp and zero. The number of U-unitigs was 7164 (8.007 Mbp), rocks 1787 (0.927 Mbp), stones 132 (0.118 Mbp) and pebbles 25,101. STS (sequence-tagged site) mapping and BAC/P1/cosmid clone tiling

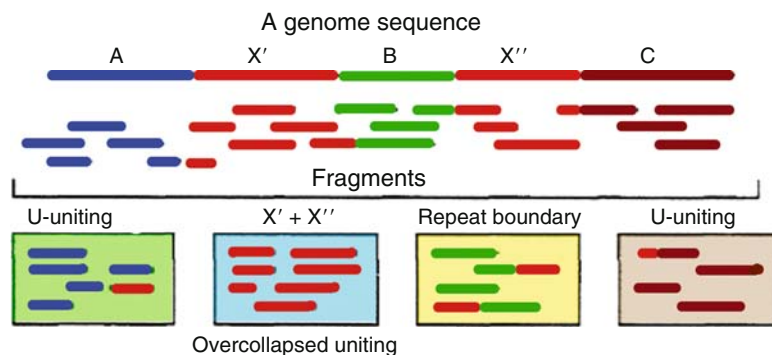

Figure S12. Scaffold. (Modified after Myers EW, et al. 2000 Science 287:2196)

Figure S13. Scaffold of a collection of ordered contigs built of unitigs. (Modified after Myers EG et al. 2000 Science 287:2196)

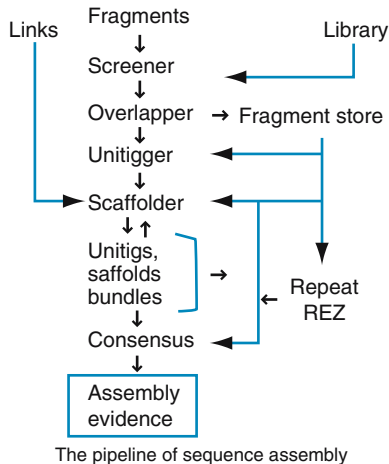

Figure S14. The overall strategy of the Celera operations. (Modified after Myers EW et al. 2000 Science 287:2196)

path (CTP) has validated the WGS map. Yet some refinement will continue, especially in the heterochromatic regions (around the centromere, etc.). ►WGS, ►genome projects, ►contig, ►mate pair, ►Bayes' theorem, ►STS, ►BAC, ►P1, ►cosmid, ►tiling, ►DNA sequencing, see Fig. S14; Myers EW et al 2000 Science 287:2196.

Scaffold-Mediated Activation: The assembly of a molecular platform in response to death stimuli and the recruitment of pro-caspases. It is initiated through cell surface receptors such as the Fas receptors, TNF α receptors and their bound ligands leading to the formation of caspases and ending up in apoptosis. ►caspase, ►TNF, ►apoptosis; Earnshaw WC et al 1999 Annu Rev Biochem 68:383.

SCAIP (single condition amplification/internal primer sequencing): Amplifies large number of exons at a single set of PCR temperatures. Sequencing specificity is gained by uniform use of a second, internal set of sequencing primers. After purification of the DNA sequencing requires three days at low cost (Flanigan KM et al 2003 Am J Hum Genet 72:931).

Scale-Free Networks: networks.

Scaling: ►quarter-power scaling, ►synaptic scaling

SCAM (substituted-cysteine accessibility method): The method used for studying cysteine substitution and covalent modification on the structure-function relationship of proteins.

SCAMP (secretory carrier membrane proteins): Integral membrane proteins of secretory and transport vesicles, like the synaptic vesicles, etc. (See Wu TT, Castle JD 1998 Mol Biol Cell 9:1661).

Scanning Electronmicroscopy (SEM): In contrast to transmission electron microscopy, the electron beam is reflected from the surface of the specimen, coated with a heavy metal vaporized in a vacuum, through a process called *shadowing*. As the electron beam scans the specimen, secondary electrons are reflected according to the varying angles of the surface of the object and generate a *three-dimensional image* corresponding to the grade of reflections. The maximal resolution is 50–100 times less than with the transmission electronmicroscopy but the image obtained can be highly magnified. It is an important technique for developmental studies. ►electronmicroscopy, ►stereomicroscopy, ►scanning tunneling microscopy, ►SPM, for picture see ►petals

Scanning Force Spectroscopy (SFS): Measures association and dissociation constants of biological molecules. ►optical tweezer; Bonin M et al 2002 Nucleic Acids Res 30(16):e81.

Scanning, Genetic: Genetic scanning.

Scanning Linker Mutagenesis: The transposon is inserted within the gene in-frame at an appropriate restriction enzyme recognition site (see Fig. S15). After transcription and translation of the construct the target protein carries a new peptide of a size depending on the size of the insertion. The procedure has been applied to both prokaryotes and eukaryotes. ►transposon, ►restriction enzyme, ►insertional mutation; Hayes F 2003 Annu Rev Genet 37:3.

Figure S15. Scanning linker mutagenesis

Scanning Mutagenesis: ▶homolog-scanning mutagenesis, ▶linker scanning

Scanning of mRNA: The eukaryotic mRNA does not have a special consensus (such as the Shine-Dalgarno box in prokaryotes) for attachment to the ribosomes, so the mRNA leader adheres by its methylated guanylic cap to the ribosomes and the ribosome runs on it until it finds an initiation codon (generally AUG) to start translation. A preferred sequence, however, may be around the AUG codon AG—CCAUGG. The 3' terminus of the 18S rRNA of mammals bears some similarity to the prokaryotic 16S terminus:

$$A^{Me2} A^{Me2} CCUGC GGAAGGAUGA—UUA-3'-OH.$$

The presence of the m⁷G-cap facilitates the initiation but is not absolutely indispensable. The average length of the 5'-untranslated (50–70 nucleotides) sequence and its structure may favor translation but only large differences from it (very short tracts) decrease substantially the initiation. A ~12-nucleotide hairpin secondary structure between the cap and AUG improves the efficiency of translation. Similarly, the polyA tail is advantageous for translation possibly by facilitating the recycling of the ribosomes on the same mRNA. *Leaky scanning* indicates that more than one initiator codons or only the second or a later AUG is used for translation and the preceding one(s) are skipped (Chen A et al 2005 Nucleic Acids Res 33:1169). In this case different polypeptides may result. ▶Shine-Dalgarno sequence, ▶eIF, ▶initiation codon; Kozak M 1989 J Cell Biol 108:229; Samuel CE 1989 Progr Nucleic Acid Res Mol Biol 37:127.

Scanning Tunneling Microscope (STM): STM can resolve biological molecules at the atomic level; its use has been proposed for DNA sequencing. With STM, vibrational spectroscopy is possible permitting the analysis of molecules adsorbed on a surface. The vibrational energies may reveal adsorption sites, orientation and adsorption changes. ▶electrospray MS, ▶laser desorption, ▶nanotechnology, ▶SPM

SCAP (SREBP cleavage-activating protein): Regulates cholesterol metabolism by promoting the cleavage of transcription factors SREBP-1 and -2 (sterol regulatory element binding proteins). In low-sterol cells, discrete proteolysis cuts of the amino-terminal of SREBPs. As a consequence, these proteins enter the nucleus and activate the LDL receptor and cholesterol and fatty acid biosynthetic enzymes. The system can be studied by mutant CHO cells that either cannot synthesize cholesterol or LDL receptors in response to sterol depletion, or are sterol resistant and cannot terminate the synthesis of sterols or their LDL receptor. ▶sterol, ▶LDL, ▶CHO, ▶Niemann-Pick disease, ▶lipodystrophy; Shimano H 2001 Progr Lipid Res 40(6):439.

SCAR (sequence-characterized amplified region): Physical markers obtained by polymerase chain reaction-amplified RAPD bands. ▶amplification, ▶RAPD, ▶PCR; Iturra P et al 2001 Heredity 84:412.

SCAR: The suppressor of cAMP receptor. ▶cAMP

SCARMD: ▶muscular dystrophy

Scatter Diagram: A two-dimensional graphic representation of the characteristics of two variables, two traits, which may be or may not be correlated, e.g., people with a certain eye and hair color.

Scatter Factor (hepatocyte growth factor): Cellular responses of scatter factor are mediated by the Met tyrosine kinase receptor. It has multiple cell targets and it is probably involved in mesenchym-alepithelial interactions and liver, kidney development, organ regeneration, metastasis, etc. ▶hepatocyte growth factor, ▶metastasis, ▶macrophage-stimulating protein; Tacchini L et al 2001 Carcinogenesis 22:1363.

Scattering: Deflection of electrons by collision(s). ▶Compton effect

Scavenger Molecules: They clean up the cells of substances that are no longer needed.

SCC: Yeast integral membrane protein with partial structural homology to cyclophilins. ▶cyclophilins, ▶double-strand breaks

Sccl1: ▶separin, ▶Rec8

SCD25: A suppressor of gene *cdc25* mutations in yeast; increases the dissociation of Ras•GDP but does not affect Ras•GTP. ▶cell cycle, ▶cdc25

SCE: ▶sister chromatid exchange

Scent: ▶fragrances

SCEUS (smallest conserved evolutionary unit sequences): Reveal evolutionary similarities of the DNA in the genomes across taxonomic boundaries. ▶unified genetic map

SCF (Skp1—CDC53—F-box protein): A complex of ubiquitination function. The SCF protein complexes have regulatory role in the cell cycle and development. ▶Skp, ▶CKS1, ▶CDC53, ▶F-box, ▶ubiquitin, ▶jasmonic acid, ▶E1, ▶E2, ▶E3, ▶cell cycle, ▶von Hippel-Lindau syndrome, ▶glucose induction; see also Patton EE et al 1998 Trends Genet 14:237; Schwab M, Tyers M 2001 Nature [Lond] 413:268; Zheng N et al 2002 Nature [Lond] 416:703.

SCF: ▶stem cell factor

ScFv (single chain fragment variable): A variable portion of the antibody molecule that may still be expressed, e.g., in plantibodies or bacteria or other cells. ▶antibody, ▶plantibody, ▶single-chain Fv antibody; Norton EJ et al 2001 Hum Reprod 16:1854.

Scheie Syndrome: ▶Hurler syndrome

Schiff Base: α -amino groups of amino acids may react reversibly with aldehydes and form a Schiff base; these are labile intermediates in amino acid reactions. ▶Schiff reagent

Schiff's Reagent: Retains a blue color in the presence of aldehydes. Aldehydes are exposed to a fuchsin solution (0.25 g/L H₂O) and decolorized by SO₂. ▶aldehyde, ▶fuchsin

Schimke Immuno-Osseus Dysplasia (SIOD): An apparently recessive disease displaying spondyloepiphyseal dysplasia, lentigines and progressive immune and other defects. The basic anomaly is due to mutation of chromosomal matrix-associated protein (SMAR-CAL1, 2q34-q36) controlling chromatin remodeling. The gene contains 17 exons and encodes a 954 amino acid protein. Variant forms exist. ▶spondyloepiphyseal dysplasia, ▶lentigines, ▶chromatin remodeling; Boerkoel CF et al 2002 Nature Genet 30:215.

Schindler Disease: An α -N-acetylgalactosaminidase deficiency (human chromosome 22), a lysosomal storage abnormality(?) leading to a neurological disease with onset before age one and progressive deterioration of motor and talking skills. ▶Kanzaki disease

Schinzel Syndrome (ulnar-mammary syndrome, 12q24.1): An autosomal dominant ulnar-mammary syndrome shows complex symptoms including malformation of the hand and shoulder, mammary glands, delayed puberty, obesity, etc. The T box gene TBX3 causes it. ▶ulna

Schinzel-Geidion Syndrome: An autosomal recessive malformation of the face and head, heart, growth retardation, telangiectasia, supernormal hair development. ▶hypertrichosis, ▶telangiectasis

Schistosomiasis: The state of disease of animals and humans seized by one or another species of the

parasitic flatworms *Schistosoma* (fluke). The parasites infect the blood vessels through contact with contaminated waters in warm climates of the world. In these species, the male carries the female in a ventral sac (gynecophoral canal) (see Fig. S16). Intermediate hosts are snails and molluscs. The *S. haematobium* is primarily a human parasite.

Figure S16. *Schistosoma haematobium* male carrying the female

The *S. japonicum* infects several animals as well. The symptoms of the disease may vary according to the various species and may include systemic irritations, cough, fever, eruptions, tenderness of the liver, diarrhea, and bladder carcinoma, etc. Without medication, the infected intestines, liver, kidneys, brain, etc., may be seriously damaged. The therapeutic antimony derivatives are highly toxic to humans. The parasite is present in millions of people of the tropics including the ancient Egyptian mummies. A codominant locus in human chromosome 5q31-q33 provides some protection against *Schistosoma mansoni*. The interferon- γ receptor (IFN- γ R1) locus (6q22-q23) also controls *S. mansoni* infection. Vaccination with attenuated larvae is feasible. ▶IFN; <http://www.tigr.org/tdb/tgi/>; Verjovski-Almeida S et al 2003 Nature Genet 35:148; Hu W et al 2003 Nature Genet 35:139.

Schizencephaly (10q26.1): A very rare brain disorder. The hemisphere is partly missing and cerebrospinal fluid fill the void. Type one is mild but type II is severe involving mental retardation, seizure, lack of speech and blindness. EMX2 linkage and EMX2 independent case are known (Tietjen I et al 2005 Am J Med Genet 135:166).

Schizocarp: A fruit where the carpels split apart in order to free the seeds.

Schizophrenia (dementia praecox): A behavioral disorder. The afflicted individuals cannot distinguish well reality from dreams and imagination. Hallucinations and paranoid behavior, delusions, inappropriate emotional responses, lack of logical thought and concentration are common symptoms. The precise mechanism of inheritance is unknown yet in about 13% of the children of afflicted parents it reoccurs, and ~45% of

the identical twins are concordant in this neurological disease but only ~15% of dizygotic twins.

The general incidence in the population varies from 1 to 4%. Both autosomal, pseudoautosomal single and multiple recessive and dominant loci were implicated. There were some indications that schizophrenia genes are in chromosomes 1q32.2 (?), 4q34.3, 5q33.2, 6q21.31, 6q25.2, 6pter-p22, 7p15.2, 7q11, 8p21-p22, 9q21, 10p, 10q22.3, 12q24, 13q34, 14q13, 15q11.2, 17p11-q25.1, 20, 21q21.2, 22q12.1-q11.23 (proline dehydrogenase), 22q21, 4q31 and in the long and short arms of chromosome 5. The 22q11 site encodes catechol-*O*-methyltransferase (COMT) and its deletion involves velocardiofacial syndrome and high incidence (20–30%) of psychiatric diseases, including schizophrenia. COMT controls the metabolism of catecholamine neurotransmitters (Shifman S et al 2002 Am J Hum Genet 71:1296). Some evidence indicates chromosomal sites 13q34 and 8p21-p22 as the most important for the determination of susceptibility. A schizophrenia locus was assigned to human chromosome 1q21-q22 with a lod score of 6.5 (Brzustowicz LM et al 2000 Science 288:678). This gene encodes the selenium-binding protein (SELENBP1) of unknown function and its upregulation is the most consistent biomarker of the disease (Glatt SJ et al 2005 Proc Natl Acad Sci USA 102:15533). DISC1 (disrupted in schizophrenia) is a major factor in developing this affective disorder. DISC1 is disrupted either by balanced translocation t(1;11)(q42;q14), or t(1;16)(p31.2;q21). The 1p31.2 breakpoint disrupts the B1 isoform of phosphodiesterase 4B gene (PDE4B). The N-terminal domain (amino acids 219-283) of DISC1 binds PDE4B. PDE4B apparently inactivates adenosine 3',5' cyclic monophosphate (cAMP), which has important function in learning, memory and mood. DISC1 interacts with the UCR2 domain of PDE4B and a raise in cAMP disrupts the association of PDE4B and DISC1; concomitantly this increases PDE4B activity (Millar JK et al 2005 Science 310:1187). *Disc1* missense mutations in mice give rise to phenotypes related to depression and schizophrenia, thus supporting the role of *DISC1* in major mental illness and can serve as an animal model for the disease (Clapcote SJ et al 2007 Neuron 54:387).

The various manifestations of schizophrenia have strong environmental components. Maternal malnutrition during the first trimester, maternal influenza during the second trimester, perinatal complications, intrauterine fetal hypoxia, or maternal pre-eclampsia may substantially aggravate the risk (Tsuang T 2000 Biol Psychiatry 47:210). Maternal-fetal incompatibility due to the presence of the Rh D protein in the pregnancy increases the chance for the psychiatric condition by a factor of ~2.6 (Palmer CGS et al 2002 Am J Hum

Genet 71:1312). Retroviral sequences have been detected in the cerebrospinal fluid in ~28% of the patients with recent onset and in ~5% of patients with chronic affliction (Karlsson H et al 2001 Proc Natl Acad Sci USA 98:4634). *Oligodendrocyte lineage transcription factor 2* (OLG2) abnormality increases susceptibility to schizophrenia by itself and by affecting other genes namely CNP, NRG1 and ERBB4 (Georgieva L et al 2006 Proc Natl Acad Sci USA 103:12469).

MAO (monoamine oxidase) level is reduced in the afflicted individuals. MAO enzyme removes amino groups from neurotransmitters. The overproduction of dopamine (3,4-dihydroxyphenyl-ethylamine), a precursor of neurotransmitters may be suspected in causing it. Glutamate decarboxylase 67 (GAD67), a marker for this system has been found by many studies to show decreased expression in schizophrenia and bipolar disorders. In the latter, suppression of transcription factors involved in cell differentiation may contribute to GABA dysfunction (Benes FM et al 2007 Proc Natl Acad Sci USA 104:10164). Chlorpromazine (a peripheral vasodilator, antiemetic drug) and reserpine (alkaloid) may alleviate the psychological symptoms by inhibiting dopamine receptors. According to the glutamate-dysfunction hypothesis the disease is caused by an imbalance between dopamine and glutamate or the glutamate receptor NMDA. In schizophrenia and other affective disorders frequently an expansion of trinucleotide repeats is detectable. Schizophrenia, other mental illnesses and drug addiction predispose to violent crime 2–6 times in excess of normal individuals (Friedman RA 2006 N Engl J Med 355:2064).
 ►paranoia, ►psychoses, ►affective disorders, ►neurological disorders, ►pseudoautosomal, ►concordant, ►twinning, ►trinucleotide repeats, ►obsessive-compulsive disorder, ►cataplexy periodic, ►eclampsia, ►Rh blood factor, ►hypoxia, ►MAO, ►NMDA; Baron M 2001 Am J Hum Genet 68:299; Gurling HMD et al 2001 Am J Hum Genet 68: 661; neuregulin and susceptibility: Stefansson H et al 2002 Am J Hum Genet 71:877; Chumakov I et al 2002 Proc Natl Acad Sci USA 99:13675; Levinson DF et al 2003 Am J Hum Genet 73:17; Lewis CM et al 2003 Am J Hum Genet 73:34; review: O'Donovan MC et al 2003 Hum Mol Genet 12:R125; research forum: <http://www.schizophreniaforum.org>.

Schizosaccharomyces pombe (fission yeast): The 3 chromosomes are of 5.7, 4.7 and 3.5 Mb size, respectively (see Fig. S17). It has the lowest number of genes among eukaryotes, 4944. The cells are 7 × 3 µm. This eukaryote, an ascomycete, has both asexual (by fission) and sexual life cycles (each meiosis producing 8 ascospores). Under good growing conditions it reproduces by mitotic divisions.

At starvation (for any factors of growth) the plus (P) and minus (M) type cells fuse and meiosis follows. The mitotic cell cycle (2.5 h) has the typical G₁, S, G₂ and M phases. The G₂ phase takes 70% of the total time whereas the other phases equally share the rest. Under severe nutritional limitations instead of sexual development, the cells are blocked in either of the G phases and this dormant state is called “GO”.

Figure S17. *S. pombe*

The mating type is determined by which of the *P* or *M* alleles is switched (transposed) from their silent position to the *mat1* locus where they are expressed. Actually both *P* and *M* genes have two alleles with different number of amino acids in their polypeptide products: *Pc* (118), *Pi* (159) and *Mc* (181) and *Mi* (42). The *c* alleles (required for meiosis and conjugation) are transcribed rightward from the centromere when nitrogen is available, and the *i* alleles (required only for meiosis) are transcribed in the opposite direction in N starvation. The product of the *Pi* allele has a protein-binding domain, whereas that of *Mc* shows some homology to the *Drosophila Tdf* (testis-determining factor) and the mouse *Tdy*. Homothallic strains can switch between mating types but the heterothallic ones are either *P* or *M*. The *MAT* site is comparable to the disk drive of a computer (or the slot of a tape player) where either the *P* or the *M* disk (or tape cassette) is plugged in and that determines whether the mating type in the heterothallic strain will be *P* or *M*. The *P* (1113 bp) and *M* (1127 bp) sites are actually the storage sites for the *P* and *M* mating type information, respectively. The recombination-promoting complex contains proteins Swi2 and Swi5 that are located near the silent mating type region and exercise long-range effects (Jia S et al 2004 Cell 119:469).

The mating type region in the right arm of chromosome II can be represented as shown in Figure S18.

The *DSB* (double-strand break) near the *MAT* site—in about 25% of the cells—is probably required so

that the chromosome would permit the insertion of one or the other cassette. This breakage is probably transient and quickly restored so that the continuity of the chromosome would not be compromised. According to new data the break at the *mat1* site is actually an artifact arising during purification of alkali-labile DNA due to a genetic imprint occurring while the lagging strand is synthesized. The imprints are one or two RNA nucleotides in the DNA (Vengrova S, Dalgaard JZ 2004 Genes Dev 18:794). This imprint may then reverse the *mat1* locus or introduce an origin of replication. The ~15 kb *L* and *K* sequences are spacers where meiotic recombination is not observed. The H₁ (59 bp) and H₂ (135 bp) homology boxes are flanking the disk drive (*MAT*) and both floppy disks while the H₃ (57 bp) only occurs at left of the *P* and *M* sequences. It has been supposed that the reason why the *P* and *M* elements are silent at the storage sites is because of the H₃ presence there but not at the *MAT* site where they are expressed. The switching (transposition) is controlled by *SAS1* and *SAS2* (switch-activating sites) right of *DSB* (within 200 kb). In addition, at least 11 other transacting (*swi*) loci regulate switching (transposition). Mating type determination in the budding yeast (*Saccharomyces cerevisiae*) is also controlled by transposition, albeit in a different way, and the homology of the DNA sequences in the elements is low. Fission yeast has contributed to learning many aspects of the cell cycle control. Its genome sequence (Wood V et al 2002 Nature [Lond] 415:871) revealed 4824 protein-coding genes, so far the smallest number in eukaryotes. Its promoter sequences are longer than those in budding yeast indicating extended control of functions. About 43% of the genes contain introns. About 50 genes seem homologous to some extent to human genes controlling disease and half of these are cancer-related. ▶*Saccharomyces cerevisiae*, ▶mating type determination, ▶SWI, ▶cell cycle, ▶imprinting; Vengrova S et al 2002 Int J Biochem Cell Biol 34:1031; http://www.sanger.ac.uk/Projects/S_pombe/; <http://pingu.salk.edu/~forsburg/pombeweb.html>.

Schneckenbecken Chondrodysplasia: Autosomal recessive, lethal defect of the cartilage. It bears similarity to thanatophoric dysplasia.

Figure S18. Mating type controls in *Schizosaccharomyces*

Schnipsel Database: Facilitates the identification of protein relationships by using Schnipsels (fragments) using SMART. ►[SMART](#)

Schwachman-Diamond Syndrome (human chromosome 7q11): Involves recessive pancreatic lipomatosis, bone marrow dysfunction and skeletal anomalies. (See Goobie S et al 2001 *Am J Hum Genet* 68:1048; Boocock GRB et al 2003 *Nature Genet* 33:97).

Schwann Cell: A glial cell (forms myelin sheath for the peripheral nerves). Its differentiation requires the Oct-6 POU factor, Ca^{2+} /calmodulin kinase, MAPK, cAMP response element-binding protein, expression of *c-fos* and *Krox24* genes. ATP arrests the differentiation of the Schwann cells before myelination. ►[myelin](#), ►[Oct-1](#), ►[POU](#), ►[calmodulin](#), ►[MAPK](#), ►[cAMP](#), ►[fos](#), ►[Krox-24](#)

Schwannoma: ►[neurofibromatosis](#)

Schwartz-Jampel Syndrome (chondrodystrophic myotonia, 1p34-p36.1): A rare recessive failure to relax muscles, reduced height, skeletal dysplasia (abnormal development). The affection is due to an altered proteoglycan (perlecan) of the basement membranes. ►[basement membrane](#); Arikawa-Hirasawa E et al 2002 *Am J Hum Genet* 70:1368.

Scianna Blood Group (Sc): Represented by antigenic groups Sc-1 and Sc-2, located in human chromosome 1. ►[blood groups](#)

Sciara: Dipteran flies with polytenic, giant chromosomes in their salivary glands. The basic chromosome number in *Sciara coprophylla* is 3 autosomes and 1 X chromosome but there are also the heteropycnotic so called *limited chromosome(s)*, which are present only in the germ-line. They are eliminated from the nuclei during the early cleavage divisions. The egg pronucleus contains three autosomes, an X chromosome and one or more limited chromosomes. The sperm contributes three autosomes, two X chromosomes and some limited chromosomes that are all of maternal origin. The first division of the spermatocyte is monocentric and separates the maternal chromosome set from the paternal one. The maternal chromosomes move to a single pole whereas the paternal set is positioned away from the pole and are never transmitted to the progeny. The single secondary spermatocyte displays an unusual unequal type division. The X-chromosome divides longitudinally and both copies are included into the same cell, and only this cell survives. From the cleavage nuclei first the limited chromosomes are eliminated and subsequently, from the cells that become male one of the X-chromosomes is also evicted thus the males become XO and the females are XX. ►[Rhynchosciara](#), ►[polytenic chromosomes](#), ►[salivary gland](#)

►[chromosomes](#), ►[sex determination](#), ►[chromosomal sex determination](#)

SCID (severe combined immunodeficiency): A heterogeneous group's genetically determined diseases. It involves defective V(J)D recombination of immunoglobulin genes. Several frameshifts, point mutations or deletions in the IL-2R γ (γc) chain (human chromosome Xq13) were found to be associated with SCID-X1. Actually, this part of the γ -chain is shared by the receptors of IL-4, IL-7, IL-9 and IL-15. Because of the deficiency, the T cells and the natural killer cells also become abnormal. The anomaly may involve also the Jak/STAT and other signaling pathways. Jak3 defects cause SCID symptoms. Introduction of genetically engineered macrophages expressing IFN- γ into the lung of mice provided marked protection against infection. IFN- γ upregulates the expression of major histocompatibility class I and class II molecules that lead to the activation of killer lymphocytes. Apparently after successful gene therapy, using IL2RG interleukin-2 receptor component in genetically engineered vector, caused lymphoma in several cases. Ora1 protein (encoded at 12q24) controls CRAC channel function, i.e., Ca^{2+} -release-activated Ca^{2+} influx. Sustained calcium supply is essential for the adaptive immune response. Some SCID patients have defect in CRAC and consequently loss of immune protection (Feske S et al 2006 *Nature [Lond]* 441:179). In a mouse model with ablated *Arf* tumor suppressor and IL-2R γ high frequency of insertional mutations occurred near or within several protooncogenes; thus this strain could be used as a model for testing potential risks of human gene therapy for XSCID constructs (Shou Y et al 2006 *Proc Natl Acad Sci USA* 103:11730). ►[adenosine deaminase deficiency](#), ►[severe combined immunodeficiency](#), ►[gene therapy](#), ►[signal transduction](#), ►[immunoglobulins](#), ►[RAG](#), ►[DNA-PK](#), ►[T cell](#), ►[killer cell](#), ►[MHC](#), ►[Jak/STAT](#), ►[IL-2](#), ►[IL-4](#), ►[IL-7](#), ►[IL-9](#), ►[IL-15](#), ►[gene therapy](#), ►[calcium signaling](#); Wu M et al 2001 *Proc Natl Acad Sci USA* 98:14589; French Gene Therapy Group 2003 *J Gene Med* 5:82.

Science: A systematic study of natural phenomena with the explicit purpose to prove or negate a working hypothesis or hypotheses by experimental means. According to K.R. Popper (1962 *Conjectures and Refutations*, Basic Books, New York, p 218), for science the “criterion of potential satisfactoriness is thus testability, or improbability: only a highly testable or improbable theory is worth testing and is actually (and not merely potentially) satisfactory if it withstands severe tests—especially those tests to which we could point as crucial for the theory before they were ever undertaken. I refuse to accept the view

that there are statements in science which we have, resignedly, accept as true merely because it does not seem possible...to test them". Science seeks to store, classify and evaluate certainties. Research is exploring uncertainties to provide facts for science. Applied science seeks to find economic use of the principles discovered by basic or pure science. Gathering information is one of the tools of science. The information becomes science when it can be integrated into a proven theoretical framework. The framework may need modification as information accrues. Science should never be subjected to ideology, politics and unproved or improvable ideas. Such influences are disastrous for science as the famous Galileo trial had shown in 1663 when the great scientist was forced to recant his valid thesis that the Earth is not the center of the Universe: "I abjure, curse, and detest the aforesaid errors and heresies, and generally every other error". Using big words and overcomplicated sentences are against the aim of sciences, which calls for lucidity. Coining new terms unless they facilitate communication must be avoided. It is important to explore the exact contents and meanings of terms before application in communication to be sure they are not preempted. ►experiment, ►genetics, ►misconduct scientific, ►lysenkoism, ►creationism; theory of scientific discovery: Koshland DE Jr 2007 Science 317:761.

Scientific Freedom: The right to pursue researches and publish the outcome. This right is limited, however, by the need to regulate activities that are directed against the well-being of humans, human economic activities and specifically the freedom to create biological and chemical terror weapons and publishing papers that may jeopardize public safety. Serious concerns arise about how to implement the regulation without fettering scientific inquiry and safeguarding society. ►bioterrorism, ►informed consent, ►bioethics; Fraser CM, Dando MR 2001 Nature Genet 29:253.

Scientific Misconduct: According to the NSF (National Science Foundation, USA) "fabrication, falsification, plagiarism, or other serious deviation from accepted practices." ►publication ethics, ►ethics, ►misconduct scientific; Federal Register 18, March, 2002.

Scintigraphy: The photographic location of radionuclides within the body after introduction of radioactive tracers. ►radioactive label, ►radioactive tracer

Scintillation Counters: Can be liquid scintillation counters or crystal scintillation-counters for solids. The counter is an electronic appliance where the sample is placed in a solution of organic compounds (cocktail). The radiation coming from the isotopes (even from the weak β -emitters) causes flashes in the fluorescing cocktail that are directed to a photoelectric

cell. The cell then releases electrons that are amplified and registered (counted). Each flash corresponds to a disintegration of an atom of the isotope so the equipment displays (or prints out) the disintegrations per minute (dpm) or counts per minute (cpm), generally with background radiation subtracted. This information provides measures of the quantity of the label (or labeled compound). In the crystal scintillation counter, the radiation (usually energetic γ -rays, X-rays or β -rays) emitted by the isotope hits a crystal of sodium iodide containing traces of thallium iodide, and again the disintegrations are registered similarly to the liquid scintillation counter. ►radioisotopic tracers, ►radiolabeling, ►isotopes, ►dpm, ►radiation hazard assessment

Scission: Cuts in both strands of a DNA molecule at the same place. ►nick

Scissors Grip: ►Max

Scissors, Molecular: ►Cre/loxP, ►excision vector, ►targeting genes

Scj1: A 40 kDa budding yeast chaperone in the endoplasmic reticulum, inducible by tunicamycin antibiotic but not by heat. ►chaperones; Nishikawa S, Endo T 1997 J Biol Chem 272:12889.

SDK: A protein with phosphotyrosine binding domain but different from the SH2 domain of SRC. ►SRC, ►SH2, ►PTB; Kojima T et al 2001 Biochem Biophys Res Commun 284:1039.

SCLC: ►small cell lung carcinoma

Sclerenchyma: Plant tissues with tough, hard cell walls.

Scleroderma: A probably autosomal dominant disease involving scaly hardening of the skin and increased frequency of chromosome breakage. ►skin diseases; Whitfield ML et al 2003 Proc Natl Acad Sci USA 100:12319.

Scleroids: Cells with unusually hardened walls.

Sclerosis: The hardening caused by inflammation or hyperplasia of the connective tissue.

Sclerosteosis (SOST/BEER, 17q12-q21): A rare recessive dysplasia of the bones displaying progressive sometimes-massive overgrowth distinct from osteopetrosis. It may distort the face and may be accompanied by syndactyly. Its highly conserved glycoprotein product, sclerostin appear to be an antagonist of the bone morphogenetic protein and other members of the TGF β family. It contains cystine-rich "knots." ►BMP, ►syndactyly, ►TGF, ►van Buchem disease; Brunkow ME 2001 Am J Hum Genet 68:577; Balemans W et al 2001 Hum Mol Genet 10:537.

Sclerotia: ►hypha, ►ergot

Sclerotome: Mesenchymal embryonic precursor of the vertebral column and ribs.

SCMRE: A cis-acting element in the c-fos protooncogene and it is responsible for induction by some mitogens. ►FOS, ►protooncogene, ►cis, ►mitogen

SCN: Sodium ion channel.

scnDNA: A single-copy nuclear DNA.

Scoliosis: In this condition, the spine is not straight but laterally curved (see Fig. S19); it may be due to polygenic causes or it can be part of skeletal syndromes. Its incidence is about 1–6% of the adult human populations. Kyphoscoliosis is a similar condition in mice. ►horizontal gaze palsy, ►lordosis, ►kyphosis; Blanco G et al 2001 Hum Mol Genet 10:9.

Figure S19. Scoliotic pig

S-Cone Syndrome (ESCS, encoded by PNR/NR2E3 gene in human chromosome15q23): A night blindness and blue light hypersensitivity because of defect in the retinal cones in the eye. ►eye diseases

SCOP: The structural classification of proteins. (See Murzin AG et al 1995 J Mol Biol 247:536; Przytycka T et al 1999 Nature Struct Biol 6:672; <http://scop.mrc-lmb.cam.ac.uk/scop>).

Scopes Trial: In 1925, John Scopes was convicted for breaking Tennessee state law (repealed in 1967) by teaching evolution in a public school. The verdict was later overturned on a technicality. ►intelligent design, ►creationism

Scopolamine: ►Datura, ►alkaloids

Score Test (Wald-Wolfowitz test): A non-parametric test to compare unmatched samples and all information is paired with a numerical score. It is assumed that the scores represent a continuous distribution. The null hypothesis is that the runs represent identical populations. (See Hays WL, Winkler RL 1971 Statistics: Probability, Inference and Decision. Holt. Rinehart and Winston, New York).

Scotomorphogenesis: The differentiation of plants in the absence of light, e.g., etiolated growth. ►brassinosteroids

SCP₂: A sterol carrier protein 2; probably the same as nsL-TP. ►sterol

Scrapie: ►encephalopathies, ►Creutzfeldt-Jakob disease, ►prion, ►kuru

Scratchy: An in vitro method of combinatorial protein engineering independent of sequence identity. It involves incremental truncation of protein coding genes and then reshuffling and DNA fusion. The purpose is to improve protein function. ►iterative truncation; Lutz S et al 2001 Proc Natl Acad Sci USA 98:11248.

Screening: Selective classification of cell cultures for mutation or for special genes, conveying auxotrophy, antibiotic or other resistance, selecting antibodies by cognate antigens, plant populations for disease- or chemical-resistance, animal progenies for blood groups, etc. Narrow sense screening may not involve selective isolation but special criteria are used to distinguish in the growing population those individuals who have a special trait. Genetic screening in animals is feasible by the use of RNAi. The RNA is introduced into pronuclear cells by injection and it is transmitted for several generations. The RNAi can knock down important genes and thus their function is revealed (Peng S et al 2006 Proc Natl Acad Sci USA 103:2252). ►genetic screening, ►genetic testing, ►knock-down, ►RNAi; Forsburg SL 2001 Nature Rev Genet 2:659; Jorgensen EM, Mango SE 2002 Nature Rev Genet 3:356.

Screwworm: ►Cochliomya hominivorax, ►genetic sterilization, ►myiasis

Scribble: ►PDZ

Scripton (transcripton): A unit of lambda phage transcription. ►lambda phage

scrRNA: Small cytoplasmic RNAs. ►snRNA

scrNAP: Small cytoplasmic ribonucleoprotein.

Scrotum: The pouch containing the testes and accessory sex organs of mammals.

Scrunching (according to the Oxford Dictionary squeezing into a compact shape): At abortive or productive initiation of transcription RNA polymerase (RNAP) “scrunches” the DNA at a stationary stage to unwind DNA and pulls it into itself. The process requires RNA synthesis. Promoter escape also involves scrunching. (See Revyakin A et al 2006 Science 314:1139; Kapanidis AN et al 2006 Science 314:1144).

Scutellum: The single cotyledon of the grass embryo (see Fig. S20).

Figure S20. S = scutellum, E = embryo

SD: ► *Segregation distorter*, ► *standard deviation*

Sdc25: A guanine-nucleotide release factor, similar to Cdc25. ► *RAS*, ► *Cdc25*, ► *EF-Tu*

SDF-1 (stromal cell-derived factor): A chemokine and natural ligand of fusin. With its receptor CXCR-4 it mobilizes and promotes the proliferation of CD34⁺ cells. ► *CD34*, ► *fusin* [*LESTR*], ► *chemokines*, ► *CXCR*; Weber KS et al 2001 *Mol Biol Cell* 12:3074.

S-DNA: A mechanically stretched DNA that might have been extended 1.7 times of its normal contour length. ► *slipped-structure DNA*, ► *trinucleotide repeats*; Cluzel P et al 1996 *Science* 271:792.

SDP: ► *short-day plants*

SDR (short dispersed repeats): Organellar DNA sequences of 50–1000 bp that may occur in direct or inverted forms and may represent more than 20% of the chloroplast genomes of *Chlamydomonas reinhardtii* alga and various land plants. Similar or shorter redundant sequences occur in the mitochondria of plants, animals and fungi. In *Saccharomyces cerevisiae* eight 200–300 bp *ori* and *rep* sequences and 200 G + C sequences of 20–50 bp may be clustered into several mtDNA gene families. Similar mobile G + C elements may occur in other fungi. SDRs have been exploited for forensic population studies. ► *chloroplasts*, ► *mtDNA*, ► *mobile genetic elements*, ► *organelle sequence transfers*; Seidl C et al 1999 *Int J Legal Med* 112(6):355.

SDR: ► *strain distribution pattern*

SDS (sodium dodecyl sulfate): A detergent, used for electrophoretic separation of protein and lipids.

Sds: A leucine-rich protein and regulates protein phosphatase 1C during mitosis of yeast. ► *protein phosphatases*; Peggie MW et al 2002 *J Cell Sci* 115:195.

SDS-PAGE: ► *SDS-polyacrylamide gel*

SDS-Polyacrylamide Gels: Electrophoretic gel containing sodium dodecyl sulfate (SDS, also called sodium lauryl sulfate [SLS], detergents) and polyacrylamide. This medium dissociates proteins into subunits and

reduces aggregation. Generally, the proteins are denatured with heat and a reducing agent before loading on the gel. The polypeptides become negatively charged by binding to SDS and are separated in the gel according to size (rather than by charge). On the basis of the mobility, the molecular weight of the subunits can be estimated with the aid of appropriate molecular size markers (ladder) but caution is required because glycosylated proteins may not reflect the molecular mass of the protein. The concentration of the polyacrylamide determines the size of the polypeptides that can be separated. Polyacrylamides (bisacrylamide: acrylamide, 1:29) separates [kDa proteins] as follows: 15% [12–43], 10% [16–68], 7.5% [36–94], 5% [57–212]. ► *gel electrophoresis*, ► *electrophoresis*

SDT Test: A non-parametric sign test used in pedigrees to compare the average number of candidate alleles between affected and non-affected siblings. ► *TDT*, ► *sib TDT*; Rieger RH et al 2001 *Genet Epidemiol* 20(2):175; <http://www.sdtcorp.com/companyprofile.html>.

SE: ► *standard error*

Sea Lion (*Eumetopias jubatus*, *Zalophus californianus*): Other species occur also in Australia and New Zealand and other parts of the coastal oceans of the world. The chromosome numbers are 2n = 32 to 36 in the different species. Some of the species form hybrids (see Fig. S21).

Figure S21. Sea lion

Sea Oncogene: An avian erythroblastosis virus oncogene. The human homolog is at human chromosome 11q13 in very close vicinity to INT2 and BCL1. ► *oncogenes*

Sea Urchins: *Strongylocentrotus purpuratus* (see Fig. S22) and *Toxopneustes lividus*, both 2n = 36, and other echinodermata have been favorable objects of cell cycle studies, fertilization, embryogenesis, development and evolution. They have very long life (>100 years) and produce annually millions of gametes. Their large-size eggs can be easily collected

and handled in the laboratory. Their non-adaptive immune system includes a highly complex system of receptors. The 814 megabase includes ~23,300 genes. The average transcript length is 8.9 kb and the average gene length is 7.7 kb. The average exon were about 100–115 nucleotides whereas the introns ~750 nucleotides. Most of the genes are in regions of 35 to 39% GC regions. Cytogenetic maps are not available. This outbreeding species is highly heterozygous and individuals display ~5% single nucleotide polymorphism (SNP), about ten times higher than that in humans. The sequenced *S. purpuratus* genome has orthologs of vertebrate genes for vision, hearing, chemosensation and several human diseases. genome: 2006 Science 314:941; immune system: Rast JP et al 2006 Science 314:952; transcriptome: Samanta MP et al 2006 Science 314:960; for genome: http://www.ncbi.nlm.nih.gov/genome/guide/sea_urchin/; for embryology: <http://www.stanford.edu/group/Urchin/>; proteins: <http://www.expasy.org/cgi-bin/get-entries?OC=Strongylocentrotus>.

Figure S22. *Strongylocentrotus*

Seal: *Callorhinus ursinus*, 2n = 36; *Zalophus californianus*, 2n = 36; *Cystophora cristata*, 2n = 34; *Erignatus barbatus* 2n = 34; *Helichoereus grypus* 2n = 32.

Search Engine: Uses the Internet as a source for finding keywords and documents. Frequently used search engines are Google, Yahoo, AltaVista and others.

Sebastian Syndrome: ► [May-Hegglin anomaly](#)

Sec6/8: A multiprotein complex that mediates cell-to-cell contacts and transport vesicle delivery. ► [Golgi apparatus](#); Matern HT et al 2001 Proc Natl Acad Sci USA 98:9648.

Sec63 (NPL1/PTL1): A 663-amino acid yeast transmembrane chaperone protein with partial homology at the near-N-end of DnaJ. It interacts with Kar2, Ces61, Sec71, and Sec72 proteins. ► [chaperones](#), ► [DnaK](#), ► [Kar2](#), ► [Sec61 complex](#), ► [Mtl1](#); Young BP et al 2001 EMBO J 20:262.

Sec61 Complex (Sec Y complex): Built of the three Sec subunits (α , β , γ) and other proteins form a protein-conducting channel across the endoplasmic reticulum (ER) membrane. It associates with the large subunit of the ribosome of prokaryotes and eukaryotes and transports some of the nascent proteins into the lumen of the ER. A small molecule, cotransin (see Fig. S23), inhibits protein translocation into ER in a discriminatory manner of signal sequence (Garrison JL et al 2005 Nature [Lond] 436:285). ► [Sec proteins](#), ► [protein-conducting channel](#), ► [ribosomes](#), ► [endoplasmic reticulum](#), ► [protein synthesis](#), ► [Sec63](#), ► [endoplasmic reticulum-associated degradation](#), ► [unfolded protein response](#), ► [CAM](#), ► [chloroplast import](#); Mori H, Ito K 2001 Proc Natl Acad Sci USA 98:5128; Beckmann R et al 2001 Cell 107:361; van den Berg B et al 2004 Nature [Lond] 427:36.

Figure S23. Cotransin

SecA (α) Protein: (seven-component complex): A peripheral membrane domain of the translocase enzyme and it is the primary receptor for the SecB/pre-protein complex by recognizing the leader domain of the pre-protein. Hydrolyzes ATP, GTP, promotes cycles of translocations and pre-protein release. ► [membranes](#), ► [translocase](#), ► [Mss](#), ► [Ypt](#), ► [Rab](#), ► [translocase](#), ► [translocon](#), ► [protein targeting](#), ► [SRP](#), ► [ARF](#), ► [protein synthesis](#), ► [endoplasmic reticulum](#), ► [exocytosis](#); Hsu SC et al 1999 Trends Cell Biol 9:150; Jilaveanu LB 2005 Proc Natl Acad Sci USA 102:7511.

SecB (β) Protein: A 17-subunit chaperone involved in translocation of pre-proteins by complexing and keeping them in the right conformation and binding to membrane surface of the endoplasmic reticulum. Recognizes both the leader and mature protein domains. ► [chaperones](#), ► [membranes](#), ► [endoplasmic reticulum](#), ► [SRP](#), ► [translocon](#), ► [translocase](#), ► [protein targeting](#); Driessen AJ 2001 Trends Microbiol 9:193.

Secis: The selenocysteine regulatory element in coding and non-coding regions of selenocystein genes in prokaryotes and eukaryotes (Mix H et al 2007 Nucleic Acids Res 35:414).

Seckel's Dwarfism (bird-headed dwarfism, 3q22.1-q24): A microcephalic autosomal recessive condition with reduced intelligence. The basic defect is in a phosphatidylinositol 3-kinase-like kinase. ▶[dwarfism](#), ▶[microcephaly](#), ▶[phosphatidylinositol](#); O'Driscoll M et al 2003 *Nature Genet* 33:497.

Second Cycle Mutation: Caused by the excision or movement of a transposable element and leave behind a footprint which still causes some type of alteration in the expression of the gene. This type of alterations may be connected with the defective nuclear localization of a transcription factor. ▶[transposon footprint](#), ▶[transposable elements](#), ▶[nuclear localization sequences](#)

Second Division Segregation: ▶[tetrad analysis](#), ▶[post-reduction](#)

Second-Harmonic Imaging Microscopy: Visualizes biomolecular arrays in cells, tissues and organisms. ▶[microscopy](#); Campagnola PJ, Loew LM 2003 *Nature Biotechnol* 21:1356.

Second-Male Sperm Preference: ▶[last-male sperm preference](#)

Second Messenger: Molecules with key roles in signal transduction pathways such as cyclic-AMP, cyclic-GMP, and others. Animal physiologists call hormones first messengers. In animal and plant cells Ca^{2+} is also considered to play the role of second messenger. Inositol triphosphate is also a second messenger. ▶[cAMP](#), ▶[cGMP](#), ▶[mRNA](#), ▶[PIK](#), ▶[PIP](#), ▶[signal transduction](#), ▶[G proteins](#)

Second Site Non-Complementation: ▶[non-allelic non-complementation](#)

Second Site Reversion: A suppressor mutation at a site different from that of the original lesion but is capable of restoring the normal reading of the mRNA. ▶[suppressor tRNA](#), ▶[suppressor gene](#), ▶[reversion](#), ▶[compensatory mutation](#)

Second Strand Synthesis: ▶[reverse transcriptase](#)

Secondary Constriction: ▶[nucleolar organizer](#), ▶[satellited chromosome](#), ▶[SAT](#)

Secondary Immune Response: An immune reaction conditioned by the memory cells when antigenic exposure occurs repeatedly. ▶[immunological memory](#)

Secondary Lymphoid Tissues: The lymph nodes and spleen (in contrast to primary lymphoid tissues, the bone marrow and thymus). ▶[immune system](#)

Secondary Metabolism: Produces molecules that are not basic essentials for the cells and their products occur only in specialized tissues, e.g., anthocyanin, hair pigments. Many of the secondary plant metabolites,

e.g., phytoalexins, phenolics, flavone, pterocarpan, chlorogenic acid, sesquiterpenes, diterpene, saponins, furanoacetylene, alkaloids, indole-derivatives, etc., are defense molecules against microbial pathogens. Jasmonate-mediated genetic reprogramming of the transcriptome may reveal some basic aspects of the complex processes (Goossens A et al 2003 *Proc Natl Acad Sci USA* 100:8595). (See Dixon RA 2001 *Nature [Lond]* 411:843).

Secondary Nondisjunction: ▶[nondisjunction](#)

Secondary Response Genes: Their transcription is preceded by protein synthesis; probably primary response genes are involved in their induction. They are stimulated by mitogens alone without cycloheximide. ▶[mitogens](#), ▶[primary response genes](#), ▶[signal transduction](#)

Secondary Sex Ratio: The proportion of males to females at birth. ▶[age of parents](#), ▶[sex ratio](#), ▶[primary sex ratio](#)

Secondary Sexual Character: Usually accompany the primary sexual characters but they are not integral part of the sexual mechanisms, e.g., facial hair in human males, red plumage of the male cardinal birds, increased size bosoms in females and higher pitch voice, etc. ▶[primary sexual characters](#), ▶[accessory sexual characters](#)

Secondary Structure: The steric relations of residues that are next to each other in a linear sequence within a polymer such as α -helix, a pleated β -sheet of amino acids. ▶[protein structure](#); http://cmgm.stanford.edu/WWW/www_predict.html.

Secondary Trisomic (isotrisomic): The third chromosome has two identical arms, originated by misdivision of the centromere or by the fusion of identical telochromosomes. ▶[trisomics](#), ▶[misdivision](#), ▶[telosome](#)

Secondary-Ion Mass Spectrometry: A focused ion beam removes neutral and ionized atoms and molecules from a solid surface. These secondary ions are then accelerated and separated according to mass-to-charge ratio in a mass spectrometer. ▶[mass spectrum](#)

Secretagogue: A compound or factor that stimulates secretion. ▶[ghrelin](#); Pombo M et al 2001 *Horm Res* 55 (Suppl. 1):11.

Secretases: α -secretase enzyme cleavage of APP (amyloid precursor protein) interferes with the production of α amyloids whereas cleavage by β - and γ -secretase contributes to the formation of amyloid plaques. γ -Secretase (transmembrane aspartyl protease) activity requires the presence of the protein nicastrin, which binds presenilin near the

active site, and there is an interaction among these and the fragment generated by β -secretase. The γ -secretase complex has four components: presenilin, nicastrin, aph-1 and pen-2 (Kimberly WT, Wolfe MS 2003 J Neurosci Res 74:353). The cytoplasmic tail of APP, released intracellularly by secretase γ , teams up with histone acetyl transferase and other proteins and may promote gene expression. Cleavage of APP by β -secretase at the N-end releases APPs β (~100 kDa, N-terminal fragment) and a membrane-bound 12 kDa C-end fragment (C99). Cleavage by α -secretase generates the N-end APPs α and a membrane-bound 10 kDa piece (C83). C99 and C83 can be further split by secretases and yield 4 kDa A β (Alzheimer plaque material) and the harmless 3 kDa p3 peptides, respectively. γ -Secretase generates the 40-residue and in smaller proportion, 42-residue A β fragments. The latter forms the tangled brain fibers and the 40-residues accumulate as brain plaques. β -Secretase cuts at Asp1, Val3 and Glu11 and most commonly, A β begins with Asp. Met \rightarrow Leu replacements favor the generation of amyloid plaques common in the early onset Alzheimer disease. Pin1 prolyl isomerase binds the phosphorylated Thr 668-Pro motif in APP and increases its polymerization by three orders of magnitude. Overexpression of Pin1 reduces A β secretion but knockout of Pin1 increases its secretion. Pin1 knockout increases amyloidogenic APP processing and selectively elevates the insoluble and toxic A β 42 (Pastorino L et al 2006 Nature [Lond] 440:528). The BACE transmembrane aspartic protease is a β -secretase. Secretase γ has a role also in Notch-controlled developmental processes. **▶Alzheimer disease, ▶ β -amyloid, ▶BACE, ▶TACE, ▶ADAM, ▶presenilins, ▶memapsin, ▶nicastrin, ▶rhomboid protease, ▶CD147, ▶Notch**; Kopan R, Goate A 2000 Genes Dev 14:2799; Cao X, Südhof TC 2001 Science 293:115; Esler WP, Wolfe MS 2001 Science 293:1449; Fortini ME 2002 Nature Rev Mol Cell Biol 3:673; Takasugi N et al 2003 Nature [Lond] 422:438.

Secretion Machine (injectisome): The bacterial pathogens of both animals and plants secrete about 20 different proteins mediating infection of the host. Of these, nine are conserved across phylogenetic boundaries and appear to have a universal mRNA targeting signal. **▶host-pathogen relation**; Lee VT, Schneewind O 1999 Immunol Rev 168:241; injectisome structure: Merlovits TC et al 2006 Nature [Lond] 441:637.

Secretion Systems: Type III (~20 proteins) is a contact-dependent mechanism of transfer of bacterial pathogenicity island genes and toxins to other organisms. Type III secretion system (T3SS) has a complex needle structure (Galán JE, Wolf-Watz H 2006 Nature [Lond] 444:567). Bacterial plasmids may encode the

pathogenicity island. Type IV/V: the autotransporters are the bacterial conjugation and the agrobacterial T-DNA transfer systems. Type II (12–14 proteins) is the general secretion system. The Type I system requires three proteins and it is encoded in pathogenicity islands or plasmids. **▶pathogenicity island, ▶T-DNA, ▶conjugation bacterial**; Galán JE, Collmer A 1999 Science 284:1322; Burns DL 1999 Curr Opin Microbiol 2:25; Cornelis GR, Van Gijsegem F 2000 Annu Rev Microbiol 54:735; Fadoulglou VE et al 2004 Proc Natl Acad Sci USA 101:70; secretion type III system assembly: Yip CK et al 2005 Nature [Lond] 435:702; secreted protein database: <http://spd.cbi.pku.edu.cn>.

Secretion Trap Vector: Inserts a reporter gene, which is expressed in a transmembrane region. The constructs may carry a region of the CD4 gene fused in-frame to the 5'-end of the reporter, e.g., *LacZ*, which can be then identified by Xgal at the membrane. **▶CD4, ▶Xgal**; Shirozu M et al 1996 Genomics 37(3):273.

Secretion Vector: Besides an expressed structural gene, it carries a secretion signal to direct the gene product to the appropriate site. (See Bolognani F et al 2001 Eur J Endocrinol 145:497).

Secretome: Type III secretion system of bacteria serve as effectors for causing disease. **▶secretion systems, ▶effector**; Guttman DS et al 2002 Science 2002 295:1722.

Secretor: Secretes the antigens of the ABH blood group into the saliva. Fucosyltransferase, FUT is the same gene locus as SEC/SE but there is a difference in tissue-specific expression. **▶ABH antigen, ▶fucosyltransferase**; D'Adamo PJ, Kelly GS 2001 Altern Med Rev 6(4):390.

Secretory Immunoglobulin A: An IgA dimer with a secretory component. **▶immunoglobulins**

Secretory Proteins: Mainly glycoproteins that are released by the cell after synthesis, such as hormones, antibodies and some enzymes. Secretory proteins (~1400) are located in the endoplasmic reticulum (~64%) and in the Golgi-derived COP transport vesicles (~14%); about 29% occur in both (Gilchrist A et al 2006 Cell 127:12165).

Secretory Vesicle (secretory granule): Releases stored molecules such as hormones within the cell. Chromogranin A appears to control the biogenesis of the granules. **▶Golgi apparatus, ▶endocytosis**; Kim T et al 2001 Cell 106:499.

Sectioning: A generally required procedure for the preparation of biological specimens for histological examination. The material may need embedding before they are cut either free hand or by microtomes. Some

microtomes cut tissues frozen by CO₂. The 1–20 µm thin sections are subsequently placed on microscope slides and subjected to a series of manipulations (paraffin wax removal, dehydration, staining) before examination. ▶microtome, ▶embedding

Sectorial-Spore Colonies: The colonies arise when the haploid spores carried heteroduplex DNA with different alleles in the heteroduplex region (see Fig. S24). ▶heteroduplex

Figure S24. Sectorial plant leaf

Sectorial: Displays sectors, e.g., mitotic recombinant, sorting-out of organelles, somatic mutation, etc. ▶mosaic, ▶chimeric

Securins: They control the onset of the separation of sister chromatids during mitosis. The anaphase-promoting complex (APC) destroys securin before the sister chromatids can separate. Deletion of securin leads to chromosomal instability as it is common in cancer cells. ▶sister chromatid cohesion, ▶APC, ▶cohesin, ▶separin, ▶meiosis I, ▶CDC2, ▶spindle; Sjögren C, Nasmyth K 2001 Curr Biol 11:991; Jallepalli PV et al 2001 Cell 105:445; Zhou Y et al 2003 J Biol Chem 278:462.

SecY Protein: An integral membrane component of bacteria involved in chaperoning the assembly of membrane and some soluble proteins. ▶membrane; Veenendaal AK et al 2001 J Biol Chem 276:32559; Osborne AP et al 2007 Cell 129:97.

SecY/E Protein: The membrane embedded domain of translocase enzyme consisting of SecY and SecE polypeptides. Stabilizes and activates SecA and facilitates membrane binding. ▶membrane, ▶SecY

SED: Spondyloepiphyseal dysplasia, bone diseases.

Sedimentation Analysis: ▶satellite DNA

Sedimentation Coefficient: The rate by what a molecule sediments in a solvent. It is characterized by the Svedberg unit (S) that is a constant of 1×10^{-13} . S is derived from the equation $s = (dx/dt)/\omega^2 x$, where x = the distance from the axis of rotation in the centrifuge, ω is the angular velocity in seconds ($\omega = \theta/t$, where θ is the angle of rotation and t is time). At a constant temperature (20 °C) in a solvent s depends on the weight, shape and hydration of a molecule. The S value is used for the characterization of macromolecules, e.g., RNA such as 16S ($= 16 \times 10^{-13}$).

Seed: ▶microRNA

Seed Alignment: Uses only one of each pair of homologs represented by a CLUSTAL W-obtained phylogenetic tree linked by a branch length <0.2. ▶CLUSTAL W, ▶phylogenetic tree, ▶MOST

Seed Coat: ▶integument

Seed Development: ▶embryogenesis in plants, ▶endosperm; seed biology: <http://www.seedbiology.de/index.html>.

Seed in Genome Sequencing: ▶genome projects

Seed Germination: Requires the activation of >2000 genes. The process begins by activation of the root apical meristem, followed by activation of the cotyledons, the shoot apical meristem and secondary meristems. Six D-type and two A-type cyclins have important roles. ▶meristem, ▶root, ▶cyclins, ▶abscisic acid; Masubelele NH et al 2005 Proc Natl Acad Sci USA 100:15694.

Seed Size: In *Arabidopsis*, seed size is controlled by at least 3 genes acting in the same pathway regulated by a kinase (Luo M et al 2005 Proc Natl Acad Sci USA 102:17531).

Seed Storage: Generally viability (germination and survival) of seed can be maintained by storage below –20 °C and low moisture content (<7–8%) well beyond the conditions of normal ambient temperature and humidity. ▶freeze drying, ▶artificial seed; Buitink J et al 2000 Proc Natl Acad Sci USA 97:2385.

Seeding: To use a set of DNA fragments (in e.g., BACs) as the beginning points for chromosome walking. ▶BAC, ▶genome projects, ▶chromosome walking, ▶parking

Seedless Fruits: May be the result of different genetic mechanisms. Aneuploids, triploids, self-incompatibility or gametic sterility genes may be most commonly responsible for this condition. ▶seedless watermelon, ▶bananas, ▶pineapple, ▶navel orange, ▶stenospermocarp, ▶seedless grapes, ▶parthenocarp

Seedless Grapes: The result of a gene that causes early embryo abortion although fertilization occurs normally (stenospermocarp). ▶seedless fruits

Seedless Watermelons: Triploids (produced by crossing tetraploids with diploids). They are more convenient to eat since seeds do not have to be removed. Their flavor and sweetness may make them superior to conventional varieties. ▶seedless fruits, ▶watermelon

Segment Polarity of the Body Genes: Segment polarity of the body genes in *Drosophila* mutations are

involved in the alteration of the characteristic body pattern and are often accompanied by inverted repetition of the remaining structures. By cell-cell communication, they maintain the pattern imposed on them through subsequent developmental processes. ▶ [morphogenesis in *Drosophila*](#)

Segmental Aneuploid: Contains an extra chromosomal fragment(s) in addition to the normal chromosome complement; it is a partial hyperploid. ▶ [hyperploid](#), ▶ [aneuploid](#)

Segmental Interchange: ▶ [translocation chromosomal](#)

Segmentation Clock: An ensemble of numerous cellular oscillators located in the unsegmented pre-somitic mesoderm, controls segmentation as it travels anteriorly in the embryo (Horikawa K et al 2006 Nature [Lond] 441:719).

Segmentation Genes: Control the polarity of body segments in animals. ▶ [morphogenesis in *Drosophila*](#), ▶ [metamerism](#); Zákány J et al 2001 Cell 106:207; Dubrulle J et al 2001 Cell 106:219; Tautz D 2004 Dev Cell 7:301.

Segmentation of Microarray Spots: The separation of the not entirely circular signal spots from the background.

Segmented Genomes: For example, the DNA of T5 phage is in four linkage groups, the RNA genetic material of alfalfa mosaic virus is in four segments.

Segregation: The separation of the homologous chromosomes and chromatids at random to the opposite pole during meiosis and carrying in them the alleles to the gametes. Independent segregation of non-syntenic genes (or ones, which are more than 50 map units apart within a chromosome) is one of the basic Mendelian rules. In the haploid products of meiosis of diploids, the 1:1 segregation of the alleles may be identified. Sometimes “x-segregation” is distinguished when after mitotic crossing over at the four-strand stage, each of the daughter cells carries one recombinant and one parental strand, and this is most common. At “z-segregation” the distribution of the chromosomes into the daughter cells is biased inasmuch as one of them carries two parental and the other two recombinant strands. Mitotic nondisjunction has been called “y-segregation.” ▶ [Mendelian laws](#), ▶ [autopolyploid](#), ▶ [tetrad analysis](#), ▶ [segregation distorter](#), ▶ [preferential segregation](#), ▶ [epistasis](#), ▶ [meiosis](#), ▶ [mitotic crossing over](#), ▶ [nondisjunction](#), ▶ [chromosome segregation](#), ▶ [partitioning](#), ▶ [condensin](#), ▶ [cohesin](#), ▶ [separin](#); Ghosh SK et al 2006 Annu Rev Biochem 75:211.

Segregation Analysis: The analysis reveals the pattern of inheritance whether it is autosomal recessive,

autosomal dominant, X-linked recessive or dominant, multifactorial, penetrance, expressivity of a gene(s). This the first, sometimes laborious step, especially in human genetics where controlled matings are not available, before gene frequencies, genetic risk, recombination, etc. can be meaningfully estimated. (See mentioned terms at separate entries; <http://hasstedt.genetics.utah.edu/>).

Segregation, Asymmetric: The differentiation and morphogenesis require that the progeny cells would differ from the mother cell after cell division. This difference is brought about by the unequal distribution of cellular proteins. ▶ [morphogenesis in *Drosophila*](#)

Segregation Distorter: A dominant mutation (*Sd*, map position 2-54 in *Drosophila*). When it is present, the homologous chromosomes (and the genes within) are not recovered in an equal proportion after meiosis. The second chromosomes that carry it are called SD and may be involved in chromosomal rearrangement and other (lethal) mutations. At the base of the left arm they may have *E(SD)* [*enhancer of Sd*] or *Rsp* (*Responder of SD*, at the base of the right arm), and more distally *St(SD)*, *Stabilizer of SD* and other components of the system. *SD*+/+ males transmit the *SD* chromosome to about 99% of the sperm. When *Rsp* is in the homologous chromosome, *Sd* is preferentially recovered. *Sd* is actually a tandem duplication of a 6.5 kb segment, and transformation by a 11.5 kb stretch of its DNA confers full *Sd* activity to the recipient flies. The sequence carries two nested genes, (*dHS2ST*), a homolog of the mammalian heparan-sulfate 2-sulfotransferase and *dRanGAP*, a guanine triphosphatase activator of the Ras-related Ran protein. It appears that the truncation of RanGAP is responsible for the poor transmission of the spermatids. Some of the other elements of the system act in a modifying manner and may cause recombination in the male. In many species of insects, the infection of males by the bacterium *Wolbachia* kills the offspring of the infected males x uninfected females but the viability of the infected eggs is normal. In mice, the transmission ratio distorter system (TRD) that impairs sperm flagellar motility and the *Tcr* (*t complex responder*) in cooperation with other genes located within chromosome 17 (t haplotype) affects chromosome segregation. The chromosome carrying the *Tcr* gene (even as a transgene at another location) enjoys high transmission in the presence of *Tcd*. The *Tcd* genes can act in both cis and trans position whereas *Tcr* (80 kb protein kinase) acts in cis position. *Tcr* represents a fusion between a part of the ribosome S6 protein kinase (*Rsk3*) and another gene of the microtubule affinity-regulating (MARK) Ser/Thr protein kinase family. The *Tcr* gene appears to have descended from a rearrangement

between a member of the *Smok* (sperm motility kinase) family and a *Rsk* allele. Eventually, a practical method can be devised to increase one or the other sex by moving *Tcr* either to the X or to the Y chromosome of farm animals without relying on sperm sorting and artificial insemination. ▶lethal factors, ▶meiotic drive, ▶transmission disequilibrium, ▶certation, ▶preferential segregation, ▶polarized segregation, ▶megaspore competition, ▶tetrad analysis, ▶gene conversion, ▶epistasis, ▶pollen-killer, ▶infectious heredity, ▶RAS, ▶RAN, ▶RSK, ▶heparan sulfate, ▶sex-ratio, ▶spirochetes, ▶dosage compensation; Powers PA, Ganetzky B 1991 Genetics 129:133; Schimenti J 2000 Trends Genet 16:240; Pardo-Manuel De Villena F, Sapienza C 2001 Mamm Genome 12:331.

Segregation Index: The gene number in quantitative traits, also called effective number of loci. ▶gene number in quantitative traits

Segregation Lag: The mutation or transformation is expressed only by third division of the bacteria until all chromosomes are sorted out. ▶phenotypic lag; Angerer WP 2001 Mutation Res 479:207.

Selectable Marker: Permits the separation of individuals (cells) that carry it from all other individuals, e.g., in an ampicillin or hygromycin medium (of critical concentration) only those cells (individuals) can survive that carry the respective resistance genes (selectable markers). The aequorin gene equipped with an appropriate promoter may light up the tissue of expression in insects. Many different genes may serve as selectable markers (mutant dihydrofolate reductase [DHFR]), methylguanine methyltransferase [MGMT] multidrugresistance [MDR1]). Selectable markers such as antibiotic (used in medical practice) resistance are undesirable in producing transgenic crops. ▶aequorin

Selectins: These are cell surface carbohydrate-binding, cytokine-inducible, transmembrane proteins. They also bind to endothelial cells in the small blood vessels along with integrins and enable white blood cells and neutrophils to ooze out at the sites of small lacerations to combat infection. L-selectin facilitates the entry of lymphocytes into the lymph nodes by

binding to CD34 cell adhesion molecules. The ESL-1 selectin ligand is a receptor of the fibroblast growth factor. The selectins contain an amino-terminal lectin domain, an element resembling epidermal growth factor and a variable number of complementary regulatory repeats and a cytoplasmic carboxyl end. The P (1q23-q25) and E (1q23-q25) selectins recruit T helper-1 but not T helper-2 cells to the site of inflammation. L-selectin may promote metastasis of cancer cells. ▶[integrins](#), ▶[cell adhesion](#), ▶[cell migration](#), ▶[FGF](#), ▶[EGF](#), ▶[lectins](#), ▶[T cell](#), ▶[TACE](#), ▶[leukocyte adhesion deficiency](#), ▶[metastasis](#), ▶[integrins](#); Dimitroff CJ et al 2001 J Biol Chem 276:47623.

Selection: The unequal rate of reproduction of different genotypes in a population. Bacteria are particularly well suited for the study of the consequences of long-term selection because on simple culture media the evolving population after 20,000 generations can be compared to the ancestral ones. In an experiment of similar nature, two genes affecting DNA supercoiling (*topA*, *fis*) proved competitive. DNA supercoiling affects cell viability, replication, repair, transcription, recombination and transposition (Croizat E et al 2005 Genetics 169:523). In the constant environment of a chemostat a bacterial population substantially diverged in several directions within less than a month (Maharjan R et al 2006 Science 313:514). ▶[selection coefficient](#), ▶[allelic fixation](#), ▶[genetic load](#), ▶[fitness of hybrids](#), ▶[selection and population size](#), ▶[mutation pressure and selection](#), ▶[genetic drift](#), ▶[selection types](#), ▶[non-Darwinian evolution](#), ▶[selection conditions](#), ▶[selection purifying](#), ▶[screening](#), ▶[natural selection](#), ▶[chemostat](#); Brookfield JFY 2001 Curr Biol 11:388.

Selection and Population Size: In very small population, chance (random drift) may be more important than the forces of selection in determining allelic frequencies. When the selection pressure becomes very large, even in small populations there is a good chance for the favored allele to become fixed. ▶[allelic fixation](#), ▶[random drift](#), ▶[genetic drift](#); in human populations: Kreitman M 2000 Annu Rev Genomics Hum Genet 1:539.

Selection, Balanced: ▶[balanced polymorphism](#)

Selection Coefficient: The measure of fitness of individuals of a particular genetic constitution relative to the wild type or heterozygotes in a defined environment. If the fitness is zero the selection coefficient is 1. In other words, if an individual does not leave offspring (fitness is zero), the selection against it in a genetic sense is 1 (100%). The selection coefficient is generally denoted as (*s*) or (*t*), where the former indicates the selection coefficient of the recessive class and (*t*) indicates the selection coefficient of the homozygous dominants. The meaning and relation of fitness and selection coefficients in a population complying with the Hardy-Weinberg theorem is best illustrated in Table S1.

In case we take the fitness of one genotype as unity (in this case we choose the heterozygotes, e.g., $w_2 = 1$), then the *standardized fitness* becomes:

$$\frac{w_1}{w_2} = 1 - s \text{ and } s = 1 - \frac{w_1}{w_2}$$

$$\text{similarly } \frac{w_3}{w_2} = 1 - t \text{ and } t = 1 - \frac{w_3}{w_2}$$

▶[fitness](#), ▶[allelic frequencies](#), ▶[Hardy-Weinberg theorem](#), ▶[advantageous mutation](#)

Selection Conditions: Selection may operate at different levels beginning in meiosis (distorters, gametic factors) or at any stage during the life of the individual beginning with the zygote through the entire reproductive period. The intensity of the selection depends on the genes, the overall genetic constitution of the individual and the environment, including the behavioral pattern of the population (e.g., protecting the young and infirm). The formulas representing the various means of selection were derived from the Hardy-Weinberg theorem $p^2 + 2pq + q^2 = 1$ (see Table S2) and their use is exemplified.

The genotypic contributions to the *AA*, *Aa* and *aa* phenotypes are p^2 , $2pq$ and $q^2(1 - s)$, respectively, where *s* is the selection coefficient (▶[selection coefficient](#) for derivation of *s*).

The total contribution is now reduced from 1 to $1 - sq^2$ because sq^2 individuals are eliminated by selection. Thus, the new frequency of the recessive alleles becomes q_1 and the

S

Table S1. Selection and fitness in a Hardy-Weinberg population

| Genotypes | AA | Aa | aa | Total |
|---------------------|----------------------|----------------------|----------------------|-------|
| Zygotic frequencies | p^2 | $2pq$ | q^2 | 1 |
| Fitness | w_1 | w_2 | w_3 | |
| Gametes produced | $(w_1) \times (p^2)$ | $(w_2) \times (2pq)$ | $(w_3) \times (q^2)$ | 1 |

Table S2. Formulas to calculate the change in allelic frequencies per generation at various conditions of selection. In case s or q is very small, omission of the sq product from the denominator may be of very little consequence for the outcome

| Type of selection | Increase (+) or decrease (-) in the rate of change of an allele (Δq) per generation |
|--|---|
| 1. Selection against gametes | $-\frac{sq(1-q)}{1-sq}$ |
| 2. Differential selection in males and females (without sex linkage) | $q^2[1 - \frac{1}{2}(s_{\text{male}} + s_{\text{female}})]$ |
| 3. Selection at X-chromosome linkage | gametic in the heterogametic and zygotic in the homogametic sex |
| 4. Selection against recessive lethals | $-\frac{q^2}{1+q}$ |
| 5. Selection against the allele in absence of dominance | $-\frac{1}{2}\frac{sq(1-q)}{1-sq}$ |
| 6. Selection against dominant lethals | $+(1-q)$ |
| 7. Partial selection against homozygous recessives in case of complete dominance | $-\frac{sq^2(1-q)}{1-sq^2}$ |
| 8. Partial selection against completely dominant alleles | $+\frac{sq^2(1-q)}{1-s(1-q)^2}$ |
| 9. Selection against recessives in autotetraploids | $-spq^4$ |
| 10. Selection against intermediate heterozygotes | $-\frac{sq(1-q)}{1-2sq}$ |
| 11. Selection against heterozygotes | $+2spq(q - \frac{1}{2})$ |
| 12. Selection against both homozygotes (heterozygote advantage) | $+\frac{pq(s_1p - s_2q)}{1-s_1p^2 - s_2q^2}$ |

$$q_1 = \frac{q^2[1-s] + pq}{1-sq^2}$$

change in the frequency of q , is $\Delta q = \frac{q^2[1-s] + pq}{1-sq^2} - q$ which reduces to $\frac{sq^2(-q)}{1-sq^2}$. The effectiveness of the selection also depends on the frequency of the allele involved. Selection against rare recessive alleles may be very ineffective because only the homozygotes are affected. Selection most frequently works at the level of the phenotype and the recessives may not influence the fitness of the heterozygotes. At low values of q the majority of the recessive alleles is in the heterozygotes and thus sheltered from the forces of selection. Dominant, semidominant and codominant alleles may be, however, very vulnerable if they lower the fitness of the individuals. As an example let us assume that the frequency of a recessive allele is $q = 0.04$ and by using formula 4 shown in Table S2 the change in allelic frequency per generation is $\Delta q = -\frac{[0.04]^2}{1+0.04} \cong -0.00154$ and after $n = 25$ generations, the initial frequency of the gene, $q_0 = 0.04$ changes to: $q_n = \frac{q_0}{1+nq_0} = \frac{0.04}{1+[25 \times 0.04]} = 0.02$ meaning that complete

elimination of all homozygotes ($s = 1$) for 25 generations reduces only to half the frequency of that recessive allele. The initial zygotic frequency of $(0.04)^2 = 0.0016$ (1/625) will thus change to $(0.02)^2 = 0.0004$ (1/2500).

If the same deleterious allele would be semidominant and it conveys a fitness of 0.5 relative to the homozygotes for the other allele, according to formula 5 in Table S2, the change of the frequency of this semidominant allele in a generation becomes: $\Delta q = -\frac{[1/2][0.5][0.04][0.96]}{1 - \{[0.5] \times [0.04]\}} \cong -0.0098$. Thus, a semidominant allele with 0.5 selection coefficient will be selected against more than six times as effectively as a recessive lethal factor because $0.0098/0.00154 \cong 6.4$ in these examples.

The number of generations required to bring about a certain change in gene frequencies can be calculated in the simple case when the homozygous recessives are lethal, i.e., the selection coefficient is, $s = 1$: $T_{\text{generations}} = \frac{q_0 - q_T}{q_0 q_T} = \frac{1}{q_T} - \frac{1}{q_0}$ where q_0 is the initial frequency of the allele and q_T is its frequency after T generations. If it is assumed that the genotypic frequency is $(q_0)^2 = 0.0001$ and $q_0 = 0.01$ then the

number of generations required to reduce the initial frequency to $q_T = 0.005$ is $T = \frac{1}{0.005} - \frac{1}{0.01} = 100$. After 100 generations then the frequency of the recessive lethal allele becomes $(q_T)^2 = (0.005)^2 = 0.000025 = 1/40,000$ compared to the initial frequency of $1/10,000$. The effectiveness of selection is much influenced by the heritability of the allele concerned. In complex cases more elaborate computations are required that cannot be illustrated here. ▶selection coefficient, ▶balanced polymorphism, ▶mutation pressure opposed by selection, ▶selection and population size, ▶allelic fixation, ▶genetic load, ▶fitness of hybrids, ▶gametophyte, ▶QTL, ▶heritability, ▶gain, ▶mutation neutral

Selection, Cyclic: Different phenotypes are selected depending on seasonal variations in the environment.

Selection Differential: ▶gain

Selection Index in Breeding: ▶gain

Selection Inferred from DNA Sequences: Different types of natural selection (negative selection, recurrent positive selection, balancing selection) affect the pattern of variation in DNA sequences although recent population growth, bottlenecks and population subdivisions confound the pattern of genetic variation and may mimic the effects of natural selection. If synonymous mutations are neutral then natural selection at non-synonymous sites can be effectively tested. A non-parametric test can compare allele frequency spectrum of segregating sites among regions of functional classes. Because of being non-parametric the comparisons encounter difficulties in biological interpretation with other methods. A maximum likelihood method can infer, however, both selection and demographic changes. Assuming that non-coding single nucleotide polymorphism (SNP) is selectively neutral and correction can be made to determine selection among non-synonymous changes. Experimental data indicate negative selection on non-synonymous alterations (as expected) and the strength of selection is most explicit when the amino acid substitutions involve radical changes (Williamson SH et al 2005 Proc Natl Acad Sci USA 102:7882). ▶non-parametric test, ▶non-synonymous codon, ▶maximum likelihood, ▶selection types, ▶SNIPs, ▶McDonald-Kreitman hypothesis

Selection Intensity: ▶gain

Selection—Medical Care: The progress of effective medical care saves increasing number of human lives. Some of the saved individuals will have a chance to transmit deleterious genes to their offspring so eventually some increase in detrimental alleles is expected. Non-synonymous mutations reduce fitness

by an average of 4.3% and selection acting against non-synonymous polymorphism is $\sim 9 \times 10^{-5}$. This also indicates that medical care may not affect the extent of fitness too much but it is very difficult to identify the gene involved in complex diseases. (Eyre-Walker A et al 2006 Genetics 173:891). ▶selective abortion, ▶genetic risk, see Fig. S26.

Selection, Long Term: Plant and animal breeders carry on selection for many generations and the effectiveness is reduced less than expected based on selection for single desirable genes/traits. The cause of the effectiveness is that multiple interacting genes determine the majority of traits of agricultural interest (Carlborg Ö et al 2006 Nature Genet 38:418). ▶polygenic inheritance, ▶QTL, ▶gain

Selection, Negative: Maintains disadvantageous alleles. The term is also used in the sense of elimination disadvantageous alleles. ▶drift genetic, ▶hitchhiking, ▶selection purifying

Selection, Natural: ▶natural selection

Selection Positive: Maintains the advantageous alleles. (See selection motif tool: <http://oxytricha.princeton.edu/SWAKK/>).

Selection Pressure: The intensity of selection affecting the frequency of genes in a population. ▶volatility

Selection, Purifying: Acts against the heterozygotes of a new allele with lower fitness. Asexual reproduction favors the accumulation of deleterious mutations. Mitochondrial mutations in asexual lineages of microcrustacean *Daphnia pulex* accumulated deleterious mutation four times the rate compared to sexual lineages (Paland S, Lynch M 2006 Science 311:990). ▶hitchhiking, ▶genetic drift, ▶Muller's ratchet

Selection Response: (heritability) \times (selection differential). ▶heritability, ▶gain

Selection Types: (i) *Stabilizing* favors the intermediate forms that have ability to survive under the most common but opposite conditions (such as cold and heat, draught and excessive precipitation). (ii) *Directional selection* shifts the mean values of a population either toward higher or lower values than the current mean. (iii) *Disruptive selection* breaks up the population into two or more subpopulations that each has adaptive advantage in particular niches of a larger habitat. (iv) *Frequency-dependent selection* favors an allele when it is relatively rare and may turn against it when it becomes abundant. Common examples are found in host-parasite, predator-prey relationships or in resource utilization (see Fig. S27) (Carius HJ et al 2001 Evolution 55:1136).

Figure S26. The effect of medical care on the incidence of human diseases. Thus the improvement of medical services may lead to deterioration of the gene pool. If the initial frequency of a detrimental recessive allele is 0.001 or less, the consequences of the selection may not be evident for about 300 years. Even after thousands of years of selection the increase of incidence is relatively modest. The frequency of dominant lethal or dominant semi-lethal alleles may increase much faster. (Redrawn after Bodmer WF, Cavalli-Sforza LL 1976 *Genetics, Evolution, and Man*. Freeman, San Francisco, California)

Figure S27. Top: Original frequency distribution of populations. Below: The shifts in distribution after selection. (After Mother K 1953 *Symp Soc Exp Biol* 7:66)

When the number of predators increase beyond a point there will not be enough prey to maintain the predators and their number will decrease. Similarly, when animals overgraze in the natural habitat, ultimately their population decreases. Similarly, highly

virulent viruses may outcompete the less aggressive types even when they may kill the host faster. ►fitness, ►selection apostatic selection, ►selection cyclic, ►competition, ►artificial selection

Selection Value: ►selection index, ►gain

Selective Abortion: The termination of a pregnancy by precocious removal of the fetus from the womb if the condition of the mother or of the fetus medically justifies it and the legal system permits it. The genetic constitution or condition of the fetus may be tested with the aid of amniocentesis or sonography. From the viewpoint of genetics, selective abortion may pose biological problems. If all families would compensate for the abortions elected based on genetic defects, the frequency of these defective genes may actually rise in the population. This may happen because it assists heterozygotes for genetic abnormalities to leave offspring that—although may not display the morbid trait—can again transmit the undesirable genes to future generations. If all carriers would refrain from reproduction, the frequency of the deleterious genes

may sink to the level of new mutations. Selective abortion may involve also ethical, moral and political problems but these are beyond the scope of genetics. ▶abortion spontaneous, ▶abortion medical, ▶pregnancy unwanted, ▶amniocentesis, ▶counseling genetic, ▶selection and medical care, ▶sterilization humans, ▶ethics, ▶bioethics, ▶genetic screening

Selective Advantage: In population genetics, selective advantage is expressed by the relative fitness of bearers of (two) genotypes. Generally the wild type has greater fitness (W_N) than a mutant type (W_M) and their relative fitness is $(W_N)/(W_M)$. W (fitness) is the reproductive success. Usually, $(W_N)/(W_M) = 1 - s$, where s is the selection coefficient indicating the disadvantage of the mutant type. In case the fitness of a genotype exceeds 1 it has an advantage in survival. ▶selection coefficient, ▶fitness, ▶beneficial mutation, ▶codon usage

Selective Fertilization: Some sperms, because of their gene content, may be at a disadvantage in competition with other sperms for penetrating the egg, or where multiple eggs or megaspore cells are formed, their success depends on their genetic constitution. Because of this, the genetic segregation may deviate from the standard Mendelian expectation. ▶gamete competition, ▶certation, ▶megaspore competition, ▶meiotic drive, ▶sperm

Selective Medium: Only permits the propagation of individuals or cells that carry a selectable marker, such as high or low temperature, antibiotic, drug resistance, etc. (see Fig. S28) ▶selectable marker

Figure S28. Hygromycin medium. Left: *Arabidopsis* plants transgenic for resistance; right: Wild type fails to grow (Rédei, unpublished)

Selective Neutrality: Assumes that random drift is responsible for the allelic frequencies in a particular population, i.e., all alleles at a locus have the same selective value. ▶random genetic drift, ▶allelic frequencies

Selective Peak: Determined by the genetic homeostasis of a population, i.e., the gene frequencies are maintained at this optimum as long as catastrophic changes in the environment do not occur. ▶homeostasis, ▶adaptive landscape

Selective Screening: ▶screening, ▶selective medium, ▶mutation detection

Selective Sieve, Extent of: The rate of substitution at a gene site/mutation rate for the gene.

Selective Sweep: The rapid establishment of advantageous allele(s) in a population. Such alleles may carry along other linked genes too by a mechanism of hitchhiking. Less advantageous mutations may also be swept along with linked advantageous ones. The selective sweep may reduce the genetic variation in the population. ▶hitchhiking, ▶selection types, ▶selective advantage, ▶mutation beneficial; Nurminsky DI et al 1998 Nature [Lond] 396:572.

Selective Value: ▶fitness, ▶selection coefficient

Selectivity Factor (SF): A human general transcription factor homologous to TFIIB of other eukaryotes. ▶transcription factors

Selectivity Filter: Functions as a gatekeeper to allow or prevent the access of another (small) molecule into a structural pocket of a protein. Aromatic amino acids (being relatively bulky) permit the access of larger structures whereas smaller amino acids are more restrictive. Selective filters have significance for the development and effectivity of special drugs.

Selector Genes: These are supposed to specify segmental differences during morphogenesis, such as anterior/posterior or dorsal/ventral. The selector genes after receiving morphogenetic signals may team up with the relevant other transcription factor genes and recruit a number of specific activators to turn on the transcription of specific morphogenetic genes (see Fig. S29). The process of differentiation of an organ may take place by two major steps. First, the body position is specified and then the pattern of differentiation is determined. Selector genes are used also for genes that facilitate selection of transformed cells, e.g., neomycin, kanamycin, hygromycin resistance and others. ▶morphogenesis, ▶morphogenesis in *Drosophila*, ▶signal transduction, ▶differentiation, ▶imaginal disc; Affolter M, Mann R 2001 Science 292:1080; Guss KA et al 2001 Science 292:1164; Ao W et al 2004 Science 305:1743.

Selenium-Binding Protein Deficiency (SP56, 1q21-q22): Causes neurological disorder and sterility due to the deficiency of a 56 kDa protein and other selenoproteins. Selenium may have anticarcinogenic property.

Figure S29. Selector gene responses and expression

► **selenocysteine**; Martin-Romero FJ et al 2001 J Biol Chem 276:29798.

Selenocysteine (SC, $C_6H_{12}N_2O_4Se_2$): A reactive, very toxic, oxygen-labile amino acid. Selenophosphate is the donor of selenium for the synthesis of selenocysteyl-tRNA, which has the UCA anticodon and SC incorporation is directed by the UGA (usually a stop) codon. In bacteria, a special mRNA fold immediately following UGA mediates the incorporation of SC, carried by its own tRNA. The loop binds the SelB protein, which acts like a somewhat unusual elongation factor. In mammals, the loop (called SECIS) is locked at the end of the mRNA. Two proteins carry out the function of SelB. SBP2 binds the SECIS element whereas eEFSec binds the selenocysteine tRNA. Incorporation of selenocystein into proteins requires a selenocystein-specific translation elongation factor (eEFSec) and a SECIS binding protein (SBP2). SBP2 associates with the 28S RNA of the ribosome (Kinzy SA et al 2005 Nucleic Acids Res 33:5172). Thus, SC is the 21st “natural” amino acid. A putative selenocysteine synthase had been identified as a pyridoxal phosphate-containing protein called soluble liver antigen. The activity of this synthase was characterized using selenophosphate and a tRNA aminoacylated with phosphoserine as substrates to generate selenocysteine. Identification of selenocysteine synthase allowed the delineation of the entire pathway of biosynthesis in mammals. Selenocysteine synthase is present only in those archaea and eukaryotes that make selenoproteins (Xu X-M et al 2007 PloS Biol 5(1):e4).

Selenocysteine-containing proteins (glutathione peroxidase, 5'-deiodinases, formate and other dehydrogenases, glycine reductase) may have substantially higher or lower catalytic activity and may have theoretical and applied interest. Selenoproteins may be scavengers of heavy metals and may favor survival of cultured neurons. Removal of the selenocysteine tRNA^{Sec} causes embryonic lethality in mice. Deiodination enzymes catalyze deiodination of thyroid

hormones and modulate the level of these hormones. Selenoprotein-binding protein binds to deiodinase 2 and causes thyroid disease (Dumitrescu AM et al 2005 Nature Genet 37:1247). In a marine gutless worm, *Olavius algarvensis* 99 selenoprotein genes that clustered into 30 families were found. In addition, several pyrrolysine-containing proteins were identified in this dataset. Most selenoproteins and pyrrolysine-containing proteins were present in a single deltaproteobacterium, $\delta 1$ symbiont (Zhang Y, Gladyshev VN 2007 Nucleic Acids Res 35:4952).

► **code genetic**, ► **antideterminant**, ► **protein synthesis**, ► **SelB**, ► **SECIS**, ► **unnatural amino acids**, ► **pyrrolysine**; Gladyshev VN, Kryukov GV 2001 Biofactors 14:87.

Selenoproteins: They appear to have roles in antioxidant defenses (protection against UV, peroxides), against tumor formation, viral resistance, thyroid and reproductive functions. The selenoprotein phospholipid, hydroperoxide glutathione peroxidase (PHHGPx) is an active, soluble enzyme during sperm maturation but in mature spermatozoa, it is enzymatically inactive and insoluble. There its role is structural, securing the stability of midpiece where mitochondria are abundant. The human genome may encode 25 selenoproteins. Deficiency of selenoproteins may accelerate the development of cancer (Diwadkar-Navsariwala V et al 2006 Proc Natl Acad Sci USA 103:8179). ► **selenocysteine**, ► **UV**, ► **sperm**, ► **glutathione peroxidase**; Copeland PR, Driscoll DM 2001 Biofactors 14:11; Kryukov GV et al 2003 Science 300:1439.

SELEX (systematic evolution of ligands by exponential enrichment): A method of aptamer selection from random oligonucleotide sequences (10^{15} to 10^{18}) resulting in the isolation of aptamers and ligands. The oligonucleotide library is synthesized by commercial DNA synthesizers and used in 20–30 or 200 base long sequences ($4^{20} \sim 10^{12}$ whereas $4^{75} \sim 1.4 \times 10^{45}$ combinations). The phage R17 coat protein provides an excellent RNA recognition site. It binds to a loop

(AUUA) and a four-base stem structure with a bulged A residue. The synthetic nucleotide sequence may use modified ribose residues such as 2' F (fluoride) or 2'NH₂ in the triphosphate nucleotides. This makes the oligonucleotides stable for several hours whereas unmodified RNA may be degraded by nucleases immediately. By "partition" (gel electrophoresis, nitrocellulose filtration) the few good sequences must be separated from the large pool. The aptamers may be truncated to limit to the minimal effective binding sites and may be further modified by extra nucleotide analogs for increased stability. The technology may be applied to the search for new drugs, diagnostic compounds and ribozymes of diverse functions. ▶aptamer, ▶nitrocellulose filter, ▶gel electrophoresis, ▶ribozyme, ▶DNA binding proteins; Wilson DS, Szostak JW 1999 Annu Rev Biochem 68:611; <http://www.mgs.bionet.nsc.ru/mgs/systems/selex/>.

Self-Antigen: Antigens synthesized within the system that may stimulate autoimmune reaction by the T cells although normally there is no immune response to the self-antigens. ▶T cells, ▶autoantigen, ▶MHC, ▶self-tolerance, ▶immune tolerance

Self-Assembly: A process of reconstituting a structure from components when there is enough information within the pieces to proceed without outside manipulation, e.g., the self-assembly of ribosomes from RNA and protein subunits.

Self-Cleavage of RNA: Some ribozymes may cleave more than 99% of the mRNAs and thereby preventing gene expression. By genetic engineering, effective ribozymes can be introduced into vectors and thus prevent transcription of functional mRNA or its translation. ▶ribozyme, ▶RNAi; Yen L et al 2004 Nature [Lond] 431:471.

Self-Compatibility: Self-fertilization can take place and the offspring is normal. ▶self-incompatibility, ▶incompatibility alleles

Self-Cross: A misnomer for self-fertilization. ▶cross

Self-Deleting Vector: A lentiviral vector may integrate into the cell and deliver a gene (Cre), which is expressed in the target and subsequently deleted in a Creb-dependent manner. The undesirable effect of the vector is thus avoided. ▶viral vectors, ▶lentivirus, ▶Cre/LoxP; CREB Pfeifer A et al 2001 Proc Natl Acad Sci USA 98:11450.

Self-Destructive Behavior: ▶Lesch-Nyhan syndrome, ▶Smith-Magenis syndrome

Self-Fertilization: Can take place between the gametes in hermaphroditic individuals; autogamy is the strictest means of inbreeding. Self-fertilization occurs in ~20% of plant species and ~33% are intermediates

between selfing and outcrossing (Vogler DW, Kalisz S 2001 Evolution 55:202). The sperm of XO males preferentially fertilizes *Caenorhabditis elegans* hermaphrodites. ▶autogamy, ▶inbreeding, ▶*Caenorhabditis*; Herlihy CR, Eckert CG 2002 Nature [Lond] 416:320.

Self-Immunity: Mediated by protein factors that bind to, for e.g., Moloney virus and thus prevent the integration into the sequences by another viral element. ▶cis-immunity, ▶phage immunity

Self-Inactivating/Self-Activating Vector: ▶E vector

Self-Incompatibility: The failure of fusion of male and female gametes produced by the same individual or lethality of the embryo formed by such fusion. Self-incompatibility may be controlled either by the sporophyte or by the gametophyte. The incompatibility for effective pollination is determined by secreted glycoproteins (SLG, on the surface of the stigma) and membrane-bound receptor protein kinases (SRK, attached to the stigma cells). The stigma cells preferentially synthesize these proteins and only low level of expression is found in the anthers of cruciferous plants. In several solanaceous plants (tomato, *Nicotiana glauca* and *Petunia inflata*), an S (self-compatibility) RNase may attack in the style the RNA in self-pollen. The S-RNase is normally compartmentalized in vacuoles of the pollen tube. Primarily protein HT-B keeps S-RNase sequestered. When HT-B is degraded RNase is released and incompatibility is established (McLure B 2004 Plant Cell 16:2840; Goldraij A et al 2006 Nature [Lond] 439:805).

In poppy plants, a receptor on the pollen recognizes a stylar protein. The binding between this ligand and receptor leads to release of calcium ions that in turn inhibit pollen-tube growth. Two soluble inorganic pyrophosphatases regulate the incompatibility reaction (de Graaf BHJ et al 2006 Nature [Lond] 444:490). In *Brassica* plants self-incompatibility is overcome if the aquaporin gene was disrupted. This indicates that functional water channels are one of the requirements for the manifestation of self-incompatibility in *Brassica*. Recent information indicates that in the stigma cell membranes of crucifers the single *S* locus encodes an *S* locus glycoprotein (SLG) and a single-pass transmembrane serine/threonine *S* receptor kinase (SRK). The latest evidence indicates that SRK and not SLG is responsible for the haplotype specificity and SLG reinforces the self-incompatibility. Transfer of the SRK and SCR genes from *Arabidopsis lyrata* to *A. thaliana* confers self-incompatibility to the latter species, which is normally autogamous (Nasrallah ME et al 2002 Science 297:247). The secretion of a cysteine-rich protein (SCR, encoded also at the

S locus) by the self-pollen catalyzes the autophosphorylation of the SLG—SRK complex. The SRK protein then interacts with ARC1 (autorejection component) stigma protein and as a consequence, through a series of events the self-pollen is incapacitated on the stigma by ubiquitination (Stone SL et al 2003 Plant Cell 15:885). It has been shown that an S-RNase with another component is responsible for the pollen tube breakdown in the incompatible combinations. The factor PiSNF encoding 389 amino acids ~161 kb downstream of the S₂ allele may protect the pollen from the decay (Sijacic P et al 2004 Nature [Lond] 429:302). In poppy, a caspase-3 type protein prevents self-fertilization in self-incompatibility (Thomas SG, Franklin-Tong VE 2004 Nature [Lond] 429:305). Accordingly, self-incompatibility in the different species may have different controls.

Self-incompatibility is usually determined by a large array of alleles in the populations (~100 haplotypes in *Brassicas*) and there are substantial differences among the species regarding the number of such alleles maintained depending on the effective population size. Heteromorphic self-incompatibility is based on mechanical barriers to self-fertilization. The stigma is located to a higher position in the flowers than the anthers, and the pollen usually does not reach the stigmatic surface. In such cases, artificial pollination is successful. Sporophytic incompatibility means that the incompatibility factors operate not at the gametophyte (pollen - egg) level but the pistil or pollensac tissues and control the growth of the pollen tube. In *Brassica rapa* sporophytic selfincompatibility is controlled methylation of the promoter of the recessive allele in the tapetal tissues (Shiba H et al 2006 Nature Genet 38:297). Selfincompatibility may break down by epigenetic mechanisms; in *Arabidopsis* species hybrids the S-locus receptor kinase transcript may be aberrantly processed and in *Capsella* hybrids the S-locus cysteine-rich protein may be suppressed (Nasrallah JB et al 2007 Genetics 175:1965). ▶incompatibility alleles, ▶S alleles, ▶HLA, ▶unilateral incongruity, ▶population effective size, ▶gametogenesis, ▶Ribonuclease-S, ▶RNA I, ▶ligand, ▶gametophyte, ▶pistil, ▶pollen, ▶tapetum, ▶aquaporin; Nasrallah JB 2005 Trends Immunol 26:412; McClure B 2006 Curr Opin Plant Biol 9:639; Dickinson HG 2000 Trends Genet 16:373; Kachroo A et al 2001 Science 293:1824; Takayama S et al 2001 Nature [Lond] 413:534; Tong N 2002 Trends Genet 18:113; Kachroo A et al 2002 Plant Cell 14: S227; Stone JL 2002 Q Rev Biol 77:17; Takayama S, Isogai A 2005 Annu Rev Plant Biol 56:467; self/nonself discrimination in pre- and post-zygotic systems: Boehm T 2006 Cell 125:845.

Self-Regulation: The process of regeneration of embryos from bisected (cut into halves) blastulas. This can take place in lower and higher animals including human, when identical twins are formed by spontaneous events. The dorsal-ventral morphogenetic gradients in the two halves are mediated by the bone morphogenetic proteins (BMP) and extracellular proteins such as Chordin, Sizzled and Bambi and others, which are situated at opposite poles and are under opposite transcriptional regulation (Reversade B, De Robertis EM 2005 Cell 123:1147).

▶Spemann's organizer, ▶organizer

Self-Renewal: An ability of cells to also produce stem cells that are not just able to divide mitotically and generate progenitor cells. ▶stem cells, ▶progenitor; Smith AG 2001 Annu Rev Cell Dev Biol 17:435.

Self-Reproduction: The general property of living systems. It means that the system can produce detached self-reproducing copies of itself. Self-reproducing machines—if they can function—may have special human interest for working in environments hazardous to humans such as outer space, mutagenic conditions, etc. Important requirement would be not just self-assembly, which would make only a copy of itself from parts but would continue—if parts provided—making additional copies continuously. The self-reproducing feature has now been achieved in principle by the use of a four-module system. It is still very far from generating a system comparable to a biological unit, which can generate 10²⁰ amino acid combinations not to consider the many other biological elements of a living organism (Zykov V et al 2005 Nature [Lond] 435:163).

Selfing: Self-fertilization; it is symbolized by ♂.

Selfish DNA: An assumption for certain DNA sequences (introns, repetitive non-coding sequences, transposable elements) that they have no selective (adaptive, evolutionary) value for the carrier, therefore, the presence of such sequences is of no advantage to the cells concerned, and are propagated only for selfish (parasitic) purposes. Some of the originally “selfish DNAs” (1979–80) turned out to have some functions, e.g., as maturases, and others represent transposable elements and continuously reshape the genome and are thus significant for mutation and evolution. Alu sequences appear to be more common within the generic GC regions hinting some regulatory functions. The minisatellite DNAs and the trinucleotide repeats are implicated in an increasing number of hereditary diseases. The majority of the Y-chromosomal sequences of *Drosophila* do not seem to have any identifiable function yet male fertility may be impaired if they are deleted. ▶junk DNA, ▶introns, ▶ignorant DNA, ▶copia, ▶trinucleotide repeats, ▶REP, ▶plasmid addiction, ▶transposable elements, ▶Alu;

van der Gaag M et al 2000 *Genetics* 156:775; Hurst GDD, Werren JH 2001 *Nature Rev Genet* 2:597; Hammerstein P, Hagen EH 2006 *Genes in Conflict. The Biology of Selfish Genetic Elements*. Harvard University Press, Cambridge, Massachusetts.

Selfish Genes: These have selective advantage over comparable ones and ensure their own propagation. The selfishness contrasts altruism when genes of the non-reproductive casts of social insects promote the welfare of the colony at the expense of their own work although they themselves are sterile. ▶ [altruism](#)

Selfish Replicon: The small circular plasmids in eukaryotic nuclei (maize) without any apparent function beyond perpetuating themselves.

Self-Organizing Map: ▶ [cluster analysis](#)

Self Protein: ▶ [self antigen](#), ▶ [molecular mimics](#), ▶ [bystander activation](#), ▶ [immune system](#)

Self-Primed Synthesis: The synthesis from single-strand DNA obtained through reverse transcription, one primer may be used at the 5' end to produce the second strand by extension at the 3'-end in a hairpin like structure. The synthesis by self-priming is slow (see Fig. S30).

Figure S30. Self-priming

Self-Replicating DNA: A replication mechanism for short double-stranded molecules that do not require assistance by proteins. Similar mechanisms may have operated during prebiotic evolution, and it can be reproduced in the laboratory. ▶ [replication](#), ▶ [self-assembly](#)

Self-Replicating Peptide: An autocatalytic molecule capable of assembling amino acids into oligopeptides. The yeast transcription factor GCN4 leucine-zipper domain can promote its own synthesis of 15–17 amino acid residues. ▶ [GCN4](#), ▶ [leucine zipper](#)

Selfrestriction: Self restriction lymphocyte recognizes foreign antigen bound to self MHC molecule. ▶ [lymphocyte](#), ▶ [MHC](#)

Self-Splicing Introns: Group I and group II introns can fold into catalytic structures capable of removing their own sequences from the RNA transcripts of genes. ▶ [intron](#)

Self-Tolerance: The unresponsiveness of the immune system to self-antigens. Apoptosis is a means for the maintenance of self-tolerance; lymphocytes and dendritic cells play an important role (Chen M et al

2006 *Science* 311:1160). *Central self-tolerance* may be caused by death of the lymphocytes when encountering autoantigens. Peripheral self-tolerance takes place among the mature lymphocytes in the peripheral lymphatic organs. *Clonal ignorance* fails to recognize the autoantigens because of their sequestration or the failure to stimulate the indispensable secondary signals, such as cytokines, etc. ▶ [immune tolerance](#), ▶ [self-antigen](#), ▶ [autoimmune diseases](#), ▶ [immune system](#), ▶ [at least one hypothesis](#); Rubin RL, Kretz-Rommel A 2001 *Crit Rev Immunol* 21:29.

Selvin: A rarely used unit of absorbed radiation dose. ▶ [Sievert](#)

SEM (scanning electronmicroscopy): ▶ [electronmicroscopy](#)

SEM-5: A homolog of *Grb2* in *Caenorhabditis* nematodes. ▶ [Grb2](#)

Semantics: The differentiating meaning of words and sentences. Also used by information-extraction programs for interpreting the correct meaning.

Semaphorin: A family of membrane-associated, secreted protein factors, required for axonal pathfinding in neural development. Semaphorin 5A can be bifunctional, promontory and inhibitory, to axon guidance depending on heparan and chondroitin sulfate proteoglycans (Kantor DB et al 2004 *Neuron* 44:961). Transduction by semaphorin III is mediated by the neuropilin-1 receptor. Semaphorins also regulate the development of the right ventricle and the right atrium of the heart as well as various cartilaginous and other tissues. Human semaphorins IV and V genes reside at the 3p21.3 chromosomal site; it is deleted in small cell lung carcinoma. Semaphorin 4A primes T cells and regulates Th1/Th2 (Kumanogoh A et al 2005 *Immunity* 22:305). Semaphorin 7A controls both axon guidance and T cell reaction (Czopik AK et al 2006 *Immunity* 24:591) and initiates T cell-mediated inflammation through α 1 β 1 integrin (Suzuki K et al 2007 *Nature [Lond]* 446:680). Semaphorin 4D links axon guidance and tumor-induced angiogenesis (Basile JR et al 2006 *Proc Natl Acad Sci USA* 103:9017). ▶ [axon](#), ▶ [col-lapsin](#), ▶ [neuropilin](#), ▶ [netrin](#), ▶ [neurogenesis](#), ▶ [small cell lung carcinoma](#), ▶ [plexin](#), ▶ [fasciclin](#), ▶ [axon guidance](#), ▶ [integrin](#); Tessier-Lavigne M, Goodman CS 1996 *Science* 274:1123; Pasterkamp RJ, Verhaagen J 2001 *Brain Res Rev* 35:36; Serini G et al 2003 *Nature [Lond]* 424:391; Pasaterkamp RJ et al 2003 *Nature [Lond]* 424:398.

SEMD: ▶ [PAPS](#)

Semelparity: The organism reproduces only once during its lifetime, e.g., *Palingea longicauda*

(Ephemeroptera) or some marsupials, which die after one mating season.

Semen: The viscous fluid in the male ejaculate composed of the spermatozoa and secreted fluids of the prostate and other glands. The seminal fluid of *Drosophila* reduces the propensity of the females to mate with another male. Its higher quantity lowers the viability of the females. Thus, the semen per se may have a role in fitness. ►testis, ►prostate

Semenogelin: A protein in the seminal fluid that promotes the viscosity of the ejaculate. It tends to prevent successful, additional insemination in promiscuous females (Dorus S et al 2004 Nature Genet 36:1326).

Semiconductor: The materials of germanium, silicon and others are characterized by increased electric conductivity as temperature increases to room temperature. These materials are called semiconductors because their conductivity is much lower than that of metals. In metals, the increase in temperature lowers conductivity. In the semiconductor material, the electronic motion is turned on through the crystal lattice structure. (The crystal lattice is a complex of atoms and molecules held together by electrons and atomic nuclei into an extremely large molecule-like structure.) The energy states are in so-called bands. When all the sites in an energy band are completely occupied by electrons, there is no flowing electric current because none of the electrons can accept increased energy even if exposed to an electric field of ordinary magnitude. This is thus a non-conductor state. When the energy gap between two bands is small, the electrons can be thermally excited into a conduction band and the electrons under the influence of an external electric source can initiate an electric current. This state of the crystal is an *intrinsic semiconductor*. The carriers of the current are called positive holes. Transistors (electronic amplifying devices utilizing single-crystal semiconductivity) operate by the principles of conduction electrodes and mobile positive holes. Industrially used semiconductors are *extrinsic semiconductors*, which mean that when small amounts of other material is introduced into them, it results in enhanced conductive properties. These devices are essential components of electronic laboratory equipments and communication systems, computers and television sets.

Semi-Conservative Replication: The regular mode of DNA replication where one old strand serves as template for the synthesis of a complementary new strand and this then with an old strand becomes the daughter double helix. ►DNA replication,

►replication, see Table P3 at ►pulse-chase entry and Fig. W4 in ►Watson and Crick model

Semi-Dominant: The dominance is incomplete, and therefore such genes may be useful because the heterozygotes can be phenotypically recognized. ►incomplete dominance, ►codominance

Semigamy: Occurs when the egg and sperm do not fuse, rather they contribute separately to the formation of the embryo that may become thus a paternal-maternal chimera. ►apomixis, ►androgenesis, ►parthenogenesis

Semi-Lethal: Genes that reduce the viability of the individual, and may cause premature death. ►lethal equivalent, ►lethal factors, ►LD50, ►LD₀

Seminal Fluid: ►semen, ►sperm

Seminal Root: The root of the embryo in plant seeds. ►root

Seminoma: Same as spermatocytoma.

Semio: In association with additional terms indicates signals or symptoms, e.g., semiochemicals such as pheromones or semiology, i.e., symptomatology.

Semi-Ortholog: The duplicated copy of a single copy ortholog. ►orthologous loci

Semiotics: The study of signs and symbols. It is used in bioinformatics and communication. Organisms interpret their environment by the signs encountered. Medicine makes diagnoses on the bases of signs.

Semisynthesis of Proteins: Non-natural amino acids, e.g., norvaline and homoserine can be inserted at specific protein sites to explore the conformational and functional consequence of the alteration. Similarly, photoactivatable cross-linkers, fluorophores, alteration of the active site of enzymes by specific amino acid replacement, cassette mutagenesis, introduction of stable isotopes have been accomplished. Selective chemical ligation of unprotected peptides may be useful to preserve solubility. Proteins can be changed posttranslationally by removing inteins and religation the flanks through different chemical reactions. Protein transsplicing can use inteins that were split into N- and C-terminal sections, which are separately inactive but activity is gained by ligation. By chemical synthesis, the D and L enantiomorphs of the HIV-1 proteases have been prepared displaying reciprocal chiral specificity as a proteases and similar specificity for enzyme inhibitors (Milton RC et al 1992 Science 256:1445). Ligation via an intein permits the production of new types of proteins from different elements and insertion of amino acid analogs may result in a cytotoxic molecule (Evans TC et al 1998 Protein Sci 7:2256). Sequential steps can link

more than two elements. These engineered proteins have great theoretical and applied utility. ▶[homoserine](#), ▶[norvaline](#), ▶[active site](#), ▶[fluorophore](#), ▶[in-tein](#), ▶[cassette mutagenesis](#), ▶[expressed protein ligation](#), ▶[HIV-1](#), ▶[enantiomorph](#), ▶[chirality](#); Wallace CJ, Clark-Lewis I 1997 *Biochemistry* 34:14733; Muir TW 2003 *Annu Rev Biochem* 72:249.

Semisterility: Indicates that in an individual some gametes or gametic combinations are not viable when others are normal. Semisterility is common after deletion and duplication in the offspring of inversion and translocation heterozygotes but it may be caused by self-incompatibility, incompatible non-allelic combinations, cytoplasmic factors, fungal or viral infections, adverse environmental conditions, etc. ▶[chromosomal aberrations](#), ▶[mtDNA](#)

Semisynthetic Compounds: Natural products but chemically modified.

Semliki Forest Virus: A member of the alphavirus group. ▶[alphavirus](#)

Sendai Virus: A parainfluenza virus. In an ultraviolet light-inactivated form, it has been used to promote fusion of cultured mammalian cells or uptake of liposomes by its modifying effect on the lipids of the plasma membrane. ▶[cell genetics](#), ▶[cell fusion](#), ▶[cell membranes](#), ▶[polyethylene glycol](#), ▶[fusigenic liposome](#), ▶[alpha viruses](#)

senDNA: Mitochondrial DNA (ca. 2.5 kb), excised from the first intron of the *cox1* gene (cytochrome oxidase) and amplified in *Podospira anserina*. This and similar structures appear to be responsible for aging in vegetative cultures. ▶[aging](#), ▶[killer plasmids](#)

Senescence: The process of aging of organisms. At the cellular level, it has a somewhat different meaning. Cell senescence indicates how many cell divisions are expected on an average from isolated mammalian cells. Generally, cell senescence is correlated with the age of the individual and organism from where it was explanted. Human fibroblast cells under normal conditions cease to proliferate after about ± 50 divisions although individual lineages may vary. Normal human mammary epithelial cells are different as they fail to senesce as fibroblasts do but eventually they develop telomerase problems and chromosomal anomalies. It has been suggested that the activity of the telomerase enzyme slows down and causes this phenomenon. The irreversible arrest of proliferation is *replicative senescence*. The tumor-suppressor protein p53, the retinoblastoma protein (Rb1), cyclin-dependent kinase (Cdk) inhibitors such as p21^{CIP1/WAF1} and p16^{INK4a} are also involved. The disruption of p21^{CIP1/WAF1} leads to an escape of senescence by human fibroblasts. Some rodent cell

lines (glia oligodendrocyte precursor cells) may not senesce. In addition, cancer cells and human fibroblast cells fused to cancer cells may divide indefinitely. Hyper-replication of the DNA induced by oncogenes may also invoke senescence (Micco RD et al 2006 *Nature [Lond]* 444:638). Senescence involves the upregulation of genes that are clustered in the chromosomes (Zhang H et al 2003 *Proc Natl Acad Sci USA* 100:3251). Plant cells when provided with an appropriate regime of phytohormones may be maintained continuously and can even be regenerated into differentiated organisms. Senescence of plant cells is regulated by cytokinins, and the increase in cytokinin level inhibits the process of senescence. ▶[aging](#), ▶[agonescence](#), ▶[monoclonal antibody](#), ▶[apoptosis](#), ▶[tissue culture](#), ▶[embryogenesis somatic](#), ▶[cell cycle](#), ▶[hybridoma](#), ▶[senDNA](#), ▶[killer plasmids](#), ▶[Hayflick's limit](#), ▶[telomerase](#), ▶[telomeres](#), ▶[p53](#), ▶[p21](#), ▶[p16^{INK4a}](#), ▶[Ets oncogene](#), ▶[Id proteins](#), ▶[Cdk](#), ▶[retinoblastoma](#), ▶[mole](#), ▶[plant hormones](#); Romanov SR et al 2001 *Nature [Lond]* 409:633; Karlseder J et al 2002 *Science* 295:2446; He Y, Gan S 2002 *Plant Cell* 14:805.

Senescence, Replicative: After a certain number of replications due to dysfunction of the telomeres, proliferation ceases. When this process goes out of control, it may involve tumorigenesis.

Senior-Loken Syndrome (NPHP1, 2q13; NPHP3, 3q22; NPHP4, 1p36; IQCB1, 3q13.31-q21.2): A heterogeneous syndrome involved in chronic kidney disease of children. NPHP1 encodes nephrocystin protein. NPHP3, responsible for nephronophtosis recessive kidney disease, encodes a 1330 amino acid protein interacting with nephrocystin. NPHP4 encodes the 1426 amino acid nephroretinin protein, which interacts with nephrocystin. IQCB1/NPHP5 also encodes nephrocystin and the patients display simultaneously retinitis pigmentosa. (See Otto EA et al 2005 *Nature Genet* 37:282.

Sense-Antisense Genes: Overlapping genes. ▶[overlapping genes](#)

Sense Codon: Specifies an amino acid. ▶[genetic code](#)

Sense Strand: The DNA strand that carries the same nucleotide sequences as the mRNA, tRNA and rRNA (of course in the RNAs U stand in place of T). It does not carry an absolute meaning because of some cases both strands are transcribed although in context of a particular RNA it is correct. ▶[template strand](#), ▶[coding strand](#)

Sense Suppression: ▶[co-suppression](#), ▶[quelling](#), ▶[RNAi](#)

Sensillum: A cuticular sensory element; *sensilla campaniformia* are small circular structures along longitudinal veins of *Drosophila* wings (see Fig. S31). ▶*Drosophila*

Figure S31. Sensillum

Sensitivity: The percentage of correct identification of (carcinogens) on the basis of the (mutagenicity or other rapid) assay system. In DNA sequencing: the correctly predicted bases divided by total length of the cDNA. ▶accuracy, ▶specificity of mutagen assays, ▶predictability, ▶bioassays for environmental mutagens

Sensor Gene: Responsible for perceiving a signal. ▶signal transduction

Sensoryneural: Affecting the nerve mechanism of sensing.

Sensory Neuropathy 1 (HSN1): A dominant (human chromosome 9q22.1-q22.3) de-generative disorder of the sensory neurons, ulcerations and bone defects. A serine palmitoyltransferase subunit maps within the HSN1 gene and it is expressed in the dorsal root ganglia. ▶neuropathy, ▶pain-insensitivity, ▶hypomyelination, ▶ganglion; Bejaoui K et al 2001 Nature Genet 27:261.

Sensory Transduction: Mediates touch, heat and pain responses in the skin. Sensory neurons of A β , A δ or differently myelinated C fibers respond to the stimuli. Thermosensation is mediated through Transient Receptor Potential (TRP) families among them is the TRPV1 vanilloid transducer protein of capsaicin (present also in pungent peppers). Neuronal fibers evoke heat and pain sensation (nociception). TRPV2 is activated at temperatures above 52 °C. Other TRPVs respond to chemical stimuli. Cooling sensation (below 32 °C) is transduced by other TRPVs, TRPA (ankyrin family) and TRPNs. Mechanotransduction (touch responses) are sensed by A β or A δ nociceptors, depending on intensity of the stimulus and other factors. Different channels exit for osmolarity, stretch, different chemicals, auditory (stereocilia) and other functions. Keratinocytes, Merkel (tactile) cells respond also to shape and texture. Some of the mechanisms have polymodality and are integrated into circuits. Many of these functions can be now be studied by mutations (Lumpkin EA, Caterina MJ 2007 Nature [Lond] 445:858).

▶nociceptor, ▶capsaicin, ▶ion channel, ▶osmolarity, ▶deafness

Sentinel Phenotypes: These are used in human genetics to detect newly occurring mutations. These traits are supposed to be relatively easily detectable by direct appearance or clinical laboratory data can be obtained through routine examinations. Their frequencies are statistically evaluated for epidemiological information regarding possible increase in mutagenicity/carcinogenicity in an environment. ▶mutation in human populations, ▶epidemiology; Czeizel A 1989 Mutat Res 212:3.

Sentrin: A ubiquitin-carrier protein (known also under other names). ▶ubiquitin, ▶UBL, ▶SUMO, ▶PIC; Kahyo T et al 2001 Mol Cell 8:713.

Seq 1: A pleiotropic eukaryotic (yeast) strand exchange protein. ▶recombination in eukaryotes, ▶STP β

Sepal: The whorl of (usually green) leaves below the petals in a flower (see Fig. S32). ▶flower differentiation

Figure S32. Sepal

Separins (Scc1, separase): Ubiquitous Esp1/Cut1-like proteins (~180–200 kDa), which are removed from their inhibitory association with securin by APC in order to separate the sister chromatids at anaphase. Separins may have endopeptidase-(cysteine proteases) like function. The Rec8 subunit of cohesin is cleaved by separin and consequently the meiotic chiasmata are resolved. The disjunction of the homologous chromosomes takes place during meiosis I. Separase also cleaves the kinetochore-associated protein Slk19 at the onset of anaphase. Slk stabilizes the anaphase spindle and assures an orderly exit from anaphase. The inner centromere-like protein–Aurora complex is regulated by the CDC14 phosphatase (Pereira G, Schiebel E 2003 Science 302:2120). ▶sister chromatid cohesion, ▶co-orientation, ▶Rec8, ▶Scc1, ▶mitosis, ▶chiasma, ▶cohesin, ▶securin, ▶shugoshin, ▶APC, ▶anaphase, ▶Aurora, ▶CDC14, ▶kinetochore, ▶spindle, ▶FEAR; Hauf S et al 2001 Science 293:1320; Sullivan M et al 2001 Nature Cell Biol 3:771.

Sephadex: An ion exchanger or gel-filtration medium on cross-linked dextran matrix. ▶[dextran](#), ▶[gel filtration](#)

Sephardic: Jews who moved to Spain after the Roman occupation of Israel and then in the Middle Ages to Western European countries. ▶[Ashkenazim](#), ▶[Jews and genetic diseases](#)

Sepharose: The anion exchanger of agarose matrix such as DEAE (diethylaminoethyl) sepharose.

Sepsis: Bacteria or bacterial toxins in the blood stream, resulting in potentially fatal condition. Sepsis induces apoptosis of the lymphocytes by the action of caspases. Caspase inhibitors or introduction or stimulation of Bcl-2 may improve survival. Caspase 12 exists in both short and long forms by genetic determination. The long form may be less effective in controlling the innate reaction of inflammation and thus in sepsis. Inflammation is the first step in the immune reaction and it is controlled by cytokines. Bacterial clearance and sepsis resistance is found in mice deficient in caspase-12 (Saleh M et al 2006 Nature [Lond] 440:1064). ▶[apoptosis](#), ▶[Bcl](#), ▶[lymphocyte](#), ▶[caspase](#), ▶[sepsis](#), ▶[caspase](#); Hotchkiss RS et al 2000 Nature Immunol 1:496; Saleh M et al 2004 Nature [Lond] 429:75.

Septal: The adjective for septum (dividing structure, a wall).

Septate: Separated by cross walls (septa) (see Fig. S33).

Figure S33. Septate fungal mycelium

Septation: ▶[tubulins](#)

Septic Shock: A bacterial lipopolysaccharide endotoxin-induced hypotension leading to inadequate blood supply to several organs; it is potentially fatal. Neutralizing MIF may alleviate it. The inflammatory responses are amplified by the triggering receptors (TREM) on neutrophils and monocytes. ▶[MIF](#); Patel BM et al 2002 Anesthesiology 96:576.

Septins: Rather ubiquitous polarizing GTPase (38–52 kDa GTP-binding) proteins, found in organisms from fungi to humans. In yeast, septins form hourglass-shaped pure proteins in between mother and daughter cells and mechanically mediate cytokinesis and growth (see Fig. S34) (Vrabioiu AM, Mitchison TJ 2006 Nature [Lond] 443:466). A human septin gene is at 17q25.3. Septin deficient spermatozoa are defective in movement because the kinesin-mediated

intraflagellar transport of sperm stalls in this case, although fertility is rescued if the spermatozoa are injected into the oocytes (Ihara M et al 2005 Dev Cell 8:343). ▶[congression](#), ▶[cytokinesis](#); McIlhatton MA et al 2001 Oncogene 20:5930.

Figure S34. Hourglass-shaped septin

Septooptic Dysplasia (SOD, De Morsier syndrome, 3p21.2-p21.1): A relatively rare disorder involving optic nerve and pituitary gland hypoplasia and absence of the septum pellucidum (the double membrane separating the anterior horn and the lateral ventricles of the brain in the median plane bounded by the corpus callosum). A phenotype is quite variable. The molecular basis is deficiency in pituitary hormone production due to mutation in the HESX1 gene. ▶[pituitary](#); Carvalhjo LR et al 2003 J Clin Invest 112:1192.

Sequatron: An automated high performance DNA sequencing apparatus (Hawkins TL et al 1997 Science 276:1887). ▶[sequenator](#), ▶[DNA chips](#), ▶[SAGE](#), ▶[DNA sequencing](#)

Sequenase: A genetically engineered DNA polymerase. It combines the 85 kDa protein of phage T7 gene 5 and the 12 kDa *E. coli* thioredoxin protein (the latter keeps it associated with the template). The 3' → 5' exonuclease activity is suppressed. It synthesizes about 300 nucleotides per second, and it is used for DNA sequencing and oligolabeling. ▶[DNA sequencing](#), ▶[oligo-labeling probes](#)

Sequenator: An automated equipment that breaks up a protein sequentially, starting at the NH₂ terminus, into amino acids, identifies them by chromatography, and thus determines their sequence. ▶[amino acid sequencing](#)

Sequence Alignment: ▶[CLUSTAL](#), ▶[Sequin](#); multiple sequence alignments algorithm: <http://msa.cgb.ki.se/cgi-bin/msa.cg>; multiple alignment tools: <http://www.igs.cnrs-mrs.fr/Tcoffee/>; multiple alignment including codons, mismatches, pseudogenes: <http://coot.embl.de/pal2nal/>; multiple alignment tool with shuffled and repeated sequences: <http://aba.nbcr.net/>.

Sequence Analysis Toolkit, for genes: <http://www.migenas.org/home/index.jsp>.

Sequence Logo: A sequence logo graphically represents DNA and amino acid sequence patterns from a set of aligned sequences (see Fig. S35). A column of

stacked symbols represents each position of the alignment with its total height, reflecting the information content in this position by the Delila Software package. It displays aligned base sequences in bits, at each position by the height of the symbols <http://biodev.hgen.pitt.edu/enologos/>. (Diagram redrawn after Shaner M et al from web site: <http://www-lecb.ncifcrf.gov/~toms/logoprograms.html>).

Figure S35. Sequence logo of 40 yeast TATA sites

Sequence Saturation Mutagenesis (SeSaM): To carry out SeSaM: 1. Generate DNA fragments of random length, 2. With the aid of terminal transferase add to the tails universal bases, 3. Elongate the fragments in a PCR to full length genes using a single-strand template and replace the universal base by standard one. Random mutations occur because the universal bases are promiscuous in pairing. ▶[terminal deoxynucleotidyl transferase](#), ▶[universal bases](#), ▶[polymerase chain reaction](#), ▶[mutagenesis](#); Wong TS et al 2004 Nucleic Acids Res 32(3):e26.

Sequence Skimming: In sequence skimming, a long DNA fragment is probed with some known genes in order to test whether the probes have homology and thus, a site within this long fragment chosen at random. ▶[probe](#); Elgar G et al 1999 Genome Res 9:960.

Sequence Space: The number of possible sequences of a particular length.

Sequence-Based Taxonomy: <http://www.ncbi.nlm.nih.gov/Taxonomy/taxonomyhome.html>.

Sequence-Tagged Connector (STC): ▶[genome project](#); Mahairas GG et al 1999 Proc Natl Acad Sci USA 96:9739.

Sequence-Tagged Site: ▶[sequenced tagged sites](#)

Sequenced Tagged Sites: Single-copy DNA regions (100–500 bp), for which polymerase chain reaction (PCR) primer pairs are available and can be used for DNA mapping. ▶[PCR](#), ▶[primer](#), ▶[expressed-sequence tag](#); Venichanon A et al 2000 Genome 43:47.

Sequencing: ▶[DNA sequencing](#), ▶[survey sequencing](#), ▶[protein sequencing](#), ▶[RNA sequencing](#), ▶[genome projects](#), ▶[deep sequencing](#)

Sequest: A software package for the analysis of mass spectral data of proteins/peptides (<http://fields.scripps.edu/sequest/>).

Sequester: To lay away or separate (into a compartment).

Sequin: A software tool for submitting nucleic acid sequence information to GenBank, EMBL, or DDBJ. It can be reached at <http://www.ncbi.nlm.nih.gov/Sequin/index.html>. ▶[GenBank](#), ▶[EMBL](#), ▶[DBJ](#)

SER (smooth endoplasmic reticulum): An internal flat vesicle system in the cytoplasm, involved in lipid synthesis. ▶[RER](#)

Serca: Sarcoplasmic reticulum Ca^{2+} ATPase. ▶[Brody disease](#), ▶[Darier-White disease](#)

SEREX (serological analysis of tumor antigens by recombinant expression cloning): SEREX screens cancer patients' own sera for (autologous) tumor cells in order to determine antigens (cDNAs), which may be used for antibody-mediated immunotherapy. ▶[cancer gene therapy](#), ▶[immunotherapy](#); Okada H et al 2001 Cancer Res 61:2625.

Serial Analysis of Gene Expression: In the serial analysis of gene expression, short DNA sequence tags are prepared from many cDNA clones and after forming concatamers the entire cDNA is sequenced.

Serine (Ser, S): An amino acid (β -oxy- α -amino-propionic acid, MW 105.09); it is soluble in water. RNA codons: UCU, UCC, UCA, UCG, AGU, AGC. Serine is derived from the glycolytic pathway (see Fig. S36).

Figure S36. Serine biosynthetic path

Serine dehydratase enzyme, with pyridoxal phosphate prosthetic group, degrades serine into pyruvate and NH_4^+ . ▶amino acids, ▶amino acid metabolism, ▶oxalosis, ▶3-phosphoglycerate dehydrogenase

Serine Kinase: ▶MCF2 oncogene for serine phosphoprotein

Serine Protease: Serine protease degrades proteins in extracellular matrix and the family includes about 98 members and regulates many physiological reactions. ▶matrix, ▶kallikrein; Stoop AA, Craik CS 2003 Nature Biotechnol 21:1063.

Serine/Threonine Kinase: Serine kinase phosphorylates serine and tyrosine residues in proteins. Their receptors are transmembrane proteins and the kinases attach to the cytosolic carboxyl end of the receptors. ▶transforming growth factor β , ▶PIM oncogene, ▶PKS oncogene, ▶activin, ▶bone morphogenetic protein, ▶membrane proteins, ▶protein kinases, ▶receptor guanylyl cyclase, ▶signal transduction, ▶SMAD

Serine/Threonine Phosphoprotein Phosphatases: Serine phosphoprotein phosphatases remove phosphate from serine and threonine residues of proteins. *Protein phosphatase-I* is inhibited by cAMP by promoting the phosphorylation of a *phosphatase inhibitor protein* through protein kinase A. *Protein phosphatase IIA* is the enzyme most widely involved in dephosphorylation of the products of serine/threonine kinases. *Protein phosphatase-IIB* (calcineurin) is most common in the brain where Ca^{2+} activates it. *Protein phosphatase-IIC* plays only a minor role in the cells. The catalytic subunit of the first three is homologous but they also contain special regulatory subunits. *Phospholipase C* (PLC) may be coupled to G-proteins and upon its activation the level of Ca^{2+} increases. This cation mediates numerous cellular reactions. ▶serine/threonine kinases, ▶phosphorylases, ▶signal transduction, ▶regulation of gene activity

Serine/Threonine Protein Kinase: ▶serine/threonine kinase

Seripauperines (PAU): A large group of proteins in eukaryotes, conspicuously low in serine and having amino-terminal signal sequence. Their function is still unknown. They are encoded at subtelomeric sites in all yeast chromosomes. ▶signal sequence; Coissac E et al 1996 Yeast 12:1555.

Seroconversion: As per seroconversion, new antibody production against an antigen alters the serological state.

Serodeme: A particular type of antigen produced by a clone. ▶antigen

Serology: Serology deals with antibody levels and with the reactions of antigens. ▶serum; serological classification: <http://fred.bioinf.uni-sb.de/sepacs.html>.

Seronegative: A seronegative fails to display antibodies against the antigen in question.

Seropositive: In a seropositive, reactive antibody to an antigen is present in the serum.

Seroswitch Vector: In a seroswitch vector, the epitope of the viral coat protein can be changed to evade the adverse serological reaction against it, in cases when the same passenger DNA must be used repeatedly, e.g., in cases of adenoviral vectors. ▶adenovirus, ▶epitope, ▶serotype

Serotonin (5-hydroxytryptamine): A tryptophan-derived neuro-transmitter modulates sensory, motor, and behavioral processes (including also feeding behavior) controlled by the nervous system (see Fig. S37). Hydroxytryptamine 2B receptor also regulates the cell cycle by interacting with the tyrosine kinase pathway through the phosphorylation of the retinoblastoma protein and the activation of cyclin D1/Cdk4 and cyclin E/Cdk2. Cyclin D1, in concert with other proteins, induces also the MAPK pathway. The 5-hydroxytryptamine receptor 5-HT_{1B} binds protein p11 and in a mouse model seems to alleviate depression. Triptan drugs used for treatment of migraine seem to act as a 5-HT_{1B} agonist (Sharp T 2006 Science 311:45; Svenningsson P et al 2006 Science 311:77). Serotonin transporter (SERT) is a polytopic membrane transporter with 12 transmembrane domains. The 5-HT_{3A} receptor is a large-conductance neuronal serotonin channel. Low activity of 5-HT serotonin transporter may cause a propensity to psychiatric disorders (Ansorge MS et al 2004 Science 306:879). ▶neurotransmitters, ▶glucocorticoid, ▶obesity, ▶substance abuse, ▶alcoholism, ▶cocaine, ▶cyclins, ▶Cdk, ▶MAPK, ▶retinoblastoma, ▶migraine

Figure S37. Serotonin

Serotype: A serotype is distinguished from other cells by its special antigenic properties. ▶antigenic variation, ▶capsule

Serovar: Same as serotype.

Serpentine Receptors: Seven-membrane spanning receptors. ▶seven membrane proteins

Serpines (serine-protease inhibitors, 14q32.1): Serpines, when mutated, may be responsible for emphysema, thrombosis, and angioedema. Viral infection may counteract them. The accumulation of neuroserpin caused by mutation leads to a familial encephalopathy with neuroserpin inclusion bodies (FENIB), a dementia. There are about 500 serpins of 350–500 amino acid residues. They occur in all organisms from mammals, to plants, to viruses. Serpin, SRPN6 seems to control innate resistance in *Anopheles* against *Plasmodium* (Abraham EG et al 2005 Proc Natl Acad Sci USA 102:16327). ▶maspin, ▶C1 inhibitor, ▶Hsp [Hsp47], ▶L-DNase II, ▶emphysema, ▶thrombosis, ▶angioedema, ▶encephalopathy, ▶antitrypsin, ▶malaria, ▶*Plasmodium*; Atchley WR et al 2001 Mol Biol Evol 18:1502; Silverman GA et al 2001 J Biol Chem 276:33293; Crowther DC 2002 Hum Mut 20:1; Lomas DA, Carrell RW 2002 Nature Rev Genet 3:759.

Serprocidin: ▶antimicrobial peptides

Sertoli Cells: ▶Wolffian ducts

Serum: The clear part of the blood, from which the cells and the fibrinogen have been removed; the clear liquid that remains of the blood after clotting. The immune serum contains antibodies against specific infections. It differs from plasma, which is the non-particulate portion of cells. ▶plasma, ▶antibody production, ▶serology

Serum Dependence: As per serum dependence, animal cells may grow or differentiate only or preferentially in cultures containing serum.

Serum Response Element (SRE): A DNA tract that assures transcriptional activation in response to growth factors in the serum. ▶SRE, ▶CARG box

Server (web server): The server delivers information available on the internet with the aid of computer programs.

S

Sesame (*Sesamum indicum*): An oil seed crop with about 37 related species; the cultivated form is $2n = 2x = 26$ but related species may have $x = 8$ and different levels of ploidy.

Sesquidiploid: A sesquidiploid contains a diploid set of chromosomes derived from one parent and a higher-number set from the other. ▶allopolyploid, ▶allopolyploid segmental

Sessile: A sessile plant is attached directly to a base without a stalk.

SET Motifs (Su[var3-9]-enhancer-of-zeste-trithorax): originally named after the three *Drosophila* regulatory proteins where they occur and modulate chromatin structure and thus gene expression. Set2 is a methyltransferases enzyme. So far the products of

at least 20 genes display such a domain with an apparent role in epigenesis/development. The *polycomb* gene of *Drosophila*, yeast telomeric silencing, heterochromatin-mediated gene silencing, variegation position effects (PEV), as well as, the Mll factors involve SET domains. ▶chromodomain, ▶integration, ▶transcription, ▶Mll, ▶w locus, ▶Polycomb, ▶Sbfl, ▶epigenesis, ▶methyltransferase; Baumbusch LO et al 2001 Nucleic Acids Res 29:4319.

Set Point, Viral: The level of circulating virus in the plasma during the nonsymptomatic phase preceding the progression to AIDS (Fellay J et al 2007 Science 317:944). ▶acquired immunodeficiency

Set Recoding: ▶fuzzy inheritance

Seta: Bristles, stiff hairs of animals or plants.

SETGAP (selectable expression of transient growth-arrest phenotype): A system suitable for the isolation of genes that interfere with the expression of certain other genes or genetic pathways. ▶negative regulator; Pestov DG, Lau LF 1994 Proc Natl Acad Sci USA 91:12549.

Sevenless (sev): X-chromosomal gene (1-33.38) of *Drosophila* controlling the R7 rhabdomeres and thus altering the photoreceptivity of the eye. The carboxy terminal of the protein product of the wild type allele shows homology to the tyrosine kinase receptor of *c-ras*, *v-src*, and EGF. ▶photoreceptor, ▶rhodopsin, ▶signal transduction, ▶ommatidium, ▶compound eye, ▶daughter of sevenless, ▶RAS, ▶EGF, ▶BOSS, ▶rhabdomere

Seven-Membrane Proteins (7tm): Integral parts of the plasma membrane that span the membrane by seven helices; they are important in signal receptor binding and in association with G-proteins. More than 800 genes encode these most versatile receptors of chemokines, hormones, neurotransmitters, odorants, and taste and light signals. Heteromeric G proteins, β -arrestin, and GRK family of proteins mediate the signal transmission to 7tm protein receptors. ▶signal transduction, ▶G-protein, ▶transmembrane receptors, ▶arrestin, ▶GRK; Pierce KL et al 2002 Nature Rev Mol Cell Biol 3:639.

Seven-Pass Transmembrane Proteins: Same as seven membrane protein.

Severe Combined Immunodeficiency (SCID): A less frequently occurring (0.00001-0.00005) autosomal disease than the X-linked agammaglobulinemia, but it is generally lethal before age two. The thymus is abnormally small and therefore there is a severe deficiency of the T- and sometimes also the B-lymphocytes. The afflicted infant cannot overcome infections. SCID-X1 may be effectively treated by

gene therapy but cancerous growth may ensue when the retroviral vector is inserted in the vicinity of the promoter of the LMO2 proto-oncogene (Hacein-Bey Abina S et al 2003 Science 302:415). In some cases, viral infection may severely damage the thymus, and this non-hereditary disease may closely mimic the symptoms of SCID. The DNA-dependent kinase (p350), encoded in human chromosome 8q11, is most likely responsible for SCID-1. A gene in chromosome 10p of humans interferes with the V(D)J recombination system and thus prevents normal function of both B- and T-lymphocytes (Moshous D et al 2001 Cell 105:177). Several other gene loci may also be involved in the development of the disease. SCID mouse devoid of T and usually also B-lymphocytes can accept human grafts and can be used to create a partial human immune system in the mouse. The most common form of it is X-chromosome-linked (Xq13). In about 40% of the cases, there is adenosine deaminase deficiency. T cell deficiency may be treated by the transplantation of hematopoietic cells. ADA may be corrected by gene therapy (Fischer A et al 2001 Immunity 15:1). In some cases, transplantation of thymus tissues may lead to improvement. ►[agam-maglobulinemia](#), ►[hypogammaglobulinemia](#), ►[immunodeficiency](#), ►[SCID](#), ►[DNA-PK](#), ►[adenosine deaminase deficiency](#), ►[gene therapy](#)

Sewall Wright Effect: Same as drift genetic.

Sex: In eukaryotes, sex makes possible the production of two kinds of gametes and it is the requisite of syngamy. By recombination and by promoting linkage equilibrium, sex facilitates selection of adaptive variation and provides a means for elimination of deleterious genes. In prokaryotes and viruses, “sex” is recombination. The majority of species reproduce sexually and the relatively few asexual species seem to represent dead ends in evolution. The tiny *Bdelloid* freshwater rotifers are exceptional because they survived and evolved for 35–40 million years without sex. The *genetic sex* in the female is determined by the X chromosome(s) whereas the Y chromosome carries the male determining genes. The *gonadal sex* is represented by the ovarian differentiation in the female and the testicular differentiation in the male. *Somatic sex* is gonadally controlled. Female differentiation takes place—irrespective of the chromosomal constitution—if the gonads are removed during early fetal development. The anti-Müllerian hormone synthesized by the Sertoli cells and the fetal androgens (testosterone, androstenedione) synthesized by the Leydig cells normally suppress female differentiation. The fetal female gonads have no effect on the female somatic sex development. In the gonadless genital tract of both sexes, the Müllerian ducts are maintained but the Wolffian ducts degenerate. Estrogen synthesized by the

female may adversely affect the male type differentiation. The anti-Müllerian hormone apparently blocks, however, an enzyme (aromatase) required for feminization and in this case the somatic sex shifts towards the direction of masculinization. ►[gender](#), ►[sex cell](#), ►[syngamy](#), ►[copulation](#), ►[sex determination](#), ►[recombination](#), ►[linkage](#), ►[meiosis](#), ►[Wolffian ducts](#), ►[Müllerian ducts](#), ►[gonads](#), ►[sex hormones](#)

Sex Allocation: The variation in sex ratio in favor of males or females due to non-chromosomal sex-determining mechanisms such as exist in social insects, and are caused by colony size, mating behavior, and available resources. ►[sex determination](#), ►[sex ratio](#)

Sex Bias in Disease Phenotype: As per the sex bias, one or the other sex is more likely to express the disease. ►[Rett syndrome](#), ►[imprinting](#)

Sex Bias in Mutation: ►[mutation rate](#)

Sex Bivalent: In the sex bivalent, the X and Y chromosomes have homology only in the short common segment where they can pair and recombine. ►[pseudoautosomal](#)

Sex Body (XY body): A structure associated with both the X and the Y chromosomes. For its formation, the H2AX (a histone 2A variant) is required apparently for chromatin remodeling. The sex body inactivates both the X and Y chromosome during the pachytene stage of sperm formation and is involved in gene silencing. The sex body presumably protects against illegitimate chromosome association and thus, aneuploidy (McKee BD, Handel MA 1993 Chromosoma 102:71). ATR localizes, under BRCA1, to the XY chromatin and after phosphorylating histone H2AX, the sex body is formed (Turner JMA et al 2004 Curr Biol 14:2135). In H2AX deficiency the males but not the females are infertile. ►[ATR](#), ►[breast cancer](#), ►[Meisetz](#), ►[histone variants](#), ►[pachytene](#); Fernandez-Capetillo O et al 2003 Dev Cell 4:497.

Sex Chromosomal Anomalies in Humans: Sex chromosomal anomalies are of various types and they may occur at a frequency of 0.002 to 0.003 of all births. *Females:* X0, XXX, XXXX, XXXXX, X0/XX, X0/XXX, X0/XXX/XX, XX/XXX, X0/XXY, XXX/XXXX, XXX/XXXX/XX and *males:* XX, XYY, XXY, XXYY, XXXY, XXXYY, XXY/XY, XYY/XYYY, X0/XXY/XY, XXYYY/XY/XX, XXXY/XXXXY. Other, even more complicated types have been reported. The most common mechanism by

which these anomalies occur is nondisjunction in meiosis and mitosis. The more complex type mosaics (indicated by /) are the result of repeated non-disjunctional events. The XO condition is called *Turner syndrome*, the XXX is *triplo-X*, while XXY and other male conditions with multiple X and Y(s) are generally referred to as Klinefelter syndrome along with the XX males, which have a Y-chromosome translocation to another chromosome. Similar sex-chromosomal anomalies have been identified in various other mammals. The XO condition results in an abnormal female in humans and mice but in a normal male in grasshopper or *Caenorhabditis*, and in an abnormal male in *Drosophila*. ▶*trisomy*, ▶*chromosomal sex determination*, ▶*Turner syndrome*, ▶*Klinefelter syndrome*, ▶*triplo-X*, ▶*XX males*, ▶*gynandromorph*, ▶*testicular feminization*

Sex Chromosome: The sex chromosome is unique in number and/or function to the sexes (such as X, Y or W, Z); see ▶*chromosomal sex determination*. In the heterogametic sex, the X and Y chromosomes pair and may recombine in a relatively short terminal region although in the heterogametic sex in insects recombination is practically absent, except when transposable elements function. ▶*PAR*, ▶*sex determination*

Sex Circle Model of Recombination: The basic tenets of the sex circle model of recombination in fungi, according to F.W. Stahl (1979 Genetic Recombination. Freeman, San Francisco, California), are: 1. Any marker can recombine either by reciprocal exchange or by gene conversion. 2. Close markers are more likely to recombine non-reciprocally. 3. Gene conversion observes the principle of parity. 4. Gene conversion is polar. 5. In half of the cases, gene conversion is accompanied by classical exchange of outside markers. 6. Reciprocal recombination is always accompanied by exchange of outside markers. 7. Conversion that does not involve outside exchange shows no interference of flanking genes. 8. Gene conversion accompanied by outside marker exchange may also involve interference. 9. Conversion asci (5:3, 6:2) obey the principles listed under 1 to 8. 10. All markers (except deletions, and a small fraction of conversion alleles) can segregate post-meiotically. 11. The very rare aberrant 4:4 conversion asci may be the results of two events. ▶*recombination*, ▶*gene conversion*

Sex Comb: Special structures on the metatarsal region of the foreleg of *Drosophila* male (see Fig. S38). ▶*Drosophila*

Sex Controlled (sex influenced): The degree of expression of a gene is determined by the sex (e.g., baldness is more common in human males than females). ▶*Hirschsprung's disease*, ▶*Huntington's disease*, ▶*imprinting*

Sex Determination: In dioecious animals and plants, sex is usually determined by the presence of two X (female) and XY (male) chromosomal constitution, respectively. In other words, the females are homogametic (i.e., the eggs all carry an X chromosome) and the males are heterogametic (i.e., they can produce sperm with either X or Y chromosomes). Exceptionally XX individuals may be males if the sex-determining section of the Y chromosome is translocated to an X. An XY individual can be a female if from the Y chromosome the sex-determining part of her Y chromosome was lost. In some species, e.g., birds and moths, the females are heterogametic (WZ) and the males are homogametic (ZZ). In the nematode *Caenorhabditis*, some grasshoppers, and some fishes, the females are XX and the males are of XO (single X) constitution. In *Drosophila*, the proportion of the X chromosome(s) and autosomes (A sets) determines sex. Normally, if the ratio is 1 X:2 sets of autosomes, the individual is male; if there are 2 Xs:2 sets of autosomes, the fly is female. All individuals with a sex ratio above 1 are also females and those with a ratio between 0.5 and 1 are intersexes. XO human and mouse individuals are females, however, and irrespective of the number of X chromosomes, as long as there is at least 1 Y chromosome, they appear male. In hermaphroditic plants the development of the gynoecia and androecia are determined by one or more gene loci. Actually, in *Drosophila* three major and some minor genes are known to control sex. *Sexlethal* (*Sxl*, 1-19.2) can mutate to recessive *loss-of-function* alleles that are deleterious to females but inconsequential to males. The dominant *gain-of-function* mutations do not affect appreciably the females but are deleterious to males. The *Sxl* locus may produce ten different transcripts. Three transcripts (4.0, 3.1 and 1.7 kb) are expressed at the blastoderm stage. Adult females have four transcripts (4.2, 3.3, 3.3, and 1.9 kb); the latter two are missing or reduced if the germline is defective. Adult males display three transcripts (4.4, 3.6 and 2.0 kb). The *Sxl* transcripts are alternatively spliced and functional in the

female and are non-functional in the male. The *Sxl* gene product is apparently required for the maintenance of sexual determination and the processing of the downstream *tra* (*transformer*, 3-45) gene product. The *Sxl* protein (354 amino acids) controls alternative splicing of the *tra* pre-messenger RNA by binding to a polypyrimidine tract (UGUUUUUUU) of a non-sex-specific 3' splice site of one *tra* intron. This binding then prevents the binding of the U2AF general splicing factor binding to the site, and U2AF is forced then to a female-specific 3' splice site. The *Sxl* protein binds also to its own pre-mRNA and promotes its female-specific splicing. The *Sxl* locus is regulated by other known genes: *da* (*daughterless*, 2-41.5) is a positive activator of *Sxl*, and it is suppressed by the gain-of-function mutations of the latter gene. The expression of *da*⁺ is necessary for the proper development of the gonads of the female in order to form viable eggs. In both sexes, the product of *da*⁺ is required also for the development of the peripheral and central nervous systems and the formation of the cells that determine the adult cuticle. Thus, the *da*⁺ gene has both maternal and embryonic influence. Females heterozygous for the *da*¹ mutations produce sterile or intersex males and masculinize the exceptional daughters, which are homozygous for *male* (*maleless*, 2-55.2); *male* is lethal to single X males but has no effect on XX females. The *DA* gene product is a helix-loop-helix protein with extensive homology to the human κE2 enhancer (human chromosome 19p13.3-p13.2) of the κ-chain family of immunoglobulins. Chromosomally, female (XX) flies homozygous for the third-chromosome recessive *tra* mutations become sterile males. XXY *tra/tra* individuals are also sterile males but XY *tra/tra* males are normal males. A 0.9 kb transcript of the locus is female-specific and is required in the female, and another 1.1 kb RNA is present in both sexes but no functions are known and is probably not essential. The splicing of the *tra* transcripts is controlled by *Sxl* gene products. When the 0.9 transcript is expressed in a XY fly, the body resembles that of a female. Another *tra* locus (*transformer 2*, 2-70) regulates spermiogenesis and mating in normal males. Null mutations of *tra2*, when homozygous, transform XX females into sterile males. Actually, the *tra2* gene products seem to mediate the splicing of the *dsx* (*double sex*, 3-48.1) transcripts. Dominant mutations at the *dsx* locus when heterozygous with the wild type allele change XX individuals into sterile males but they have no effect on XY males. Null alleles of *dsx*, when homozygous, transform XX flies into intersexes. The recessive allele *dsx11* transforms XY flies into intersexes, and the null alleles change both XX and XY flies into intersexes. Germline sexual differentiation is not affected by the normal allele of this gene but it is controlled by the X: autosome

ratio. A 3.5 kb female-specific transcript is present in the larvae and adults. In the larvae, 3.8 and a 2.8 kb male-specific transcripts are detectable and by adult stage, in addition, a 0.7 kb RNA also appears. The *ix* (*intersex*, 2-60.5) mutations when homozygous also change the XX flies into intersexes. Homozygous *ix* XY males appear normal morphologically but their courtship and mating behavior is altered. Thus, sex determination in *Drosophila* appears to follow the cascade and *fru* regulates mating behavior and sexual orientation through the *tra* and *tra2* genes:

In summary: the X:autosome ratio is the trigger mechanism for the alternate sex developmental pathways. In the males, the *Sxl* and *tra* genes are expressed but their transcript is not spliced to functional forms (see Fig. S39). The critical male sex-determining function is attributed to locus *dsx*, which in the wild type produces a protein blocking the genes required for female development. In the females, with a chromosomal constitution of 2X:2A sets, a functional *Sxl* product is manufactured that mediates the female-specific splicing of its own transcripts. The *Sxl* protein mediates then the splicing of the *tra* transcripts, leading to the synthesis of a Tra protein, which along with the Tra2 protein directs the female-specific splicing of the *dsx* transcript. The synthesized DSX protein blocks then all the genes with functions that would be conducive to male development. Sex determination in *Caenorhabditis* is different from that in *Drosophila*, probably because the XX individuals are hermaphrodites and the nondisjunctive gametes lead to the development of the rare XO males. The level of expression of the known sex-determination genes is shown in Figure S40.

Figure S39. Major sex genes in *Drosophila*

Early in the pathway, *fox* (female X) acts as a numerator of the X-chromosomes, and 5 X-linked *dpy* (*dumpy*) alleles regulate dosage compensation. The hermaphroditic XX females of *Caenorhabditis* originally may produce sperm, oocyte production is then switched on. The *fem-3* gene turns on sperm production in the XX animals. The 3'-untranslated region of the mRNA of the *fem-3* gene mediates the switch after the cytoplasmic binding factor FBF protein binds to this region.

Six *mog* genes are important regulators of female ⇌ male switching. In XX *Caenorhabditis*, the sex determination complex protein (SDC-2) blocks the expression of the male-determining gene *her-1* and in that state hermaphrodites are formed. The SDC-2

Figure S40. Sex chromosome: autosome ratio. (Diagram modified after Kuwabara, PE & Kimble, J 1992. *Trends Genet* 8:164.)

recruits to the X chromosome SDC-3, DUMPY (dpy), MIX-1 (mitosis and X), and other proteins, resulting in the reduced expression of the X chromosomal genes; thus, dosage compensation is realized. In the XO males, *her-1* is transcribed and the SOC complex does not attach to the single X chromosome and all its genes are expressed normally. Sex determination in mammals is much more complex and the pathway is not entirely clear. For a number of years, the H-Y antigen was thought to have a major role but this turned out to be an incorrect notion. A major critical difference was found in an 11 amino acid segment of SMCX (structural maintenance chromosome X) and SMCY proteins encoded within the X and Y homology region. The genes DMRT1 and 2 in the short arm of human chromosome 9 have homologs in other mammals. Also, the Z chromosomes in chicken, alligators, *Drosophila*, and *Caenorhabditis* display higher expression in the male gonads than in the female gonads and appear to be basic regulators of sexual dimorphism. Sex chromosomal anomalies in humans generally also lead to mental retardation. In several reptiles, sex is determined by the temperature the eggs are exposed to during incubation in the sand they are laid in. Thus climate change and vegetation change can affect population structure in these animals (Kamel SJ, Mrosovsky N 2006 *Ecol Appl* 16:923). The actual manifestation of sex may be deeply affected by endocrine hormones directly or indirectly through environmental pollutants. In *Plasmodium* (causing malaria), induction of blood formation favors an increased production of the male parasite. In both plants and some hermaphroditic animals, stress conditions promotes maleness (Hughes RN et al 2003 *Proc Natl Acad Sci USA* 100:10326). ▶mating type determination in yeast, ▶freemartins, ▶hormones in sex determination, ▶fru, ▶gynandromorphs, ▶chimera, ▶intersex, ▶fat body, ▶hermaphrodite, ▶testicular feminization, ▶sex hormones, ▶pheromones, ▶accessory sexual characters, ▶sex phenotypic, ▶mental retardation, ▶chromosomal sex determination, ▶X-chromosome

Sex Determination in Plants: In dioecious plants, sex determination is very similar to that in animals (▶sex determination). In monoecious and hermaphroditic plants, sex is controlled without the presence of special chromosomes and a number of genes (nuclear, mitochondrial, and plastidic) involved in morphogenesis, phytohormone synthesis, and environmental responses determine the differentiation of the flowers and the oogenesis (female) and microsporogenesis (male), and therefore, sexuality. Genes are known that are similar to those of sex reversal in animals and feminize or masculinize, respectively, the monoecious or hermaphroditic flowers (e.g., *tassel seed*, *silkless* [in maize], *superman*, *gametophyte female* [in *Arabidopsis*], etc.). *Tasselseed 2* encodes a short-chain alcohol dehydrogenase that is involved in stage-specific floral organ abortion. Gibberellic acids, brassinosteroids, ethylene, chromosome-breaking agents, and mutagens may also influence the expression of sexual development as well as temperature regimes and other environmental factors. ▶gametophyte, ▶gametophyte factors, ▶vernalization,

►photoperiodism, ►self-incompatibility, ►flower differentiation, ►phytohormones; Juarez C, Banks JA 1998 *Curr Opin Plant Biol* 1:68.

Sex Differences: Sex differences vary among phylogenetic groups in both morphology and function. In humans, the chromosomal constitution (XX, XY) is different. The more than single X chromosome generally undergoes lyonization. The ribosomal protein RPS4Y encoded by the Y chromosome is different from the X chromosome RPS4X. The relative level of hormones depends on sex; the ovaries produce more estrogen and progesterone (correlated with incidence of breast cancer). Reduction of the natural supply of estrogen may involve reduced memory and increase autoimmune disorders in females. Other, phenotypic differences are obvious. A survey of the expression of 13,977 mouse genes in males and females indicated differences besides the reproductive tissues; differences were also found in the kidney and liver genes involved in drug and steroid metabolism and osmotic regulation (Rinn JL et al 2004 *Dev Cell* 6:791). Sex hormones quantitatively affect the expression of many genes involved in different metabolic functions and disease (Weiss LA et al 2006 *Nature Genet* 28:218). ►sex, ►sex determination, ►lyonization, ►estrogen, ►androgen, ►autoimmune diseases, ►gender; human sex differences between men and women: Federman DD 2006 *N Engl J Med* 354:1507.

Sex Differentiation: ►sex, ►sex determination

Sex, Evolutionary Significance: It has generally been assumed that sex facilitates the purging of linked deleterious parental genes by recombination. But Keightley, P.D. and Eyre-Walker, A. (*Science* 290:331) arrived to the conclusion that sex is not maintained by its ability to purge deleterious mutations. Sex may be disadvantageous for evolution. Experimental evidence in yeast supports the advantage of sex in selective environment (Goddard MR et al 2005 *Nature [Lond]* 434:636). Sex selects for robustness and evolutionary advantage (Azevedo RBR et al 2006 *Nature [Lond]* 440:87). Acquisition of sex led to the evolution of diploidy, which is protective against the consequences of deleterious recessive mutations. ►sex, ►Kondrashov's deterministic model of evolution of sex; Rice WR, Chippindale AK 2001 *Science* 294:555; Kondrashov FA, Kondrashov AS 2001 *Proc Natl Acad Sci USA* 98:12089; Bachtrog D 2003 *Nature Genet* 34:215.

Sex Factor: A transmissible plasmid in bacteria that carries the fertility factor(s) F. ►F⁺, ►Hfr, ►F plasmid

Sex Hormones: Sex hormones have either estrogenic (female) or androgenic (male) influence. These are

steroids of the ovaries and placenta (estradiol, progesterone), the testes (testosterone), or of the adrenal cortex (cortisol and aldosterone). Gene expression patterns of the uterine luminal epithelial cells might be regulated by estradiol-17 β and inhibited by progesterone. Progesterone rapidly downregulated about 20 genes associated with DNA replication. Among the down-regulated group were all six minichromosome maintenance proteins (MCM), suggesting that replication licensing is a key in sex steroid hormone regulation of cell proliferation in the uterus (Pan H et al 2006 *Proc Natl Acad Sci USA* 103:14021). Testosterone is also required in females, although in smaller amounts. Androgens control the reproductive organs but also affect hair growth (beard) and the early death of the hair follicles causing preferential male baldness. Androgens promote bone and increased muscle growth as well. Some of the synthetic "anabolic hormones," without androgenic effects, are used (illegally) by athletes to boost performance. Testosterones are also precursors of estrogens. Estrogens are formed in the female-specific organs and their targets include the mammary glands, bones, and fat tissues. Estrogen synthesis is regulated by the follicle-stimulating hormone (FSH) of the anterior pituitary. The pituitary luteinizing hormone mediates the release of the egg, and progesterone is required for the maintenance of pregnancy. The administration of exogenous estrogens and progestins inhibit ovulation and can be used as contraceptives. Other compounds act by prevention of the fusion of the sperm with the egg or implantation of the egg in the uterus, e.g., the drug RU486. Before the development of the contraceptive pills, in the ancient world herbal medicine had been used, prepared from plants (berries of *Juniperus sabina*, gentiana) (see Fig. S41) that contained estrogens. Sperm production may be stopped by injection of progestin and androgen combinations, while inhibiting epididymal functions can prevent sperm maturation or may interfere with the release of enzymes required for breaking through the protective coat of the egg. Antiprogestins, antiestrogens, or other inhibitors of steroid biosynthesis and non-peptide antigonadotropin-releasing hormone antagonists may serve as female contraceptives. The steroid hormone-controlled sexual behavior is also mediated by neuronal activity. Prolonged use of steroid contraceptives or androgenic or anabolic steroids may increase the risk of liver, ovarian, or uterine carcinomas. There are several diseases or conditions (heart diseases, thromboses, embolism, diabetes, skin irritations, *Chlamydia* infection, etc.) where contraceptive drugs are not or conditionally permissive. In some conditions (ovarian and endometrial cancer, uterine myoma, rheumatoid arthritis, etc.), oral

contraceptives may be beneficial. Ethinylestradiol may occur in human females taking oral contraceptives and if they become pregnant accidentally (3%), the fetus is exposed to this compound. Bisphenol leached out from resin-coated lining of food and beverage containers, dental sealers, and polycarbonate plastic is also an estrogen. Male mouse fetus, when exposed to these substances, develops prostate duct abnormalities (Timms BG et al 2005 Proc Natl Acad Sci USA 102:7014). ▶animal hormones, ▶hormone receptors, ▶RU486, ▶bisphenol, ▶estradiol, ▶progesterone, ▶MCM, ▶hyperlipoproteinemia, ▶epididymis, ▶transsexual, ▶sex, ▶fertilization, ▶fertility, ▶infertility, ▶ART, ▶contraceptives

Figure S41. *Juniper*

Sex Influenced: ▶sex-influenced, ▶sex controlled, ▶imprinting

Sex Linkage: In sex linkage, various genes in the sex chromosomes are inherited with the transmission of that chromosome. Sex linkage in females is generally partial because the two X-chromosomes may recombine. The recombination between the X and Y chromosomes is limited only to the homologous (pseudoautosomal) regions. In some insects (*Drosophila*, silkworm), recombination even between autosomes is usually absent in the heterogametic sex. ▶recombination frequency, ▶recombination mechanisms, ▶crossing over, ▶hemophilia, ▶autosexing, ▶genetic equilibrium, ▶pseudoautosomal, ▶criss-cross inheritance; Morgan TH 1910 Science 32:120; Morgan TH 1912 Science 36:719.

Sex Mosaic: The sex-chromosomal constitution in the body cells may vary in a sectorial manner. Typical examples are the gynandromorphs in insects, which have body sectors with both XX and XO constitution. Sex mosaicism also occurs in humans with variable numbers of X and Y chromosomal sectors. The mosaicism is generally the result of non-disjunction or chromosome elimination. ▶sex determination, ▶non-disjunction, ▶gynandromorphs

Sex, Phenotypic: The phenotypic manifestations of the influence of the steroid sex hormones, such as facial hair, increased phallic size in males, horns or

special plumage in animals, and enlarged breast and mammary glands development in females. ▶sex determination, ▶animal hormones

Sex Pilus: ▶pilus

Sex Plasmid: The bacterial F plasmid. ▶F element, ▶F plasmid

Sex Proportion: The proportion of male individuals in a population. ▶sex ratio

Sex Ratio: The *primary sex ratio* is the number of male conceptuses relative to that of females. The *secondary sex ratio* indicates the number of females:males at birth. The *tertiary sex ratio* states the ratio among adult males and females. Since XX females are mated with XY males, the proportion—just as in a testcross—should be 1:1. In the United States, at birth the proportion is about 105–106 males:100 females. In the West Indies the proportion is about 1:1 or the number of females is slightly more. In China and Korea, the sex ratio in newborns is about 115 males to 100 females. Generally the female:male ratio shifts in favor of females by progressing age. By about 21–22, in the USA, the female:male proportion becomes about 1:1, and because of mortality differential of the sexes, by age 65 there are about 145 females for 100 males. In dioecious plants, the sex ratio may vary a great deal because of modifier genes and physiological factors (hormone supply). Since the 1930s, population geneticists have repeatedly considered the problem whether infanticide alters the sex ratio by selection. Infanticide generally biases the childhood ratio against females. This might have the consequence that the genes of families producing males would be favored, would have greater fitness, and the secondary sex ratio would tend to be biased in favor of males. The problem is more complicated, however, in human societies because systems of mating and the socio-economical conditions have a substantial influence. Statistical data seems to indicate that under stressful living conditions, women preferentially abort male fetuses and this reduces the secondary sex ratio (Catalano R, Bruckner T 2006 Proc Natl Acad Sci USA 103:1639).

In some *Drosophila* stocks, infection by filiform bacteria results in female offspring. The *sex-ratio* genes in the *Drosophila* X chromosome cause an excess of females in the progeny of the males carrying this gene(s). Usually, drive suppressors in the autosomes and in the Y chromosome balance the sex-ratio gene expression. Some gynandromorphs with very small XO sectors may also survive. Triploid intersexes live, as do females sex-transformed by *tra*, *ix*, and *dsx* genes (i.e., phenotypically males, although XX). The sex ratio in the Seychelles warbler's (*Acrocephalus sechellensis*) eggs may vary according

to the availability of food supply; in low-food territories they may have 77% male offspring, whereas with high food supply the proportion of sons may be only 13%. This difference is not due to the different viability of the eggs. In some species of the *Cyrtodiopsis* flies in Malaysia, the sex ratio may be biased either toward the females or toward the males. In the cases of female bias, the males carry a *driver-X* chromosome that by some means eliminates from fertilization most of the Y-bearing sperms resulting in predominantly female (XX) offspring. In the male biased stocks, the Y chromosome carries a suppressor for the driver-X and actually somewhat increases the chances of function for the Y-bearing sperms, resulting in more than 50% male progeny. Irrespective of the actual mechanism of sex determination, natural selection tends to promote the 1:1 proportion of the two sexes because as long as sexual reproduction is maintained, both males and females contribute to the offspring. ▶hermaphroditism, ▶sex determination, ▶sex-reversal, ▶spirochete, ▶infectious heredity, ▶sex proportion, ▶gynandromorph, ▶age of parents and secondary sex ratio, ▶male-stuffing, ▶sex selection, ▶segregation distorter, ▶meiotic drive, ▶dosage compensation, ▶*Wolbachia*; Jaenike J 2001 Annu Rev Ecol Syst 32:25; Hardy ICW (Ed.) 2002 Sex Ratios. Sex Realizer: A substance that determines whether male or female gonads would develop.

Sex Reversal (sex change): Sex reversal involves sex phenotypes that do not match the expectation based on chromosomal sex determination. Gene *fru* splices differently in males and females of *Drosophila*. If the splicing in males is according to the female pattern or in the females in the male pattern, the sexual behavior (courtship) is reversed and males and females court the same sex (Demir E, Dickson BJ 2005 Cell 121:785) because of altered response to pheromones through the olfactory system (Stockinger P et al 2005 Cell 123:795). It has been suggested that a certain number of trinucleotide repeats (glutamine) in the *Sry* gene would be responsible for this reversal but other studies could not confirm the mechanism in mice and it appears that alteration in the function of autosomal regulator genes may be involved. There are apparently sex-determining autosomal (17q24.3-q25.1 and 9p24) factors, which may cause sex reversal in 46XY individuals. Other autosomal and X-chromosomal genes (Xp21.3-p21.2) may also be responsible for sex reversal. In young mice with knockout for the estrogen receptors α and β ($\alpha\beta$ ERKO), the development of the sexual organs is near normal. By adult stage in the ovaries of the females, seminiferous

tubule-like structures develop, Müllerian inhibitory substance is formed at an elevated level, and Sox9 protein has been found indicating that the estrogen receptors (ER) are essential for the maintenance of the normal ovarian phenotype. The $\alpha\beta$ ERKO males displayed some spermatogenesis but also became sterile. In both males and females, the α ER is most essential for normal sexuality. Male-to-female sex change in mice seems to be controlled by fibroblast growth factor 9. Defect in the nuclear localization of SRY may lead to gonadal dysgenesis in humans. Mutation in the R-spondins family of human growth gene results in a recessive syndrome in the absence of the testis-determining SRY gene, characterized by complete XX sex reversal, palmo-plantar hyperkeratosis, and predisposition to squamous cell carcinoma of the skin (Parma P et al 2006 Nature Genet 38:1304). R-spondins are ligands interacting with Fzd/LRP (Frizzled/Lipoprotein related) receptor complexes and inducing beta-catenin-T cell factor (TCF) gene activation in different species both in vitro and in vivo. ▶SRY, ▶*tra*, ▶sex determination, ▶campomelic dysplasia, ▶hermaphroditism, ▶pseudohermaphroditism, ▶homosexual, ▶testicular feminization, ▶SF-1, ▶estradiol, ▶SOX, ▶knockout, ▶gonads, ▶Müllerian ducts, ▶*Wingless*, ▶adrenal hypoplasia congenital, ▶FGF, ▶gonadal dysgenesis, ▶thrombospondin, ▶R-spondin; Ostrer H 2000 Semin Reprod Med 18:41; Colvin JS et al 2001 Cell 104:875; Li B et al 2001 J Biol Chem 276:46480; sex reversal—sex determination review: Camerino G et al 2006 Curr Opin Genet Dev 16:289.

Sex Selection: Sex selection is possible with the use of cell sorters, followed by artificial insemination. Sex determination is feasible also by FISH or PCR before implantation. The mammalian X-chromosome-bearing sperm has 2.8 to 7.5% more DNA than the Y bearing sperms. The sperm can be classified and selected with high efficiency and at high speed (18 million sperm/h). It is used in animal husbandry for artificial insemination and its effectiveness is 85–95%. It would be technically feasible also in human artificial insemination and ethically less objectionable than the preimplantation selection of fertilized eggs. Sex selection involves not just ethical problems but it may also affect the sex ratio in the population. It has been estimated that in China the males exceed females by ~30% because of selective abortion. This also leads to a social imbalance because many males may not find mates. ▶cell sorter, ▶segregation distorter, ▶sex determination, ▶ART, ▶PGD, ▶social selection, ▶sex ratio; Garner DL 2001 J Androl 22:519; Johnson LA 2000 Anim Repr Sci 60–61:93; van Munster EB 2002 Cytometry 47:192; Welch GR, Johnson LA 1999

Sex Vesicle (XY body): The meiotically paired mammalian sex chromosomes in the males may be heterochromatinized and form the sex vesicle, a special, visible structure. ▶sex chromosomes, ▶heterochromatin

Sexduction (F-duction): F-duction takes place when genes carried in the bacterial sex element (F' plasmid) recombine with the bacterial chromosome. ▶F' plasmid, ▶Hfr, ▶conjugational mapping, ▶transduction; Jacob F et al 1960 Symp Soc Gen Microbiol 10:67; Lederberg EM 1960 Symp Soc Gen Microbiol 10:115; see Fig. S42.

Figure S42. Sexduction

Sex-Influenced: A sex-influenced trait is that, which has a different degree of expression in male and female individuals, e.g., facial hairs in humans, color of plumage in birds, horns in deer, etc. ▶hare lip, ▶pyloric stenosis, ▶Hirschsprung's disease, ▶lupus erythematosus, ▶imprinting

Sexing: Distinguishing female from male forms of animals. This procedure may be difficult in young birds because the genitalia may appear ambiguous to those who do not have special expertise (▶autosexing). The avian males are homogametic (WW) and

the females are heterogametic (ZW). Sexing may be carried out also by the karyotyping of the tissues or Barr body detection. Molecular sexing may make possible the identification of sex on the basis of DNA markers from any tissue sample. On the Z chromosomes, there are both the CHD-W and the CHD-NW genes whereas the W chromosome carry only the CHD-NW gene. The base sequences of these two genes are very similar, except in a short tract. When a restriction enzyme cuts within this segment of CHD-W, the females display three electrophoretic bands but the males show only one.

A non-invasive sexing may be carried out on preimplantation embryos by inserting a green fluorescent transgene into the X chromosome. The male offspring of green fluorescent mammalian males will not display fluorescence. Such transgenic animals are apparently normal. ▶sex determination, ▶autosexing, ▶genetic sexing lines, ▶aquorin

Sex-Limited: The expression of a sex-limited trait is limited to one sex (e.g., lactation in females, Wildervanck syndrome).

Sex-Linked Lethal Mutations: Sex-linked lethal mutations in *Drosophila* served as the first laboratory test to quantitate mutation frequency and assess the mutagenic properties of physical and chemical agents. The old procedure was called the *CIB* test (C stands for crossover exclusion brought about by the presence of usually three inversions, *I* is a recessive lethal gene, and *B* indicates the dominant *Bar* eye mutation.) The principle of the techniques is diagrammed at *CIB*. If any new recessive mutation takes place in the X chromosome of a male, then in the F_2 only females may occur because the original recessive *I* gene present in the inverted *B I* chromosome will kill the hemizygous male progeny. If a new lethal mutation occurs, it may kill (or much reduce the proportion) of the other type of males in F_2 . Nowadays instead of the *CIB* method, generally the improved *Basc* chromosome is used (*B*: *Bar*, *a*: *apricot* eye color [*w* locus] and *sc*: *scute* inversions). Any recessive lethal mutation in the X-chromosome of the grandfather's sperm results in the death of one of the grandsons. Rarely, some exceptional females are also found, which are the result of unequal sister chromatid exchange in the inversion heterozygote mother. Somewhat similar manner autosomal recessive lethals can also be detected in *Cy L/Pm* stocks. ▶bioassays in genetic toxicology, ▶autosomal recessive lethal assay, ▶*Basc*, ▶*Cib* and diagrams there.

Sex-Reversal: As per sex-reversal, the sex by karyotype does not always correspond to sex phenotype. By translocation, a testis-determining factor (TDF/SRY) may move from the Y chromosome to an X

chromosome, and thus 46 autosome XX males can occur. Also, it has been claimed that an autosomal testis-determining factor (TDFA) may be responsible for some of the intersexes and sex reversion cases. Terminal deletions of human chromosome 9p and 10q may result in sex-reversal. ▶intersexes, ▶H-Y antigen, ▶SRY, ▶hermaphroditism, ▶pseudohermaphroditism, ▶testicular feminization, ▶Swyer syndrome, ▶gonadal dysgenesis, ▶sex determination, ▶campomelic dysplasia, ▶DSS, ▶Polycomb; Osterer H 2001 J Appl Physiol 91:2384; Li B et al 2001 J Biol Chem 276:46480.

Sex-Selection: As per sex selection, X-bearing sperms can be separated with reasonably good efficiency from their Y-bearing counterparts with the aid of cell sorters and fluorescent labeling, on the basis of the increased DNA content of X-bearing sperms. This process then can be used in artificial insemination in animal breeding. For humans, sex-selection is primarily an ethical issue. ▶sex determination, ▶sex ratio; Johnson LA 2000 Anim Reprod Sci 60–61:93; Welch GR, Johnson LA 1999 Theriogenology 52:1343.

Sexual Conflict: In sexual conflict, the enhanced reproductive success of one of the sexes reduces the fitness of the other, e.g., polyspermic fertilization. The seminal fluid of the male (mating success) may be toxic to the female and reduces the lifespan of the female *Drosophila*. ▶polyspermic fertilization, ▶sexual selection; Rice WR 1996 Nature [Lond] 381:232.

Sexual Differentiation: The realization of sex-determination (gonads) and development of secondary sexual characters, such as facial hair in men, differential plumage in birds, etc. In *Drosophila*, for the male gonad differentiation and normal sexual development the expression of the JAK-STAT signal transduction pathway is required in the somatic cells. For the female gonads, JAK-STAT activity is not necessary (Waversik M et al 2005 Nature [Lond] 436:563). ▶gonad, ▶signal transduction; Wedell A et al 2000 Lakartidningen 97:449; Burtis KC 2002 Science 297:1135; Reiner WG, Gearhart JP 2004 N Engl J Med 350:333; gonadal and functional abnormalities: MacLaughlin DT, Donahoe PK 2004 N Engl J Med 350:367.

Sexual Dimorphism: As per sexual dimorphism, the two sexes are morphologically distinguishable. In some species, the differences appear only during later development or by the time of sexual maturity. The differences are not limited to morphology but also various functions may differ. In the males, the language centers are localized in the left inferior frontal gyrus region of the brain, while in females both left and right regions are active. Conversion of

testosterone to estradiol by neuronal tissue critically affects sexual differentiation of the brain. GABA and calcium-binding proteins are more abundant in the newborn male rats relative to females. This difference appears to be a switch from excitatory action in the males to inhibitory signals in the females. GABA would increase phosphorylation of CREB at Ser¹³³ by protein kinase A, calcium-activated calmodulin kinase, ribosomal S6 kinase 2, and mitogen-activated kinase-activated protein kinase 2 in the brain of the male. This appears to be the initial signal to sexual dimorphism. Wnt-7a regulates sexual dimorphism of mouse by controlling the Müllerian inhibitory substance. ▶human intelligence, ▶autosexing, ▶sex determination, ▶GABA, ▶protein kinases, ▶calmodulin, ▶CREB, ▶wingless, ▶Müllerian duct, ▶gonads; Auger AP et al 2001 Proc Natl Acad Sci USA 98:8059; Vincent S et al 2001 Cell 106:399.

Sexual Dysfunction: ▶erectile dysfunction, ▶priapism, ▶Peyronie disease, ▶vaginismus

Sexual Incompatibility: ▶incompatibility

Sexual Isolation: Sexual isolation has significance in speciation by, either preventing mating (isolation by life cycle, behavior or generative organs) between certain genotypes, or because of gametic or zygotic death or inviability of their offspring. A very common form of sexual isolation is the inviability of the recombinants of chromosomal inversions. The cross-breeding at the incipient speciation may be prevented by pheromone gene(s) responsible for the production of differences in the female cuticular hydrocarbons in *Drosophila*. ▶incompatibility, ▶inversions, ▶speciation, ▶fertility, ▶pheromone; Majestic J 2001 FEMS Lett 199:161; Fang S et al 2002 Genetics 162:781.

Sexual Maturity: The developmental stage by which reproductive ability is attained. It varies in different organisms (m: month, y: year): cat 6–12 m, cattle 6–12 m, chimpanzee 8–10 y, dog 9 m, elephant 8–16 y, horse 12 m, humans 12–14 y, mouse 1 m, rabbit 3–4 m, rat 2 m, sheep 6 m, swine 5–6 m. Sexual maturity is affected also by environmental factors. ▶gestation

Sexual Orientation: ▶homosexual

Sexual Reproduction: The production of offspring by mating of gametes of opposites sex or mating type. Sexual reproduction seems to have evolved because it facilitates segregation of alleles and recombination among linked loci, resulting in increased fitness in different environments. The fungus *Cryptococcus neoformans* has both *a* and *α* mating types, yet the majority of the populations are represented by *a* mating type only. In these cases, the same mating type

spores may fuse, undergo meiosis and produce four α spores (see Fig. S43) (Lin X et al 2005 Nature [Lond] 434:1017). ►meiosis, ►gametogenesis; <http://www.germonline.org/index.html>.

Figure S43. Sexual reproduction between same mating type

Sexual Selection: Competition among mates of the same sex or gametes or preferential choice of one or another type of mates. The general purpose of sexual selection is to find mates with selective advantage for the offspring. Some body ornaments of the male birds may increase their sexual attractiveness to females and provides a selective advantage in mating and producing offspring. Some body features may be associated with high viability genes and are evolutionarily advantageous to the bearer as a means of higher chances of leaving offspring by mate choice. A quantitative analysis of the correlation between body-ornament (white head-spot) of the male flycatcher bird (*Ficedula albicollis*) indicated that the ornament did not evolve by hitchhiking with genes of otherwise higher fitness but by its own merit (see Fig. S44) (Qvarnström A et al 2006 Nature [Lond] 411:84). In some instances, the actual value of the selected trait, e.g., the fancy tail of the peacock may not easily be rationalized (see Fig. S45). The gynogen Sailfin Molly fish females reproduce clonally, yet they rely on sperm of heterospecific males to initiate embryogenesis; thus, it appears that the males do not contribute to the progeny. Yet the sexual forms of the females prefer those males, which mate with the gynogens. Consequently, the males exploited by the gynogens still benefit from the unusual sexual selection. Although sexual selection most frequently involves the selection of the males, in the sand lizard (*Lacerta agilis*), the females achieve selection. The

Figure S44. *Ficedula albicollis*

Figure S45. Peacock, Chinese handiwork

females may copulate with several closely or distantly related males but it appears that the share of offspring sired by the remotely or unrelated males is higher in the same clutch. Thus, the females select apparently the sperm of the more distantly related males. Females of feral fowl may eject the sperm acquired through coerced mating by inferior males. Mate preference in male and female rats whose progenitors had been treated with the antiandrogenic fungicide vinclozolin (LD₅₀ 10 mg/kg, rat) has been observed. This effect is sex-specific, and females three generations removed from the exposure discriminate (transgenerational effect) and prefer males who do not have a history of exposure, whereas similarly epigenetically imprinted males do not exhibit such a preference (Crews D et al 2007 Proc Natl Acad Sci USA 104:5942). Polymorphism exists in binding a protein that facilitates the attachment of the sperm to the egg and that may affect male selection by the egg. In some instances, the sexual selection is based on meiotic drive. In *Drosophila* species, mate recognition/preference is influenced by cuticular hydrocarbon composition. In guppy fish, sexual attractiveness of the males is positively

correlated with ornamentation (encoded in the Y chromosome) but negatively correlated with survival. Asexual populations may have higher fitness than the sexual ones because every individual has a chance to reproduce, especially when the deleterious mutation rate is higher in males than in females, as is most commonly the case. ►meiotic drive, ►sexual dimorphism, ►certation, ►megaspore selection, ►assortative mating, ►disassortative mating, ►gynogenesis, ►heterospecific, ►conflict evolutionary, ►sexual conflict, ►transgenerational effect; mate choice: Chenoweth SF, Blows MW 2006 *Nature Rev Genet* 7:681; Swanson WJ et al 2001 *Proc Natl Acad Sci USA* 98:2509; Snook RR 2001 *Curr Biol* 11:R337; Knight J 2002 *Nature [Lond]* 415:254; Pizzari T, Birkhead TR 2002 *Biol Rev* 77:183.

Sexual Swelling: A large, conspicuous reddish structure in between the vulva and the anus of the females of many Old World primates at the time of ovulation. It is a mating attractant for the males and has a value in sexual selection. ►vulva, ►anus, ►sexual selection

Sexuparous: The sexual production of offspring in species where parthenogenetic reproduction co-exists with sexual reproduction. ►parthenogenesis

SF: ►hybrid dysgenesis I-R system. Also ►splicing factor protein. ►introns

SF1 (stimulatory factor): A yeast protein (33 kDa) reducing the binding requirement (at the concentration of 1 SF/20 nucleotides) of protein Sep 1 to DNA during recombination, by two orders of magnitude. It probably has a role in DNA pairing. ►synapsis

SF1 (splicing-transcription factor): SF1 represses transcription. (See Goldstrohm AC et al 2001 *Mol Cell Biol* 21:7617).

SF-1 (Ftz-F1, fushi tarazu factor homolog, nuclear receptor subfamily 5 group A member 1 [NR5A1]): The steroidogenic factor (adrenal 4 binding protein [Ad4bp]) at human chromosome 9q33 (30 kb genomic DNA) regulates cytochrome 450 steroid 21-hydroxylase, aldosterone synthase, anti-Müllerian hormone (MIS), XY sex reversal, and adrenal failure and plays key role in steroid biosynthesis. SF-1 function is modulated by phospholipids through mediating ligand binding (Li Y et al 2005 *Mol Cell* 17:491). ►steroid hormones, ►fushi tarazu, ►Müllerian ducts; Whitworth DJ et al 2001 *Gene* 277:209; crystal structure: Wang W 2005 *Proc Natl Acad Sci USA* 102:7505.

SF2/ASF: ►SR protein, ►SR motif

SFF: A cell cycle regulating yeast protein. ►cell cycle

SFK: A group of tyrosine protein kinases, SFKs, reside on the interior part of the cell membrane and respond to external signals. They are members of the Src family. When phosphorylated by Csk or other kinases, the proteins assume an inactive conformation and their activation requires phosphatases. Cbp attracts Csk to the membrane. The active SFK then phosphorylates other proteins. Rafts localized on the outer surface of the membrane modify SFKs. ►CBP, ►Csk, ►RAFT, ►Src; Vara JA et al 2001 *Mol Biol Cell* 12:2171.

SFM: Serum-free medium.

Sfp1: A protooncogene; probably the same transcription factor as PU.1 and Spi1. ►Spi1, ►PU.1

SGLT (sodium/glucose co-transporter): A defect in SGLT results in Glucose-Galactose Malabsorption (GGM), a potentially fatal neonatal (human chromosome 22) recessive disorder, unless the diet is made sugar-free. (See Xie Z et al 2000 *J Biol Chem* 275:25959).

SGP-1: The syntenic gene predictor in homologous sequences of genomes. ►gene predictor; Wiehe T et al 2001 *Genome Res* 11:1574; <http://soft.ice.mg.de/spg-1>.

SGT1: A proteolysis factor controlled by ubiquitin. ►ubiquitin; Tor M et al 2002 *Plant Cell* 14:993.

SH₂ (src homology domain): An about 100 amino acid long binding site for tyrosine phosphoproteins. These phosphoproteins such as the SRC and ABL cellular oncogenes, phosphotyrosine phosphatases, GTPase activating protein, phospholipase C, and the Grb/Sem 5 adaptor protein have important role in signal transduction. In the human genome, there are about 115 SH₂ domains. ►SH₃, ►SRC, ►WW, ►PTB, ►pleckstrin, ►signal transduction

SH₃ (src homology domain): The binding site for the proline-rich motif (Arg-X-Leu-Pro-Pro-Z-Pro [the latter is Leu for the Src oncoprotein and Z is Arg for phosphoinositide kinase] or it can be X-Pro-Pro-Leu-Pro-X-Arg) in an adaptor or mediator protein in the signal transduction pathway through RAS. By binding, conformational and functional changes take place. The activity of the cellular SRC protein increases during normal and neoplastic mitoses. Protein p68, closely related to the GAP-associated p62, is bound to the SH₃ domain of SRC. The SH₃ binding is specific in vivo, yet of low affinity. The human genome encodes about 250 SH₃ domains (see Fig. S46). ►SH₂, ►SRC, ►RAS, ►signal transduction, ►GAP; SH₃ site detection: <http://cbm.bio.uniroma2.it/SH3-Hunter/>.

Figure S46. Structure of the SH3 domain. From Alm E and Baker D 1999 Proc. Natl. Acad. Sci. USA 96:11305

Shade-Avoidance Syndrome: The shade-avoidance syndrome of plants results in elongated stem, reduced leaf expansion, and accelerated flowering under reduced light. Several phytochrome genes mediate it. ▶[phytochrome](#), ▶[floral evocation](#); Cerdán PD, Chory J 2003 Nature [Lond] 423:881.

Shadow Bands: Same as stutter band.

Shadowing: An electronmicroscopic preparatory procedure by which the surface of the specimen is coated with a vaporized metal, such as platinum. The shadowed objects display a three-dimensional effect in scanning, but in some cases, even in transmission electronmicroscopy. ▶[scanning electronmicroscopy](#)

Shadowing, Phylogenetic: A cross-species base sequence comparison in order to find important functional, structural, and regulatory elements in different evolutionary categories. (See Boffelli D et al 2003 Science 299:1391).

Shah-Waardenburg Syndrome (SOX10/WS4, 22q13; EDN3/ET3 20q13.2-q13.3): The Shah-Waardenburg Syndrome involves the endothelin-3 signaling pathway; it shows the combined symptoms of the Hirschsprung disease and the Waardenburg syndrome. The embryonic neural crest appears to have recessive (EDN3) or dominant (SOX10) defects. ▶[Hirschsprung disease](#), ▶[Waardenburg syndrome](#), ▶[endothelin](#), ▶[RET oncogene](#), ▶[SOX](#); Touraine RL et al 2000 Am J Hum Genet 66:1496.

Shaking (shak): Alleles at several chromosomal locations in *Drosophila* cause shaking of the legs under anesthesia to a variable degree, depending on the locus and allele involved. Some mutants may display

hyperactive behavior in a temperature-dependent manner. Some may be viable, while others are homozygous lethals. The *shakB* mutants may cause a defect in the synapse between the giant fiber neuron, postsynaptic interneuron, the dorsal longitudinal muscle, and the nerves operating the tergotrochanter (back-neck) muscle (see illustrations at ▶[Drosophila](#)). The shaking may be caused by a defect in a protein of a potassium ion channel. ▶[ion channel](#)

Shannon-Weaver Index: ▶[diversity](#)

Shark Cartilage: Sharks, mainly sea-inhabiting cartilaginous fishes, are presumably rarely afflicted by tumors. The prevailing assumption was that their cartilage protects from cancer. Experimental evidence—contrary to some early studies—indicates, however, that shark cartilage products are ineffective against advanced cancer (Loprinzi CL et al 2005 Cancer 104:176).

SHARP (SMRT and histone deacetylase-associated repressor protein): A regulator of PPAR. ▶[PPAR](#), ▶[SMRT](#); Shi Y et al 2002 Proc Natl Acad Sci USA 99:2613.

Shasta Daisy (*Chrysanthemum maximum*): An ornamental plant; $2n \approx 90$ (see Fig. [S47](#)).

Figure S47. Shasta daisy

SHC: An adaptor protein involved in RAS-dependent MAP kinase activation after stimulation by insulin, epidermal (EGF), nerve (NGF), platelet derived growth factor (PDGF), interleukins (IL-2,-3,-5), erythropoietin and granulocyte/macrophage colony-stimulating growth factor (CSF), and lymphocyte antigen receptors. It binds to tyrosine-phosphorylated receptors and when phosphorylated at tyrosine it interacts with the SH2 domain of Grb2, which interacts with SOS in the RAS signal transduction pathway. The phosphotyrosine-binding (PTB) domain can also recognize the tyrosine-phosphorylated protein. The latter is similar to the pleckstrin homology domain and most likely binds the acidic phospholipids of the cell membrane. SHC is also an oncogene, involved in the development of phaeochromocytoma neoplasias. ▶[signal transduction](#), ▶[phaeochromocytoma](#),

►adenomatosis endocrine multiple, ►neoplasia, ►insulin, ►EGF, ►NGF, ►PDGF, ►SOS, ►interleukins, ►CSF, ►pleckstrin domain; Ravichandran KS 2001 *Oncogene* 20:6322.

Shearing: Cutting DNA to fragments by mechanical means, e.g., by rapid stirring or brusque pipetting.

Sheats: Any tube-like structure surrounding another, also the part of a leaf that wraps the stem.

Sheep, Domesticated (*Ovis aries*): $2n = 54$; some wild sheep have higher number of chromosomes. A medium-density linkage map of 1062 unique loci became available by 2001 and has helped in mapping the cattle and goat genomes (Maddox JF et al 2001 *Genome Res* 11:1275; Cockett NE et al 2001 *Physiol Genomics* 7:69; <http://www.wool.com.au/LivePage.aspx?pagel=116#mainBody>; <http://www.angis.org.au/Databases/BIRX/mis/>; <http://www.ncbi.nlm.nih.gov/genome/guide/sheep>).

Sheep Hybrids: Domesticated sheep (*Ovis aries*, $2n = 54$) forms fertile hybrids with muflons but the goat x sheep hybrid embryos rarely develop normally. ►transplantation nuclear; Ruffing NA 1993 *Biol Reprod* 49:1260.

Sheldon-Hall Syndrome (distal arthrogryposis): ►Freeman-Sheldon syndrome

Shelterin: ►telosome

Sherman Paradox: The various recurrence risks among relatives caused by expansion of fragile X sites transmitted by non-symptomatic males. ►mental retardation, ►recurrence risk, ►fragile X, ►trinucleotide repeats; Sherman SL et al 1985 *Hum Genet* 69:289; Fu YH et al 1991 *Cell* 67:1047.

Shift: An internal chromosomal segment, generated by two break points, translocated within the same or into another chromosome, within a gap opened by a single break. It is a rare phenomenon. Shifting of the relative proportion of mitochondrial recombination products commonly occurs in plants. ►transposition, ►reciprocal interchange, ►translocation

Shifting-Balance Theory of Evolution: According to the Shiftin-balance theory of evolution, polymorphism in a population is determined by a dynamic interplay of the forces of pleiotropy, epistasis, genotypic values, fitness, and population structure. Alternative ideas would be the discredited neo-Lamarckian internal drive or the well-documented neutral mutation concepts. ►polymorphism, ►pleiotropy, ►genotype, ►fitness, ►neo-Lamarckism, ►neutral mutation, ►population structure; Wade MJ, Goodnight CJ 1991 *Science* 253:1015.

Shigella: A group of gram-negative enterobacteria causing dysentery (intestinal inflammation and

diarrhea) in humans and higher monkeys. Butyrate treatment effectively mitigates shigellosis by up-regulation of a natural antibiotic (LL-37/cathelicidin) in the intestinal epithelium (Raquib R et al 2006 *Proc Natl Acad Sci USA* 103:9178). ►primates; database: <http://www.mgc.ac.cn/ShiBASE/>.

Shikimic Acid: An intermediate in aromatic amino acid-, flavonoid-, fragrance-, alkaloid- and plant pigment biosynthesis (see Fig. S48).

Figure S48. Shikimic acid

Shine-Dalgarno Sequence: Nucleotide consensus (AGGAGG) in the non-translated 5' region of the prokaryotic mRNA (close to the translation initiation codon), complementary to the binding sites of the ribosomes. The terminus of the 16S ribosomal RNA is generally:

$A^{Me2} A^{Me2} CCUGCGGUUGGAUGACCUCCUUA-3'-OH$. The eukaryotic mRNAs do not have this sequence and the mRNA attaches to the ribosomes by means of ribosomal scanning. In the polycistronic messages, each cistron generally has a Shine-Dalgarno sequence. Mitochondrial and ribosome mRNAs, generally but not always, have this or a modified Shine-Dalgarno. ►anti-Shine-Dalgarno, ►ribosome scanning, ►IF, ►initiation codon, ►polycistronic mRNA; Shultzaberger RK et al 2001 *J Mol Biol* 313:215.

Shingles: The herpes (varicella-zoster) virus responsible for chicken pox may emerge from a latent stage, later in the life of an individual when immunity has waned. It then causes shingles (sore eruptions) in parts of the body innervated by ganglions harboring the earlier latent virus (see Fig. S49). About 20% of adults become affected. Chickenpox is highly contagious but shingles are transmitted only from the open eruptions and not by sneezing or casual contact and the risk of infection is very low. Hand washing is helpful to prevent infection from afflicted individuals. Guanosine analogs (acyclovir) are commonly used for treatment, which interfere with replication by viral DNA or RNA polymerases (see Fig. S50). ►herpes, ►chickenpox, ►Varicella zoster virus, ►ganglion; Dwyer DE, Cunningham AL 2002 *Med J Austral* 177(5):267; vaccine: Vázquez M et al 2005 *N Engl J Med* 352:439.

Figure S49. Shingles

Figure S50. Acyclovir

SHIP: Inositol phosphatase with SH₂ domain. SHIP proteins in tyrosine phosphorylated form signal to hematopoiesis, cytokines, PTEN, etc. ▶SH₂, ▶inositol, ▶cytokines, ▶hematopoiesis, ▶PTEN, ▶ITIM; Rohrschneider LR et al 2000 Genes Dev 14:505.

SHIRPA: A protocol for phenotypic characterization of mutation in mice (Rogers DC et al 1997 Mammalian Genome 8:711).

SHIV: A simian immunodeficiency virus (SIV) engineered to carry an HIV coat protein and thus capable of infection of, and symptoms of AIDS in macaque monkeys. ▶HIV, ▶SIV, ▶acquired immunodeficiency syndrome, ▶primates

SHMOOs: Mating projections in yeast.

S

SHOM (sequencing by hybridization to oligonucleotide microchips): One of the automated (robotic) procedures developed for nucleotide sequence diagnostics. (See Yershov G et al 1996 Proc Natl Acad Sci USA 93:4913; ▶DNA chips, ▶microarray hybridization).

Shoot: The plant part(s) above ground or a branch of a stem.

Shope Papilloma: A viral disease of rabbits causing nodules under the tongue. The double-stranded DNA virus of about 8 kbp has 49 mole percent G + C content. ▶bovine papilloma

Short-Day Plants: Short-day plants require generally less than 12–15 h daily illumination for flowering; at longer light periods they usually remain vegetative. ▶photoperiodism, ▶long-day plants

Short Dispersed Repeats: ▶SDR

Short Patch Repair: An excision repair removing, and then replacing, about 20 nucleotides. ▶DNA repair, ▶excision repair, ▶mismatch repair; Mansour CA et al 2001 Mutat Res 485:331.

Short RNA (sRNA): ▶microRNA, ▶RNAi

SHORT Syndrome: An autosomal recessive phenotype characterized by the initials of the SHORT acronym: short Stature, Hyperextensibility of joints and hernia, Ocular depression, Rieger anomaly (partial absence of teeth, anal stenosis [narrow anus], hypertelorism [increased distance between organs or parts], mental and bone deficiencies, and Teething delay). ▶stature in humans, ▶dwarfism, ▶pseudoautosomal

Shortstop Promoter: The shortstop promoter mediates the transcription of only some of the exons although some repeats within the exons may be expanded.

Shotgun Cloning: In shotgun cloning, the DNA of an entire genome is cloned without aiming at particular sequences. From the cloned array of DNA fragments (library), the sequences of interest may be identified by appropriate genetic probes. ▶cloning, ▶DNA probe, ▶DNA library; Matsumoto S et al 1998 Microbiol Immunol 42:15.

Shotgun Sequencing: In shotgun sequencing, random samples of cloned DNA, e.g., the segments of a cosmid are sequenced at random. *Whole-genome pairwise shotgun* procedure sequences paired ends of cloned DNAs of varying sizes and fragmented them into a larger number of contigs ordered with the aid of high-power computers. If there are still gaps between the contigs those are filled in by “finishing.” The *hierarchical shotgun sequencing* procedure is based on mapped clones generated by BACs. The *Double-barrel shotgun* sequences the DNA from both ends. The short sequences are arranged into longer tracts by computers. The *Full shotgun sequence* indicates that the cloned inserts have been covered about 8–10 times. *Half shotgun coverage* is only 4–5-fold random sequence. ▶DNA sequencing, ▶first-draft sequence, ▶contig, ▶completion, ▶WGS, ▶scaffolds in genome sequencing, ▶human genome, ▶genome projects; Bankier AT 2001 Methods Mol Biol 167:89; whole genome shotgun (WGS) products: <http://www.ncbi.nlm.nih.gov/projects/WGS/WGSprojectlist.cgi>.

Shoufflons: Clustered (generally 6 to 7) recombination/inversion sites and a shoufflon-specific recombinase in bacteria. These elements determine the nature of the bacterial pili, thick rigid or thin pilus. A typical

shoufflon is plasmid R64, a 120.8 kb conjugative plasmid encoding streptomycin and tetracycline resistance and at least 49 genes in the 54 kb transfer region. Various types of shoufflons occur in different bacteria. ▶[site-specific recombination](#), ▶[pilus](#); Komano T 1999 *Annu Rev Genet* 33:171.

SHP-1 (synonymous with SH-PTP1, PTP1C, HCP): Tyrosine phosphatase; it contains the SRC homology domain SH2. Upon activation of T cells, it binds to the kinase ZAP-70 resulting in increased phosphatase activity but in a decrease in ZAP-70 kinase activity. It is a negative regulator of the T cell antigen receptor. It is activated by radiation stress. ▶[T cell](#), ▶[ZAP-70](#), ▶[ITIM](#); Kosugi A et al 2001 *Immunity* 14:669.

Shprintzen-Goldberg Syndrome: ▶[Marfanoid syndromes](#)

SHREC: A multienzyme effector complex, which regulates nucleosome positioning to assemble higher-order chromatin structures critical for heterochromatin functions and gene silencing (Sugiyama T et al 2007 *Cell* 128:491).

Shrew: The smallest insectivorous mammals; *Blarina brevicauda*, 2n = 50; *Cryptotis parva*, 2n = 52; *Neomys fodiens*, 2n = 52; *Notiosorex crawfordi*, 2n = 68; *Sorex caecutiens*, 2n = 42; *Suncus murinus*, 2n = 40; *Tupaia belangeri* tree shrew, 2n = 62 (see Fig. S51).

Figure S51. Tree shrew

Shrinkage: Shrinkage occurs when multiple regression data are applied to new information and the regression decreases. ▶[correlation](#), ▶[multiple regression](#)

shRNA (short heterochromatic RNA): shRNA is instrumental in the formation of heterochromatin and the epigenetic remodeling of chromatin. ▶[heterochromatin](#), ▶[epigenesis](#), ▶[RNAi](#); Jenuwein T 2002 *Science* 297:2215.

shRNA (short hairpin RNA): shRNA can be used for global identification of genes involved in certain functional pathways by blocking their expression

(Moffat J et al 2006 *Cell* 124:1283). By intravenous infusion of 49 Adeno-associated virus vectors carrying different shRNAs, 36 caused dose-dependent liver injuries and 23 caused death in adult mice. Liver-derived microRNA pathway was down-regulated by nuclear karyopherin/exportin-5. (Grimm D et al 2006 *Nature [Lond]* 441:537). Reversible gene inactivation was attained by expression of an insulin receptor (*Insr*)-specific shRNA. Upon induction by doxycycline, mice developed severe hyperglycemia within seven days. The onset and progression of the disease correlates with the concentration of doxycycline, and the phenotype returns to the baseline, shortly after the withdrawal of the inductor doxycycline (Seibler J et al 2007 *Nucleic Acids Res* 35(7):e54). ▶[RNAi](#), ▶[microRNA](#), ▶[karyopherin](#); Paddison PJ 2002 *Genes Dev* 8:948.

sHsp (small heat-shock proteins): Diverse ubiquitous proteins (15–80 kDa) formed in response to heat or other stress. Their transcriptional activation requires three inverted repeats of NNGAAN motif (HSE) where the heat shock transcription factor (HSF) binds. Their regulation may require other factors (e.g., estrogen, ecdysterone, etc.). The homology among the different types resides in the COOH-terminal half (α -crystalline domain). They may form large oligomers. Their role is heat and chemical protection of cells. Plant sHSP chaperones respond to various stresses to resist irreversible protein denaturation. ▶[heat-shock proteins](#), ▶[ibp](#); Haley DA et al 2000 *J Mol Biol* 298:261.

Shuffling: ▶[DNA shuffling](#)

Shufflon: A region in the chromosome with structural rearrangements.

Shugoshin: The shugoshin cohesin keeps sister chromatids together during anaphase I of meiosis. At meiosis I, Rec8, which replaces SCC1/RAD21 in meiosis, mediates the separation of the chromatids in the chromosome arms but keeps cohesion intact around the centromere until meiosis II. In yeast and probably in other eukaryotes as well, shugoshin protects the separation of chromatids from separase cleavage in meiosis I. Shugoshin is associated with serine/threonine protein phosphatase 2A (PP2A) protein in humans. Shugoshin and PP2A protect the separation of chromatids at the centromere. Shugoshin probably dephosphorylates cohesin and protects separation at the centromere (see Fig. S52). ▶[meiosis I](#), ▶[meiosis II](#), ▶[cohesin](#), ▶[separin](#); Kitajima TS et al 2006 *Nature [Lond]* 441:46; Riedel CG et al 2006 *Nature [Lond]* 441:53.

Figure S52. Sister chromatids separated at the centromere

Shunting: In shunting, during scanning the 40S ribosomal subunit jumps from the region of capture of the mRNA at the 5' m7 GpppN cap or at another sequence until it locates the translation initiation codon. Thus, the ribosome bypasses the 5' leader. For efficient translation of the mRNA with an internal ribosomal entry site (IRES), the homeodomain protein Gtx translated from IRES and a 9 to 7 nucleotide long sequence complementary to a site in the 18S eukaryotic ribosomal subunit was necessary (Chappell SA et al 2004 Proc Natl Acad Sci USA 101:9590). The presence of the Gtx translation element and the complementary 8 nucleotide sequence facilitates shunting even across an upstream uAUG codon in the leader and across a hairpin structure in the leader (Chappell SA et al 2006 Proc Natl Acad Sci USA 103:9488). ▶scanning, ▶translational hopping, ▶IRES, ▶leader sequence, ▶Cap

Shuttle Vector: A “promiscuous” plasmid that can carry genes to more than one organism and can propagate the genes in different cells, e.g., in *Agrobacterium*, *E. coli*, and plant cells. ▶vectors, ▶cloning vectors, ▶transformation genetic, ▶promiscuous DNA; Perez-Arellano I et al 2001 Plasmid 46:106.

Shwachman-Diamond Syndrome (Shwachman-Bodian-Diamond syndrome, 7q11): Pancreatic insufficiency, blood and bone abnormalities, and increased hematological cancer risk; probably recessive. The yeast ortholog, Sdo1 is critical for the release and recycling of the nucleolar shuttling factor Tif6 (ribosome biogenesis factor) from pre-60S ribosomes, a key step in 60S maturation and translational activation of ribosomes and its defect predisposes to bone marrow failure and leukemia (Menne TF et al 2007 Nature Genet 39:486).

SI: The unit of absorbed dose (1 Joule/kg) of electromagnetic radiation; it is generally expressed in Gray (Gy) or Sievert (Sv = 1 rem) units. Earlier rad (= 0.01 Gy) was used. ▶r, ▶rem, ▶Gray, ▶Sievert, ▶Curie, ▶Becquerel

Sialic Acid: An acidic sugar such as *N*-acetylneuraminic acid or *N*-glycolylneuraminic acid; it is present in the gangliosides (see Fig. S53). Polysialic acid is involved

in cell and tissue type differentiation, learning, memory, and tumor biology. The synthesis is mediated by polysialyl transferase under the regulation of neural cell adhesion molecules. The recessive sialic acid storage diseases (e.g., Salla disease, 6q14-q15) involve hypotonia and cerebellar ataxia, while mental retardation is caused by a family of anion/cation symporters.

Figure S53. Sialic acid

The enzyme CMP-sialic acid hydroxylase changes *N*-acetylneuraminic acid into *N*-glycolylneuraminic acid. This enzyme is active in all mammals, except humans, where the 6p22.3-p22.2 locus suffered a 92-base deletion in the 5' region after the separation of humans from the primate lineage of evolution. Also, the human lineage—in contrast to that of chimpanzee—has only pseudogenes for the receptor (Siglec-L1) of *N*-glycolneuraminic acid. ▶gangliosides, ▶gangliosidosis, ▶CAM, ▶neuraminidase deficiency, ▶fusogenic liposome, ▶lysosomal storage disease, ▶symport, ▶sphingolipids, ▶cytidylic acid, ▶sialuria; Chou H-H et al 1998 Proc Natl Acad Sci USA 95:11751; Angata T et al 2002 J Biol Chem 277:24466; Aula N et al 2000 Am J Hum Genet 2000 67:832.

Sialidase Deficiency: ▶neuraminidase deficiency

Sialidosis: ▶neuraminidase deficiency

Sialolipidosis: ▶mucopolidosis IV

Sialuria (9p12-p11): Sialuria is caused by a semidominant/recessive gene defective in the feedback-sensitivity of uridine diphosphate *N*-acetylglucosamine 2-epimerase enzyme by cytidine monophosphate-neuroaminic acid. The afflicted have defects in bone (dysostosis) and psychomotor [movement and psychic activity] development and infantile death may occur. Salla disease (6q14-q15) is a sialic acid storage disease with mental and psychomotor retardation. ▶neuroaminidase deficiency

Siamese Cat: A Siamese cat displays darker fur color at its extremities because during slow blood circulation, more pigment develops at specific locations of the body. This is due to the presence of a temperature-sensitive gene, similar to Himalayan rabbits and other animals. The pattern distribution is due to a transition mutation from G→A in the 2nd exon of a tyrosinase gene, resulting in replacement of glycine by arginine (Lyons LA et al 2005 *Anim Genet* 36(2):119). The mutant allele produces pigment at the lower temperature of the extremities; it is thus a modification of albinism when pigment formation is absent in the entire body. Normal function of tyrosinase is required for the production of melanin, a pigment of fur color. ▶pigmentation of animals, ▶Himalayan rabbit, ▶temperature-sensitive mutation, see Fig. S54.

Figure S54. Siamese cat

Sib: Same as sibling. ▶full sib, ▶half sib

Sib Pair Method: ▶affected-sib-pair method

Sib TDT (s-TDT): A transmission disequilibrium test to detect genetic linkage/association on the basis of analysis of close genetic markers and disease among sibs. ▶SDT; Spielman RS, Ewens WJ 1998 *Am J Hum Genet* 62:450.

Sibling: Natural children of the same parents. ▶ λ_s , ▶risk, ▶genetic risk, ▶genotypic risk ratio

Sibling Species: Sibling species are morphologically very similar and frequently share habitat but they are reproductively isolated. ▶species, ▶speciation, ▶fertility

Sibpal: A linkage analysis computer program for sib-pairs. ▶sibling; Fann CS et al 1999 *Genet Epidemiol* 17(Suppl. 1):S151.

Sibship: Natural brothers and sisters. ▶kindred, ▶sibpal

SIC1: Cell cycle S-phase cyclin-dependent kinase (CDK, Cdc28-C1b) inhibitor. ▶CDC34, ▶CDC6,

▶cell cycle [START], ▶mitotic exit, ▶APC; Verma R et al 2001 *Mol Cell* 8:439.

Sickle-Cell Anemia: A human hereditary disease caused by homozygosity of a recessive mutation(s) or deletions in the hemoglobin β chain gene. Heterozygosity causes the sickle cell trait. Under low oxygen supply, the red blood cells lose their plump appearance and partially collapse into sickle or odd shapes because of the aggregation of the abnormal hemoglobin molecules (see Fig. S55).

The disease is not absolutely fatal but crises may occur when the blood vessels are clogged. Complications may arise due to poor blood circulation. In the classical form of the sickle cell disease, in the hemoglobin S a valine residue replaced a glutamine residue of the normal beta chain (hemoglobin A). In the hemoglobin C at the same position, a lysine replacement occurs, and this condition causes less severe clinical symptoms. Other forms, hemoglobin D and E are less common. This disease provided the first molecular evidence that mutation leads to amino acid replacement. Sickle cell anemia affects more than 2 million persons worldwide. About 10% the population of African descent in the USA are carriers (heterozygous) for this mutation and about 1/400 is afflicted with homozygosity at birth. In populations of European (except southern Europeans) descent, the frequency of this mutant gene is about 1/20 of that in Mediterraneans and Africans. The high frequency of the genetic condition in areas of the world with high infestation by malaria is correlated. The individuals without sickle cell anemia gene have about 2–3 times higher chance to be infected by *Plasmodium falciparum*. The mutation is selectively advantageous by protecting heterozygotes against malaria. The globin gene cluster has been located to human chromosome 11p15. The order is 5'— γ G— γ A— δ — β —3'. Correction of the defective allele is possible by transduction of the defective cells with retroviral or adenoviral vectors that can deliver the normal gene to the hematopoietic stem cells. However, these viral vectors may have deleterious consequences for the body. There is a problem of the low expression of the transgene. In a mouse model, embryonic stem cells containing the normal β^A allele, when introduced into β^S embryonic mouse blastocysts produced both types of globins indicating a promise that this approach may help in curing human β -thalassemia (Chang JC et al 2006 *Proc Natl Acad Sci USA* 103:1046).

Another method is to introduce into the lymphoblastoid cells chimeric DNA-RNA oligonucleotides with a correction for the β^S allele mutation, brought about through gene conversion in the target cells. This procedure may eventually be clinically applicable.

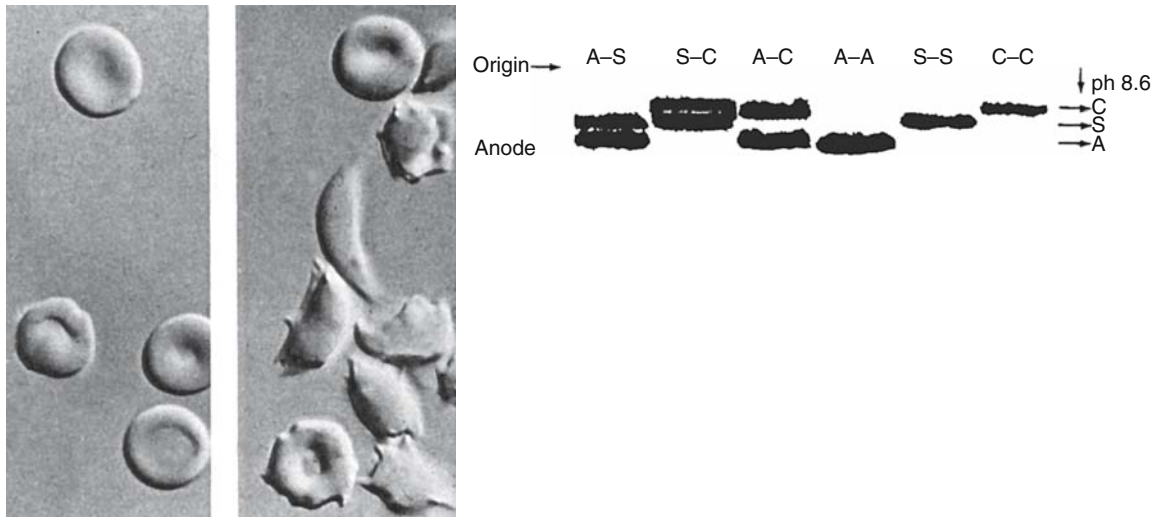

Figure S55. Human red blood cells from a sickle cell anemia patient. Left: In the presence of normal oxygen supply, Right: At low oxygen supply. Normal red blood cells look like biconcave discs very similar to that at left here. The sickling cells are unable to hold oxygen and that condition is responsible for the disease. (Photographs are the courtesy of Cerami A, Manning JM 1971 Proc Natl Acad Sci USA 68:1180). At far right: Carriers or sufferers can be unambiguously identified by electrophoretic separation of the blood proteohomozygotes for the normal blood protein (A-A), sickle cell anemia (S-S), hemoglobin C (C-C). In the heterozygotes (A-S, S-C and A-C)—because of codominance—both types of parental proteins are detected. (From Edington GM, Lehman H 1954 Trans R Soc Trop Med Hyg 48:332)

Another possible therapeutic approach involves correction of the defective β -globin mRNA by the similar (fetal) normal (anti-sickling) protein transcript using a transsplicing ribozyme and the generation of a normally functional transcript. When the hemoglobin α and β genes were knocked out of mouse and mated with animals transgenic for the human sickle cell gene, an animal model was generated for experimentation with this human disease. Attempts are being made to activate the silent fetal hemoglobin genes—by urea compounds—at later developmental stages in order to compensate for the defective adult hemoglobin. ▶malaria, ▶hemoglobin, ▶thalassemia, ▶sickle cell trait, ▶genetic screening, ▶viral vectors, ▶gene therapy, ▶gene conversion, ▶ribozymes, ▶transsplicing, ▶introns, ▶SAD mouse; Pawliuk R et al 2001 Science 294:2368; Vichinsky E 2002 Lancet 360:629.

Sickle Cell Trait: The sickle cell trait is due to heterozygosity of the recessive mutation in the gene controlling the β -chain of hemoglobin. Normally, these heterozygotes do not suffer from this condition but under low oxygen supply, e.g., at high elevations, adverse consequences may arise. ▶sickle cell anemia, ▶hemoglobin

Side-Arm Bridge: An attachment of chromatids resembling chiasma but actually only an anomaly in mitosis or meiosis, usually arising when chemicals or radiation

disturb division (see Fig. S56). ▶bridge, photo is the courtesy of Dr. BR Brinkley & WN Hittelman.

Figure S56. Side-arm bridge

Siderocyte Anemia (sideroblastic anemia): An anemia with erythrocytes containing non-hemoglobin iron; it may be controlled by either autosomal recessive or dominant or X- linked genes and based on defects in erythroid β -aminolevulinatase synthase. ▶anemia

Siderophore: Iron transporter. Transformation into rice plants highly efficient siderophore system genes (for nicotinamine aminotransferase) from barley facilitates iron uptake on alkaline soils and substantially improves growth (Takahashi M et al 2001 Nature Biotechnol 19:466). Mammals sequester excess iron into bacterial siderophores through the mediation of the host protein lipocalin 2. When the Toll receptor

senses infection and the system fights bacteria. This constitutes a novel means of innate immunity (Flo TH et al 2004 Nature [Lond] 432:917). ►immunity innate, ►Toll

Siderosis: Iron overload in the bloodstream.

SIE: STAT-inducible element. ►Jak-Stat pathway

Siemens (SI): A unit of conductance; 1 Ampere/Volt in a tissue of 1 Ohm resistance. ►Ampere, ►Volt, ►Ohm

SIEVE TUBE: A plant food transporting tube-shape, tapered, long cells; they may be connected by sieve plates that hold them together.

SIEVERT (Sv): The name for Sv (unit of absorbed dose equivalent [J/kg]) = 100 rem = 1 Sv. It is commonly used for measuring the occupational radiation hazards. ►rem, ►Gray, ►rad, ►R

SIGLECs (sialic acid recognizing Ig-superfamily lectins, 19q13.3): Immune inhibitory receptors with sialic acid ligands. During evolution, T cell Siglec expression was largely lost from humans while it was retained in apes. This fact explains why human are more at risk by T-cell-mediated diseases, such as AIDS and hepatitis B and C, compared to apes (Nguyen DH et al 2006 Proc Natl Acad Sci USA 103:7765). ►sialic acid, ►AIDS, ►hepatitis

Sigma Factor: A subunit of DNA-dependent bacterial RNA polymerase, required for the initiation of transcription and for promoter selection. It has been reported that in *Bacillus subtilis*, the σ factor alone is sufficient for melting the DNA around site -10 of the promoter (Hsu HH et al 2006 Cell 127:317). The documentation of this finding has been, however, questioned (Xin H 2006 Science 314:1669) and the paper was retracted (2007 Cell 128:211). ►open promoter complex, ►RNA polymerase, ► σ

Sigma Replication: ►rolling circle

Sigma Virus of *Drosophila*: ►CO₂ sensitivity

Sign Mutations: Frameshift mutations because an equal number base addition(s) (+) and deletion(s) (–) at the gene locus may restore the reading frame, although may not always restore normal function. ►frameshift

Signal: A molecular determinant, emitted by an extracellular source, or by an intracellular organizer and is directed either to an adjacent tissue (vertical signal) or to adjacent cells of the same tissue (planar signal). The response to a signal frequently involves change in transcription. ►signal transduction; Camili A, Bassaler BL 2006 Science 311:1113.

Signal End: ►immunoglobulins

Signal Joint: ►signal end

Signal Hypothesis: The signal hypothesis postulated that the signal peptide of the nascent polypeptide chain guides it to the endoplasmic reticulum (and to other) membranes where the signal peptidase cleaves it off, and subsequently the peptide chain is completed within the lumen of the membranes. It has now been validated for transport through bacterial cell membranes, mitochondria, plastids, peroxisomes, etc. ►signal peptides, ►transit peptide, ►protein targeting; Loureiro J et al 2006 Nature [Lond] 441:894.

Signal-Noise Ratio: The signal-noise ratio determines the sensitivity of an instrument or procedure to detect the presence or the function of a molecule in a reliable manner.

Signal Peptidase: ►signal hypothesis

Signal Peptides (signal sequence): 15 to 35-amino acid long sequences generally occurring at the NH₂ terminus of the nascent polypeptide chains of proteins that have a destination for an intra-organellar or transmembrane location. They are made in eukaryotes and prokaryotes but not all the secreted proteins possess signal peptides. At the beginning of the sequence, generally there are one or more positively charged amino acids, followed by a tract of hydrophobic amino acid residues that occupy about three-fourth of the length of the chain. This hydrophobic region may be required to pass into the lipoprotein membrane. The amino acid sequences among the various signal peptides are not conserved, indicating that the secondary structure is critical for recognition by the signal peptide recognition particles and for the function within the membrane. The eukaryotic signal sequences are recognized by the prokaryotic transport systems and the prokaryotic signal peptides can function in eukaryotes. After the passage of the nascent peptide has started the signal, peptides are split off by peptidases on the carboxyl end of (generally) glycine, alanine, and serine. Consequently, the majority of the proteins in the membrane or transported through the membranes, have the nearest downstream neighbor in one of these three amino acids at the amino end. One major characteristic of the signal peptide is the co-transcriptional targeting, whereas the transit peptides are targeted posttranslationally. The signal sequences may show polymorphism that might result in incorrect targeting. ►signal sequence recognition particle, ►transit peptide, ►leader peptide, ►endoplasmic reticulum; von Heijne G et al 1989 Eur J Biochem 180:535; Watanabe N et al 2001 J Biol Chem 276:20474; transmembrane and signal peptide server: <http://phobius.cgb.ki.se/>.

Signal Recognition Particle: ►signal sequence recognition particle, ►SRP

Signal Sequence: The amino terminal of some proteins signals the cellular destination of these proteins, such as the signal peptides. ►[signal peptide](#)

Signal Sequence Recognition Particle (SRP): In mammals, a complex of six proteins and an RNA (7SL RNA) that recognizes the *SRP receptor protein* on the surface of the endoplasmic reticulum and the *signal peptides* of the nascent proteins translated on the ribosomes associated with the endoplasmic reticulum (rough endoplasmic reticulum) and facilitate the transport of these polypeptides into the lumen of the Golgi apparatus and lysosomes (co-translational transport) (see Fig. S57). Signal recognition particle proteins have been located to human chromosomes, 5q21, 15q22, 17q25 and 18.

Figure S57. Schematic illustration of a signal recognition particle. The boxes represent the six proteins around the RNA. SRP9—SRP14 and SRP72—SRP68, respectively form dimeric structures. (Modified after Weichenrieder O et al 2000 Nature [Lond] 408:167)

The SRP binds to the signal peptide after a about 70-amino acid chain is completed at the beginning of translation. The polypeptide chain elongation is somewhat relaxed until the SRP attaches to the SRP receptor. Then, the SRP comes off the amino acid chain, elongation resumes its normal rate, and the entry of the chain through the membrane proceeds. In the meantime, a peptidase inside the endoplasmic reticulum cuts off the 15–30 amino acid long signal peptide sequences. ►[lysosomes](#), ►[Golgi](#), ►[signal peptides](#), ►[protein synthesis](#), ►[signal sequence particle](#), ►[RNA 7S](#), ►[protein targeting](#), ►[translocon](#), ►[translocase](#), ►[TRAM](#), ►[protein conducting channel](#); Keenan RJ et al 2001 Annu Rev Biochem 70:755; Fulga TA et al 2001 EMBO J 20:2338; Wild K et al 2001 Science 294:598; Hainzl T et al 2002 Nature [Lond] 417:767; Pool MR et al 2002 Science 297:1345; structure: Egea PF et al 2004 Nature [Lond] 427:215; structure of *E. coli* signal recognition particle bound to ribosome: Schaffitzel C et al 2006 Nature [Lond] 444:503; <http://psyche.uthct.edu/dbs/SRPDB/SRPDB.html>.

Signal Transduction: A system of proteins transforming various stimuli into cellular responses. The process requires four major categories of elements: signals, receptors, adaptors, and effectors.

Signals. The extracellular signals interact with cell membrane receptors (EGFR, FGFR) and subsequently make contacts with intracellular target molecules to stimulate a cascade of events leading to the formation of effector molecules that switch genes on and off and control cellular differentiation in structure and time by regulating transcription. The *signals* are proteins, peptides, nucleotides, steroids, retinoids, fatty acids, hormones, gases (ethylene, nitric oxide, carbon monoxide), inorganic compounds, light, etc. The target cells accept the signals by special sensors, *receptors*. The receptors are generally specific proteins with high binding specificities and positioned on the cell surface or within the plasma membranes and thus readily accept the signal *ligands*. The receptors may be also inside the cells, and the ligands may have to pass the cell membranes to reach them. As a consequence of the binding, a cascade of events is triggered and eventually the instruction reaches the cell nucleus and the relevant genes. The *paracrine signals* are restricted in movement to the proper, a generally nearby, target. The nerve cells are communicating by *synaptic signals*. The *endocrine hormone* signals may affect also distant targets in the entire body. The neurotransmitters are activated through long circuits of the nervous system by electric impulses emitted by neurons in response to the environment. The travel of the electric signals through the neurons is very fast, may pass through meters per second. The neurotransmitters have only a few nanometers to pass and the process takes only a few milliseconds. The local concentration of the endocrine hormones is extremely low. In contrast, the neurotransmitters may be quite concentrated at very small target area. The neurotransmitters also may very rapidly be removed either by re-absorption or by enzymatic hydrolysis. Generally, the hydrophobic signals persist longer in the cells than the hydrophilic ones. The membrane anchored growth factors and cell adhesion molecules are signaled through the *juxtacrine* mediators.

Receptors. The target cells respond by *receptor proteins*. These receptors are endowed with specificities regarding the signal they respond to. Also, the same signal may have different receptors in differently specialized cells. In addition, the interpretation and use of the signal within similar cells may vary. The signals may act also in a combinatorial manner: several signals together may be involved in the cellular decisions and influence the length and quality of the effect of a signal received. The various receptors, despite substantial chemical differences of the signals (e.g., cortisol, estrogen, progesteron,

thyroid hormones, retinoic acid, vitamin D), may bind ligands that control through the signal transduction path closely related and interchangeable upstream DNA consensus elements, involved in the regulation of transcription of different genes. Steroid hormone receptors, after bound to cognate hormones, may activate the transcription of the so-called *primary response genes*. These proteins then repress the further transcription of the primary response genes and turn on the transcription of *secondary response genes* (►regulation of gene activity).

Receptors can be (i) *ion-channel* or (ii) *G-protein* or (iii) *enzyme-linked* types. Group (i), also called transmitter-regulated ion channels, are involved in transmitting neuronal signals (►ion channels). Group (ii) receptors are transmembrane proteins of the so-called seven-membrane type (►seven-membrane proteins) associated with guanosine phosphate-binding G proteins (►G-proteins).

When GTP is bound to the G-protein, a cascade of enzymes or other proteins may be activated or an ion channel may become more permeable. G-protein linked receptors represent a large family of proteins, more than 100 of which, have been already identified in a variety of eukaryotes. The receptors, generally monomeric and evolutionarily related proteins, respond to a variety of signals, such as hormones, mitogens, light, pheromones, etc. Activation of group (iii) receptors may directly or indirectly lead to the activation of enzymes. These three different types of signal transduction may not be entirely distinct because the function of the ion channels may interact with the pathways mediated through G-proteins and various kinases. Some of the receptors are *protein tyrosine phosphatases* (e.g., CD45 protein) and *serine/threonine phosphatases* residing within the membrane or in the cytosolic domain of transmembrane proteins or in the cytosol.

Pathways. Pathways may show a great variation depending on the signals and receptors involved. Ca^{2+} is a general regulator. It may enter nerve cell terminals through voltage-gated Ca^{2+} channels in the cell membranes and stimulates the secretion of neurotransmitters (►ion channels, ►voltage-gated ion channel). Alternatively, Ca^{2+} may play a more general role by binding to G-protein linked receptors in the metabolism of inositol phospholipids, PIP (phospho-inositol phosphate), and PIP_2 (phosphoinositol biphosphate). The specific trimeric G-protein, Gq is involved in the activation of *phospholipase C- β* , that is specific for phosphoinositides, and splits PIP_2 into inositol triphosphates and diacylglycerol. Hydrolysis of PIP_2 yields IP_3 (inositol 1,4,5-triphosphate). The latter sets free calcium from the endoplasmic reticulum through IP_3 -gated channels, ryanodine receptors (►ryanodine). Upon further

phosphorylation, IP_3 may give rise to IP_4 (inositol 1,3,4,5-tetrakisphosphate) that slowly yet steadily replenishes cytosolic calcium. The calcium level in the cytosol rises and subsides in very short bursts according to how phosphatidyl-inositols regulate it (calcium oscillations). These oscillations still may assure increased secretion of second messengers and spare the cell from a constant level of the toxic Ca^{2+} in the cytosol. Besides pumping out Ca^{2+} shielded in the endoplasmic reticulum, diacylglycerol and eicosanoids (arachidonic acid) may be produced.

Diacylglycerol and the latter lipid derivatives may activate the Ca^{2+} -dependent enzymes, serine/threonine kinases, which have key role in activating proteins that mediate signal transduction (►protein kinases). *Protein kinase C* may activate the cytosolic *MAPK* (mitogen activated protein kinase) by phosphorylation and may phosphorylate a cytoplasmic inhibitor complex such as $\text{I}\kappa\text{B} + \text{NF-}\kappa\text{B}$. Thus, *MAPK* may phosphorylate DNA-binding proteins such as *SRF* (serum response factor) and *Elk* (member of the *ETS* oncoprotein family), sitting already at the upstream regulatory regions of a gene(s), such as the serum-response element (*SRE*). The phosphorylation then initiates transcription (►regulation of gene activity). The released protein factor *NF-}\kappa\text{B}* may migrate to the nucleus and, by binding to its cognate DNA site, sets into motion transcription (if other factors are also present). The response of the genes to the transducing signals depends on the number of regulatory proteins responding to the signal. Monomolecular reactions display relatively slow response to the concentration of the signal molecules, whereas if the number of effectors is multiple, the reaction to them may follow 3rd or multiple order kinetics. Similarly, prompt response is expected if the signal activates one reaction (e.g., phosphorylation) and at the same time deactivates an inhibitor or suppressor (e.g., by phosphatase action).

The enzyme-linked signal receptors do not need G-proteins. The transmembrane receptor binds the ligand at the cell surface and the cytosolic domain functions as an enzyme or it associates with an enzyme and the transfer of the signal to the cell nucleus is more direct. An example is the cytokine-activated cell membrane receptor *Jak tyrosine kinases*, which when dimerize, can combine with cytoplasmic *STATs* (signal transducers and activators of transcription) and chromosomal responsive elements. In response of interferon or other cytokine signals, the *JAK* phosphorylates tyrosine of the *SH2* domains in a variety of *STAT* proteins. This may be followed by dimerization and the transfer of these proteins to the nucleus where they may turn on transcription of particular genes (see Fig. S58). It has been estimated that about 1% of the human genes code for protein kinases.

Figure S58. The JAK-STAT signal transduction pathway, based on interferon (IFN)-mediated receptors. *JAK* is a family of the Janus tyrosine protein kinase proteins, and *STAT* stands for signal transducer and activator of transcription. When the ligand binds to the signal-transducing receptors (ST), the receptor-attached *JAK* kinases modify the *STAT* proteins. After dimerization (using SH2 domains), they are transported directly to *ISRE* (interferon- α -response element) or to *GAS* (γ -interferon activation site) in the chromosomal DNA. These two elements vary, yet consensus sequences exist (as shown in the diagram). The 84, 91, 113, and 48 are proteins (in kDa), but additional ones may also be involved, depending on the nature of the signals received. The diagram does not display IFNGR1 and IFNGR2 integral membrane proteins, which are also essential parts of the γ -receptor. (After Darnell JE Jr., et al. 1994. *Science* 264:14125 and Heim MH et al. 1995. *Science* 267:1347.)

In case of autophosphorylation or other reactions involving enzymes, which may bind their own products, the activity of the enzyme may be increased in the course of time with the increase of the number of product molecules, through a positive feedback.

These kinases may be mainly either serine/threonine or tyrosine kinases. Some proteins may phosphorylate all three of these amino acids. The reliance on protein tyrosine kinases for signal transduction is rather general. Epidermal growth factor (EGF), nerve growth factor (NGF), fibroblast growth factor (FGF), hepatocyte growth factor (HGF), insulin, insulin-like growth factor (IGF), vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), macrophage colony stimulating factor (M-CSF), etc., function with the assistance of transmembrane *receptor tyrosine kinases*. Upon the arrival of the ligand (signal), the receptor is dimerized either by cross-linking two receptors by the dimeric ligand or by inducing autophosphorylation and linkage of two cytosolic domains of the receptors. The different phosphorylated sites may bind different cytoplasmic proteins. The insulin itself is a tetramer ($\alpha\alpha\beta\beta$) and thus does not need dimerization. After autophosphorylation, it phosphorylates an

insulin receptor (IRS-1) at tyrosine sites and that may bind to other proteins, which also may become phosphorylated and may form different complexes, thus, generating a variety of transcription factors. Alternatively, the *tyrosine kinase-associated receptors* themselves are not tyrosine kinases but associate with proteins of this capability. Some of the enzyme-linked receptors are *serine/threonine kinases* with specificities for these two amino acids. The phosphorylated tyrosine residues are binding sites for proteins with SH2 domains. The *receptor tyrosine phosphatases* may activate or inhibit the signal pathways by the removal of phosphate from tyrosine residues. The receptor guanylate (guanylyl) cyclases operate in the cytosolic domain of the receptors and function by serine/threonine phosphorylation in association with trimeric G-proteins. Within the last decade, discoveries about signal transduction have changed the views about cellular functions and added a new dimension to biology by integrating reversed and classical genetics. The signal transduction mechanisms have a large variety of means to regulate diverse functions of metabolism, differentiation, and development (see Fig. S59). The different signaling molecules are organized into separate pathways. The

different protein components appear to be regulated and coordinated into signaling complexes by SH, pleckstrin-homology, phosphotyrosine, and PDZ (post-synaptic density, dislodge, zo-1) protein domains through protein-protein interactions.

Figure S59. A signal transduction pathway leading through the G-protein RAS. This pathway controls cell division, differentiation, development of cancer, mating type, cell wall biosynthesis, and a variety of other processes. The signal can be a variety of molecules such as epidermal growth factor (EGF), nerve growth factor (NGF) or their homologs in various other animals such as *LET-23* in *Caenorhabditis* or *DER* in *Drosophila* the RAS-mediated pathway operates also in fungi and plants. The process begins with the (mitogen) signal arriving to the double membrane of the cell (see at 12 O'clock). The signal is recognized by a signal receptor protein, which may vary from signal to signal. This is a transmembrane protein with a hydrophobic tract forming generally seven turns within the cell membrane. When the signal arrives, the receptor is activated. The protein tyrosine kinase receptors (e.g., SEV) recruit then the down-stream receptor kinases or adaptor proteins such as GRB (or homologs e.g., SEM-5 in *Caenorhabditis*, DRK in *Drosophila*). The GRB proteins have an SH2 domain, which is a binding site for tyrosine kinase proteins and the SH3 domains are binding sites for proline-rich motif proteins. The SH domains were originally identified in the SRC protein (product of the Rous sarcoma oncoprotein) and both are characteristic for mediators of the signal transduction path. The GRB protein then binds another mediator or adaptor protein, SOS (named after the product of a *Drosophila* gene, called *son of sevenless*). The sevenless gene encodes Rhabdome seven light receptors in the eyes of the flies. In place of SOS, there may also be SHC (an oncoprotein of the pheochromocytoma tumor of the adrenal medulla or in paraganglia and thus causing increased secretion of the hormones epinephrine and norepinephrine). Upon the influence of the GRB-SOS

complex, the membrane-bound RAS G-protein (see at 3 O'clock) becomes activated. The membrane association of RAS is mediated by a carboxy-terminal CAAX box, a signal for farnesylation, proteolysis and carboxymethylation and by the neighboring six lysine residues. RAS (named after rat sarcoma) is also a GTPase. The RAS serves as a turnstile for a series of processes. It is shut down when the situation is RAS*GDP (RAS guanosine diphosphate) and it opens when it becomes RAS*GTP (RAS-guanosine triphosphate). RAS activation may be prevented by another gene, encoding a GTP-ase activating protein (GAP). The RAF protein (its homologs in budding yeast is STE11, and BYR 2 in fission yeast) is also membrane bound by a CAAX box. RAF is a Ser-Thr kinase and it phosphorylates, independently of RAS, also MEK, a protein of the extra-cellular signal regulated kinase (ERK) family. The extracellular regulators can be growth factors (e.g., EGF, NGF), receptor kinases and TPA (12-O-tetradecanoyl-phorbol-13-acetate). MEK kinase (MEKK) is phosphorylated on Thr and Ser residues by RAF. Protein MAPK (mitogen-activated protein kinase) may be capable of autophosphorylation and it may be phosphorylated by the ERK family of kinases at Tyr and Thr residues. MAPK homologs are KSS, HOG-1, FUS3, SLT-2, SPK-1, SAPK (a stress activated kinase), FRS (FOS regulating kinase), etc. MAPK may then activate the FOS and JUN oncogene complex that is also known as the AP-1 heterodimeric transcription factor of mitogen-inducible genes. The RAS to MAPK route may branch downstream through several effector proteins and may control the transcription of several different genes. The specificity of activation depends on combinatorial arrangements of the effectors. (The size, shape or shading of the symbols is not intended to represent their structure.)

Plant Signals. Plant signals are somewhat different from the signals in animals. The plant hormones, similarly to animal hormones, are signaling molecules but most of them—except the brassinosteroids—are very different molecules. In plants, light and temperature signals (photoperiodism, vernalization, phytochrome) are very important for growth and differentiation. Salicylic acid is a signaling molecule for defense genes, etc. In plants, signaling depends a great deal on positional cues.

Several signal transduction pathways may be simultaneously operational within an organism and they may interact at various levels. In addition, the pathways and components may operate differently in different cellular compartments (e.g., plasma membrane, cytosol, nucleus, organelles). The cytoskeleton network may serve in various capacities to direct the flow of reactions through the signaling pathways. The current view is that signaling proteins translocate in the cytoplasm and bind in a reversible manner and dynamic fashion (soft-wired signaling concept). The

JAK-STAT: see more above

RAS: see more above

CREB: cAMP-response element-binding protein

pCIP: p300/CBP/cointegrator-associated protein

CBP: CREB-binding protein

pCAF: chromatin assembly factor

NcoA: nuclear receptor coactivator

SRC1, TIF, SUG: nuclear coactivator proteins

NR: nuclear receptors

HAT: histone acetyltransferase

Besides the molecules shown and named, several other proteins may be involved. Some of the proteins are activated only after binding with their ligands. The size or shape of the structures shown does not reflect the actual nature of these molecules.

Figure S60. Transactions inside the nucleus after the signals arrived

earlier idea was that receptors and other signalling proteins occupy fixed positions in the cell and second messengers mediate the connections with aid diffusion (hard-wired signaling). As opposed to electric circuits, a model signal of transduction is that of a gradient of quantitative information propagated outwards throughout the dense protein network following an input through an individual receptor. A central maximum of information transfer can include the old canonical pathways but the propagation throughout the signaling network may be in part stochastic and influenced by the local network composition. Although, large-scale, global static interaction maps are useful initially, these rarely recapitulate the often-transient connections of known signaling modules. Understanding signal transduction from a network perspective allows an appreciation of how variants of proteins (by mutation or concentration) within the network can lead to quantitatively different outputs. Thus, for diseases linked to disruption of particular signaling networks, comparison of QTLs with functional genomic RNAi screens of those networks synergistically provides a mechanistic insight into disease etiology. Sequencing of a large number of genes from breast and colorectal cancers (Sjöblom T et al 2006 Science 314:268), projected an average of 90 mutated genes per tumor, 11 of which occurred at significant frequency, suggesting that many mutations are needed to attack the robust cell signaling network. It is logical that signal transduction and transcriptional machinery components are extremely common functional categories mutated in these cancers (Friedman A, Perrimon N 2007 Cell 128:225).

The introduction of GFP labeling now facilitates the tracing of the signaling traffic. The interacting

signals are usually expressed in a quantitatively variable manner. Understanding how different cells work under the control of the genetic potentials and the environment will be the most challenging task of the research on growth, differentiation, development, the nervous system, behavior, productivity, pathogenesis, evolution, etc.

Signaling: The phosphorylation of enzymes mediated by second messengers leads to their activation through outfolding of the pseudosubstrate domains of the enzymes and thus opens the active sites for the true substrate. ►signal transduction

Signaling Molecule: A signaling molecule alerts cells to the behavior of other cells and environmental factors. ►autoinduction

Signaling to Translation: Signaling transduction is directed toward the 5'-untranslated region (UTR) and involves the translation of ribosomal proteins and elongation factors (eEF1A, eEF2). The target of the signals appears to be the 5'-terminal oligopyrimidine sequences (5'-TOP) and the UTR polypyrimidine tracts. Secondary structure formation with long UTRs may also be regulatory. Growth factors may phosphorylate the eukaryotic initiation factor eIF4E-binding protein, 4E-BP-1, and cause its dissociation from eIF4E. In order that the translation would proceed, the initiation factors eIF4A, -4B, -4G, -4E attach to the methylguanine cap and the secondary structure of the RNA is untwisted by the helicase action of eIF4A. Phosphorylation by the p70^{S6k} kinase activates the S6 protein of the 40S ribosomal subunit, a process subject to enhancement by mitogens. This process is not a general requirement for translation, indicating that it affects only special genes with 5'-TOP and polypyrimidine tracts in their UTRs. Cycloheximide and puromycin are also involved in the phosphorylation of S6. Both of these phosphorylations are inhibited by rapamycin. ►F506, ►P70^{S6k}, ►secondary structure, ►cycloheximide, ►puromycin, ►cap, ►regulation of gene activity, ►regulation of enzyme activity, ►protein synthesis, ►signal transduction; Wilson KF, Cerione RA 2000 Biol Chem 381(5-6):357.

Signalosome: A molecular complex transmitting various cues. ►signal transduction; Lyapina S et al 2001

Science 292:1382; Zhang SQ et al 2000 Immunity 12:301.

Signature, Evolutionary: Within the various genomes (mammalian, mitochondrial, plants, prokaryotes, etc.), there appears to be a characteristic distribution of dinucleotide sequences, which is different from that of the other species. This constitutes an evolutionary signature. (See Campbell A et al 1999 Proc Natl Acad Sci USA 96:9184).

Signature of a Molecule: The characteristic feature(s) convenient for identification. Discriminating sequences of DNA, RNA, or the proteins of organisms may serve as signatures. Molecular signatures can predict the course of diseases (O'Shaughnessy JA 2006 N Engl J Med 355:615).

Signature-Tagged Mutagenesis (STM): The induction of mutation by the insertion of plasmids, transposable elements, or passengers of specially constructed vectors into the genetic material. An insertional mutagenesis system that uses transposons carrying unique DNA sequence tags—flanked by PCR-amplifiable short tracts—was developed for the isolation of bacterial virulence genes. Originally in a murine model of typhoid fever caused by *Salmonella typhimurium*, mutants with attenuated virulence were revealed by use of tags that were present in the inoculum but not in bacteria recovered from infected mice (Hensel M et al 1995 Science 269:400). ►targeting genes, ►vectors, ►insertional mutation; Nelson RT et al 2001 Genetics 157:935; Shea JE et al 2000 Curr Opin Microbiol 3:451; Mazurkiewicz P et al 2006 Nature Rev Genet 7:929.

Significance Level: The significance level indicates the probability of error by rejecting a null hypothesis that is valid (Type I error, α) or accepting one that is not correct (Type II error, β). By convention, 5% (*, significant), 1% (**, highly significant), and 0.1% (***, very highly significant) levels are used most commonly. These are not sacrosanct limits. In field experiments with crops, the 5% level may be a satisfactory measure for comparative yields but even the 0.1% may not be acceptable for pharmaceutical tests because the chance of harming 1/1000 persons is unacceptable. In general experimental practice, levels above 5% and below 0.1% are not considered meaningful although they may have relevance for pharmacology. ►goodness of fit, ►t-test, ►probability, ►power of the test, ►inference

Sign-R1: A lectin, which captures microbial polysaccharides in the spleen and interacts with complement component C1q. ►lectins, ►complement

SIL (short insert library): The SIL is generated by the restriction cleavage of gap-bridging clones (used in

the final stages of physical mapping) into 0.5 kb or smaller fragments to break up secondary structures of the DNA that complicate the determination of continuity in sequencing. ►[chromosome walking](#), ►[physical mapping](#), ►[restriction enzymes](#)

SILAC (stable isotope labeling by amino acid in cell culture): A proteomics technique used for separate identification of similar proteins in high performance liquid chromatography–mass spectrometry (Foster LJ et al 2003 Proc Natl Acad Sci USA 100:5813).

Silencer: A negative regulatory element reducing transcription of the region involving the target genes. Their action bears similarity to the heterochromatic chromosomal regions, which reduce transcription of genes transposed to their vicinity. The Sir proteins may interact with the amino-terminal of histones 3 and 4. Sir2 deacetylates histone H4 lysine¹⁶ tail and mediates the synthesis of 0-acetyl-ADP-ribose. As a consequence, Sir2, Sir3, and Sir4 bind to the histone tail and mediate chromatin silencing (Liou G-G et al 2005 Cell 121:515). Sir2 homotrimer is required for histone deacetylation and rDNA suppression, whereas telomere silencing requires the heterotrimeric complex of Sir2, Sir3, and Sir 4 (Cubizolles F et al 2006 Mol Cell 21:825). Silencing requires combination of a protein(s) and the site where silencing takes place. There is evidence that Sir-generated heterochromatinization interferes with the assembly of the components of the pre-initiation complex (Sekinger EA, Gross DS 2001 Cell 105:403). Some evidence in yeast indicates that TFIIB, RNA polymerase II, and TFIIE occupancy is reduced by a silencer at downstream of the gene activator protein (Chen L, Widom J 2005 Cell 120:37). For example, the *MATa* and *MATα* genes of yeast encode regulatory proteins that permit the expression of *a* and *α* mating types, respectively, of the haploid cells and the non-mating phenotype of the sporulation-deficient *a/a* diploid cells. When these genes are at the *HMLa* and *HMRa* sites, they are silenced until they are transposed to the *MAT* locus. The mating type switch is catalyzed by a cut mediated through HO endonuclease when the mating type alleles are at the *MAT* locus, but not at the *HMLa* and *HMRa* locations. This indicates that the silencing is under the dual control of the repressed domains, which appear to extend to 0.8 kb proximal to the centromere from *HML-E* and a silencer protein and a specific site. Inactivation of *SIR2*, *SIR3*, and *SIR4* derepresses *HML* and *HMR*. These genes affect the telomeric position effect of other genes as well. *SIR2*, *SIR3*, and *SIR4* are also involved in DNA repair and recombination in cooperation with the *HDF1* locus of yeasts (a *Ku* homolog). Mutations at the amino terminus of the *HISTONE 4* gene also have a similar

effect. Over-expression of *SIR2* causes its hypoacetylation, while *SIR3* mutations may alter the conformation of this histone bound to *HMR*. Loci *HML* and *HMR* both are flanked by *HML-E* and *HML-I* silencer elements. These silencers are similar to the autonomously replicating elements of yeast that are involved in DNA synthesis and apparently also in silencing. *HML-E* is capable of repression only in the presence of *HML-I* and is 0.4 kb distal from *HML-I* (based on Loo, Rine 1994 Science 264:1768). *HMR-E* is a very potent silencer endowed with binding sites for ORC (origin recognition complex), Rap1 (a suppressor of RAS-induced replication), and Abf1 (another silencer) suppressors of the S phase of the cell cycle. Recent evidence indicates that transcriptional silencing does not require DNA replication, although it seems to require some cell cycle events. Silencer elements are also present in animal and plant systems. In plants, when multiple copies of a gene are introduced into the genome by transformation, all or most copies of the gene are inactivated (trans-inactivation). The mechanism of this phenomenon is unclear. It has been suggested that when the level of a particular RNA is increased, a degradative process is initiated. This has been attributed to a defense mechanism, since the majority of plant viruses are RNA viruses. Some of the silencing appears, however, post-transcriptional. In fungi, silencing has been attributed to premeiotic methylation when multiple copies are present in cis position. This view is supported by the long-standing knowledge that the repetitive sequences of the heterochromatin are not expressed. Position effect has also been known as a type of silencing. The reversible type of paramutation can also be considered a transinactivation mechanism. Silencing of genes may be accomplished by moving the region of the intact chromosome toward the centromere (position effect). Transposition to the vicinity of heterochromatin may also result in silencing. Sir1 protein is most common in the telomeric region of yeast chromosomes but it may be present also in the nucleolus. Sir3 and Sir4 normally are absent from the nucleolus, but are present in case Sir2 is mutant. The *SIR2* homolog in mammalian cell is *SIRT2*, which controls caloric intake and thereby extends life span. Absence of *SIRT6* in mammals results in genomic instability, autoimmune disease (lymphopenia), metabolic defects, and premature death as a consequence of deficiency in excision repair of DNA (Mostoslavsky R et al 2006 Cell 124:315).

Although silencers have some similarities to insulators, the latter are different because they must be situated in between the enhancer and the target promoter. Unpaired DNA may cause meiotic silencing in *Neurospora*. Hypermethylation of CpXpG nucleotides by chromomethylase 3 in *Arabidopsis*

silences the expression of some genes and its mutation restores wild phenotype to the epigenetically silenced genes and reactivates retrotransposons.

Silent Information Regulators: Silent information regulators are involved in the assembly of the silent chromatin domains. ►silencer; Moazed D et al 1997 Proc Natl Acad Sci USA 94:2186.

Silent Mutation: Base-pair substitution in DNA that does not involve amino acid replacement in protein and entails no change in function. ►mutation

Silent Sites: Silent sites are where mutations in the DNA base sequence have no consequence for function. ►synonymous codons

Silicon (Si): The second most abundant element (27.6%) in nature. Si occurs in quartz, sand, and sandstone, or as silicate, e.g., in kaolinite. Plants take up 0.1 to 10% of their dry weight as silicic acid (H_2SiO_3) by using genetically determined silicon transporter proteins. It increases firmness of plant tissues and disease resistance (Ma JF et al 2006 Nature [Lond] 440:688). Silicons, organosilicon oxides polymers, are used in the laboratory as lubricants and seals. Silica gels are lustrous granules used for absorption and column chromatography.

Siliconization: In siliconization, glassware used in genetic laboratories is treated in a vacuum by dichlorodimethylsilane in order to prevent DNA molecules sticking to the vessel, and resulting in loss of recovery. ►DNA extraction

Silique: A typical fruit of cruciferous plants; two carpels, dehiscing at the base at maturity, enclose the placenta which sit in one row on each of the opposite sides of the replum. In Figure S61, the carpels were removed before maturity.

Figure S61. Silique

Silk Fibroin: A protein rich in glycine and alanine residues arranged largely in β sheets (β keratin). It is synthesized within the silk gland to protect the pupa. The pupa is called also chrysalis or cocoon. A fibroin gene is transcribed into about 10,000 long-life molecules of mRNA within a few days and they are translated several times into about a billion protein molecules. Each gland manufactures about 10^{15} fibroin molecules (300 μg) in four days. Actually, the gland is a single cell but it contains polytenic chromosomes and thus the fibroin locus is amplified about a million fold ($10^9 \times 10^6 = 10^{15}$ fibroins). In spiders, there is great diversity and also conservation in the silk fibroin genes (Garb JE et al 2006 Science 312:1762). Some of the spiders' silks are tougher than that of silkworm and rival the best man-made fibers. The spider dragline silk, besides its outstanding tensile strength, has unrivalled torsional quality that stop the spider from twisting and swinging and thus makes the animal less conspicuous to predators (Emile O et al 2006 Nature [Lond] 440:621). Spider dragline silk can be synthesized in transgenic tobacco, potato plants, and also in transgenic mammalian cells. ►polytenic chromosomes, ►silk worm, ►resilin; Vollrath F, Knight DP 2001 Nature [Lond] 410:541; Scheller J et al 2001 Nature Biotechnol 19:573; Lazaris A et al 2002 Science 295:472; Jin H-J, Kaplan DL 2003 Nature [Lond] 424:1057.

Silk: The botanical term for the pistils of the maize female inflorescence (see Fig. S62).

Figure S62. Maize female inflorescence

Silkworm (*Bombyx mori*, $2n = 56$): One of the best-studied insects in genetics (see Fig. S63). There are about 1000 markers in the genetic map spacing at ~ 2 cM. Its RAPD map (~ 2000 cM), includes ~ 1018 markers scattered over all chromosomes.

Figure S63. Silkworm larva; at top (a) male (ZZ), at right ZW female (b); wild type Asian imagoes. The pattern varies in the different wild insects and also in the domesticated varieties

About 91% of the genome of the domesticated silkworm has been sequenced and it contains $\sim 18,510$ genes (Xia Q et al 2004 Science 306:1397). Its genome contains a special type of transposable element, R2Bm, that is present also in some other insects. R2Bm has no long terminal repeats. It is inserted in the 28S rRNA genes only and encodes an integrase and a reverse transcriptase function within one protein molecule. The R2 protein nicks one of the DNA strands and uses it also as a primer to transcribe its RNA genome, which is then integrated as DNA-RNA heteroduplex. Subsequently, a host polymerase synthesizes the second DNA strand. Silyl-Phosphite Chemistry: Silyl-phosphite chemistry is used in oligoribonucleotide synthesis. (See Agarwal S (Ed.) 1995 Methods in Molecular Biology. Humana, Totowa, New Jersey, p 81).

Simian: Ape or monkey type. [▶primates](#), [▶hominidae](#)

Simian Crease: See [▶Down's syndrome](#) for illustration. It can be rarely observed (1–4%) in normal infants but it is characteristic for human trisomy 21, De Lange, Aarskoog, and other syndromes. [▶Down syndrome](#), [▶Aarskoog syndrome](#), [▶De Lange syndrome](#)

Simian Sarcoma Virus (SSAV): A gibbon/ape leukemia retrovirus with a homologous element in human chromosome 18q21. The long terminal repeat (535 bp) appears to contain transcriptional control and signal sequences. The human chronic lymphatic type leukemia seems to be associated with a break point of chromosome 18. [▶leukemia](#)

Simian Virus 40: A eukaryotic virus of a molecular weight of 3.5×10^6 with double-stranded, supercoiled DNA genetic material of 5243 bp (see Fig. S64). The DNA is organized into a nucleosomal structure that does not have H1 histone. The DNA around the nucleosome cores is 187 ± 11 bp and the cores are separated by 42 ± 39 bp linkers. The viral particles are skewed icosahedral capsids and have 72 protein units.

Figure S64. SV40

In primates, the virus generally follows a lytic lifestyle and the virions multiply in the cytoplasm, i.e., primates are *permissive hosts* for replication. SV40 encodes microRNAs that protect to some extent against the host cytotoxic T cells (Sullivan CS et al 2005 Nature [Lond] 435:682).

Occasionally, in humans the viral DNA integrates into the chromosomes. Such an event may lead to cancerous transformation. Rodent cells are *non-permissive hosts* for viral replication and the viral DNA integrates into the chromosomes leading to cancerous tumor formation. The correlation between

Figure S65. Organization of SV40

SV40 infection and cancer has been questioned (Paulin DL, DeCaprio JA 2006 J Clin Oncol 24:4356). The virus codes for early (t and T antigens) and late (VP1, 2, 3) viral proteins (see Fig. S65).

The viral replication and transcription are bidirectional (see Fig. S66). In the non-permissive host, only the early genes are expressed that are needed for replication of the genetic material before integration, but there is no need for the coat proteins. The integration can take place at different sites, therefore it uses a mechanism of illegitimate recombination. The few integrated copies may be rearranged and may cause continued chromosomal rearrangement in the host. The infectious cycle spans about 70 h. The joint replication and transcriptional origin (*ori*) area extends to about 300 bp and includes a rather sophisticated control system. The replication of the SV40 DNA begins at the 27 bp palindrome of the *ori* site that is adjacent to a region consisting of 17 A-T base pairs. Next to it, on the side of the late genes, there are three other units of 22, 21, and 21 GC-rich repeats that also promote replication, although are not absolutely essential to the process. The SPH elements have an overlapping *octamer* that is present in other eukaryotic genes as well. Several other sequence motifs are similar to those in other promoters. The 72 elements include the 47 bp B and the shorter 29 bp A domains that are parts of the essential enhancer region. The A-T box is essentially a TATA box: 5'-TATTTAT-3'. For the start of replication, the large T has to bind to the Tag binding sites Δ . At the initiation, when low amounts of Tag are available, binding begins at the T1 site located at the pre-mRNA region (right of *ori*). As more Tag will become available, Tag binds to T2 and becomes an ATP-dependent helicase and with the cooperation of

Figure S66. Gene and polypeptide map of SV40

cellular proteins (DNA primase, polymerase, etc.), DNA replication proceeds.

Transcription. For the function of *ori* in transcription the 17 bp A-T sequence is needed, although this TATA box does not affect the rate of transcription. The 21 \diamond 21 \diamond 21 \diamond sequences promote transcription and the two hexamers 5'-GGGCGG-3' within these elements are essential for transcription. Their orientation and inversion does not interfere with transcription. The 72 bp element of SV40 is a capable enhancer also for mammalian, amphibian, plant, and fission yeast genes. The natural host of SV40 is the rhesus monkey (*Macaca mulatta*). In the laboratory, the kidney cell cultures of the African green monkey (*Cercopithecus aethiops*) are used primarily for its

propagation. Single cells, each, may produce 100,000 viral genomes after lysis. The general assumption is that SV40 does not cause human cancer, yet in many tumors its presence was detected by some laboratories, but not by others. ►SV40 vectors, ►COS cell, ►CTL, ►microRNA; Butel JS, Ledniczky JA 1999 J Natl Cancer Inst 91(2):119; see reviews in Semin Cancer Biol 2001 11:5–85; replication initiation complex: Simmons DT et al 2004 Nucleic Acids Res 32:1103; review of virus entry into mammalian cell: Damm EM, Pelkmans L 2006 Cell Microbiol 8:1219.

SimIBD: A computer procedure to assess affected-relative pair calculations.

Similarity Index: ►character index

SIMLINK: A simulation based computer program for estimating linkage information. ►SLINK, ►simulation

Simple Protein: Upon the hydrolysis of a simple protein, only amino acids are produced.

Simple Sequence Length Polymorphism (SSLP): In SSLP, variations in microsatellite sequences can be used for DNA mapping. PCR primers are designed for the unique flanking sequences and their length can thus be determined in the PCR products. ►microsatellite, ►PCR; Cai W-W et al 2001 Nature Genet 29:133.

Simple Sequence Repeats (SSR): SSRs are common in genomes and can be used for mapping genes and for taxonomic studies. (See SSR primer tool: <http://bioinformatics.pcbasc.la.trobe.edu.au/ssrdiscovery.html>).

Simplesiomorphy: The primitive features retained during evolution. It is not very useful to trace evolutionary development. ►synapomorphy, ►homology

Simplex: A polyploid having only a single dominant allele at a particular gene locus; the other alleles are recessive at the locus. ►duplex, ►triplex, ►quadriplex

Simplexvirus: A member of the herpes family of viruses infecting humans and other mammals. ►herpes

Simpson-Golabi-Behmel Syndrome (Simpson Dysmorphia, SGBS): A human Xq26 (500 kilobase stretch) syndrome, encoding the GPC3 gene responsible for the synthesis of glypican (cell surface molecules of heparan sulphate proteoglycans), associated with the insulin-like growth factor (IGF2). Individuals afflicted by this condition are generally very tall, usually have facial anomalies, heart and kidney defects, cryptorchidism, hypospadias, hernias, and bone anomalies and show susceptibility to cancer.

Many of the symptoms involving overgrowth are shared with the Beckwith-Wiedeman syndrome. ►Beckwith-Wiedeman syndrome, ►IGF, see terms at corresponding entries.

SIMS (secondary ions MS): A method for the production of intact molecular ions for mass spectrometry. ►mass spectrometer

Simulation: The representation of a biological system by a mathematical model generated frequently by a computer program. ►modeling; <http://www.nrcam.uchc.edu>; ►Monte Carlo method

Simulon: ►origon

Sin3/RPD: A repressor protein complex probably involved in chromatin remodeling by being recruited to histone deacetylase. It may be associated with SAP18, SAP30, and the retinoblastoma binding protein. ►Mad, ►chromatin remodeling, ►histone deacetylase, ►NuRD; Brubaker K et al 2000 Cell 103:655.

SIN Vector (self-inactivating vector): The SIN vector has a deletion in the U3 element of the 3'-LTR of the retroviral construct, and after replication results in a deletion also in the 5'-LTR promoter and enhancer and prevents the transcription from the cell-specific internal promoter, which may otherwise activate silent cellular oncogenes. This happens because the viral polymerase enzyme uses the 3'-U3 as template for the replication of both 3'- and 5'-U3 sequences. A disadvantage of this construct is the generally slow replication. A high-efficiency heterologous promoter to enhance the expression of the transgene in the retroviral vector may also replace the deleted viral promoter. ►retroviral vector, ►double-copy vector, ►E vector, ►gene therapy; Gatlin J et al 2001 Hum Gene Ther 12:1079.

Sindbis Virus: A single-stranded RNA virus.

sine: The ratio of the side opposite (a) to an acute angle (A) of a right triangle and the hypotenuse (c): a/c, sine of angle A. ►arcsine, ►angular transformation

SINE: Short (≈0.5 kbp) interspersed repetitive DNA sequences that may occur over 100,000 times in the mammalian genomes. The B1 SINE of mice is 130 to 150 bp in length and constitutes nearly 1% of the genome; it is homologous to the human Alu sequences. The B2 SINE (≈190 bp) constitutes about 0.7% of the mouse genome but it apparently has no human homolog or its abundance is very low. In the dog genome, 3 to 5% of the genes have SINE insertions, may differ in the different breeds, and may be a major source of allelic differences (Wang W, Kirkness EF 2005 Genome Res 15:1798). RNA

polymerase III transcribes the B2 SINE elements into short sequences that are not translated. The mouse gene carries an active RNA polymerase II promoter and can support transcription by pol II (Ferrigno O et al 2001 *Nature Genet* 28:77). The SINE elements are retroposons, but lack reverse transcriptase function. SINE type elements occur in all eukaryotes, including birds, fungi, insects, and higher plants. They may be pseudogenes of small RNA genes. The SINE sequences can also be used for fingerprinting and evolutionary studies. These are remnants of ancient retroviral insertions but once they were inserted—because of the loss of the LTR [transposase] function—they remained at the position of insertion. ▶retroposons, ▶transposable elements, ▶LINE, ▶Alu family, ▶DNA fingerprinting, ▶reverse transcriptase; Cantrell MA et al 2001 *Genetics* 158:769; Weiner AM 2002 *Curr Opin Cell Biol* 14:343.

Singing Ability: The ability to sing has genetic determination and some of the “song genes” of birds have been mapped for expression in different parts of the brain. (See Marler P, Doupe AJ 2000 *Proc Natl Acad Sci USA* 97:2965).

Single Burst Experiment: Virus-infected bacterial population diluted and distributed into vessels in such a way that each vessel would contain a single infected bacterial cell. (See Ellis EL, Delbrück M 1939 *J Gen Physiol* 22:365).

Single Cell Analytical Methods (chemical/physical): ▶MALDI/TOF/MS, ▶FISH, ▶immunocytochemistry, ▶immuno-electronmicroscopy, ▶immunoelectrophoresis, ▶immuno-fluorescence, ▶SMART; Cannon DM Jr et al 2000 *Annu Rev Biophys Biomol Struct* 29:239; Slepchenko BM et al 2002 *Annu Rev Biophys Biomol Struct* 31:423; Subkhankulova T, Livesey FJ 2006 *Genome Biol* 7:R18; Xie XS et al 2006 *Science* 312:228.

Single-Chain Fv Fragment: A monoclonal single heavy plus light chain immunoglobulin that can be encoded by a single transgene. Because of its single structure, it is a monovalent antibody in contrast to the common antibodies, which are divalent. It lacks effector function. ▶antibody monovalent, ▶antibody effector function, ▶monoclonal antibody, ▶ScFv, ▶immunostimulatory DNA

Single Copy Plasmids: ▶plasmids

Single Copy Sequence: DNA sequences containing non-redundant, genic portions.

Single Cross: ▶double cross

Single-Feature Polymorphism: ▶allele; Borevitz JO et al 2007 *Proc Natl Acad Sci USA* 104:12057.

Single Gene Trait: A single gene trait is controlled by one gene locus, and shows monogenic inheritance.

Single Nucleotide Polymorphism: ▶SNIPS

Single Strand Assimilation: A single strand displaces another homologous strand and then takes its place during a recombinational event. ▶recombination molecular models

Single Strand Binding Protein: A single strand binding protein binds to both separated single strands of DNA and thus stabilizes the open region to facilitate replication, repair, and recombination. ▶recombination molecular mechanisms, ▶binding proteins; Witte G et al 2005 *Nucleic Acids Res* 33:1662.

Single Strand Conformation Polymorphism (SSCP): In SSCP, when small deletions or even single base substitutions take place in one of the DNA strands of a gene locus, the alteration may be detectable by the electrophoretic mobility of the DNA in denaturing polyacrylamide gels. The two strands, the normal and the affected, may differ. If the individual is heterozygous for the amplified segment of the locus concerned, the electrophoretic analysis may indicate three or more band differences. In some cases, even the homozygotes may show multiple bands. With this method, nearly all of the alterations are detected in fragments of 200–300 bp. ▶gel electrophoresis, ▶polymerase chain reaction, ▶gene isolation, ▶DGGE, ▶mutation detection, ▶dideoxy fingerprinting, ▶MASDA; Orita M et al 1989 *Proc Natl Acad Sci USA* 86:2766.

Single-End Invasion (SEI): A meiotic recombination intermediate during the transition from double-strand breaks to double-Holliday junction. SEIs are formed by strand exchange between one and then the other double strand. The appearance of SEI coincides with that of the synaptonemal complex. SEI is preceded by a nascent double-strand partner intermediate that differentiates into a crossover and a non-crossover type after the synaptonemal complex has formed. Strand exchange occurs relatively late after synapsis and recombination may be avoided between homeologous and structurally rearranged partners. ▶Holliday model, ▶synaptonemal complex, ▶homeologous; Hunter N, Kleckner N 2001 *Cell* 106:59.

Single-Feature Polymorphism (SPF): SPF reveals detailed information about the genomic variations between/among species or different accessions of a species. The genomic DNA is hybridized to an RNA expression platform (gene chip) and single-base differences prevent the hybridization of 25 mer probes. By such a procedure, 4000 SPFs were found

between the Columbia wild type and the Ler genotype *Arabidopsis* plants. On the basis of SPFs, gene map locations, including QTLs, can be readily identified. It can also reveal organizational differences along the chromosomes, e.g., in centromeric or telomeric tracts versus the rest of the yeast chromosomes or various functional regions. (See Borevitz JO et al 2003 *Genome Res* 13:513; Winzeler EA et al *Genetics* 163:79).

Single-Molecule Chemistry: With the currently available optical facilities, it is now possible to observe the dynamic behavior of single biomolecules and to study their kinetics. Within a group of molecules (e.g., in an enzyme), static and dynamic heterogeneity exists among the different molecules; there is also an inherent and ubiquitous fluctuation in the structure and function of these molecules. Classical chemistry could detect only the behavioral average of these molecules. Recent approaches open new vistas in biological chemistry. Conformational change could be detected by fluorescence of an added fluorophore within the T7 DNA polymerase ternary complex, upon binding of a dNTP substrate. This fluorescence change is believed to reflect the closing of the T7 pol fingers domain, which is crucial for polymerase function (Luo G et al 2007 *Proc Natl Acad Sci USA* 104:12610). The single-molecule spectroscopy method directly probes kinetic reversibility and the chaperone role of the nucleocapsid of the HIV-1 immunodeficiency virus strand transfer to cell at various stages along the reaction sequence, giving access to previously inaccessible kinetic processes and rate constants (Zeng Y et al 2007 *Proc Natl Acad Sci USA* 104:12651).

Single-Positive T Cell: The single-positive cell expresses either the CD4 or the CD8 surface proteins. ▶CD4, ▶CD8, ▶T cell

S

Single-Strand Annealing Repair: ▶SSA

Singlet Oxygen ($^1\text{O}_2$): A highly reactive O_2 molecule produced during inflammation, by photosensitization in UV light, chemiexcitation in dark, decomposition of NDPO_2 , etc. $^1\text{O}_2$ may be toxic to molecules in the cell, oxidizes DNA, and produces mutagenic 7-hydro-8-oxodeoxyguanosine. It may affect gene expression and carcinogenesis. ▶ROS, ▶8-oxodeoxyguanosine, ▶photodynamic effect

Singleton: Singly occurring whole-body mutations; the spontaneous frequency in mice for seven standard loci is 6.6×10^{-6} per locus. ▶mutation rate

Singleton-Merten Syndrome: A rare disease involving aortic calcification but defects in bone development.

Singlets: Genes that occur only once in the genome.

Singular Value Decomposition (SVD) of RNA: SVD uncovers in the mRNA data matrix of genes, x arrays, i.e., electrophoretic migration length (Alter O, Golub GH 2006 *Proc Natl Acad Sci USA* 103:11828).

Sink: The storage of metabolites from where they can be mobilized on need.

Sink Habitat: A habitat in which some individuals contribute less to the future generations than the average individual. ▶source habitat, ▶habitat

Sinndakiss: A receptor internalization signal.

Sinorhizobium: ▶nitrogen fixation

Siphonogamy: In siphonogamy, the immotile microgametes of higher plants are delivered to the archegonia through the elongating pollen tube. ▶pollen tube, ▶embryosac, ▶zoidogamy

Sipple Syndrome: ▶phaeochromocytoma

SIR: ▶silencer

Sire: The male mammal; the term used primarily in animal breeding and applied animal genetics. ▶dam

Sirenomelia: A developmental malformation showing fused legs and usually lack of feet.

SIRM: The sterile insect release method. ▶genetic sterilization

siRNA (silencing RNA): A 29-amino-acid peptide specifically binds to the acetylcholine receptor expressed by neuronal cells. To enable siRNA binding, a chimeric peptide was synthesized by adding nine arginine residues at the carboxy terminus of rabies virus glycoprotein (RVG.) This RVG-9R peptide was able to bind and transduce siRNA to neuronal cells in vitro, resulting in efficient gene silencing (Kumar P et al 2007 *Nature [Lond]* 448:39). Low-copy promoter-associated siRNAs transcribed through RNAPII are recognized by the antisense strand of the siRNA and function as a recognition motif to direct epigenetic silencing complexes to the corresponding targeted promoters, in order to mediate transcriptional silencing in human cells (Han J et al 2007 *Proc Natl Acad Sci USA* 104:12422). ▶RNAi, ▶rasiRNA, ▶microRNA, ▶RNA polymerase IV, ▶BBB; Pikaard CS 2006 *Cold Spring Harb Symp Quant Biol* 71:473; human siRNA database: <http://siRNA.cgb.ki.se>; <http://itb.biologie.hu-berlin.de/~nebulus/sirna/v2/>.

Siolimus: ▶rapamycin

SIRPs (signal regulatory proteins, 20p13): Members of the SIRP family inhibit signaling through tyrosine kinase receptors and represent immune inhibitory receptors expressed on macrophages or other blood cells. ▶[tyrosine kinase receptor](#), ▶[macrophage](#); Latour S et al 2001 J Immunol 167:2547.

Sirtuin (Sirt): NAD-dependent histone deacetylase and ADP ribosylase proteins of the Sir2 family. Sirtinol also activates many auxin-inducible plant genes. More than 65% of the 138 sirtinol-induced genes are auxin-inducible. Both auxin- and sirtinol-induction are apparently mediated by ubiquitin-activated protein degradation (Zhao Y et al 2003 Science 301:1107). Resveratrol may activate sirtuins and prolong life (Howitz K et al 2003 Nature [Lond] 425:191). Sirtuin mediates the mobilization of fat by repressing genes controlling the peroxisome proliferator-activator receptor- γ . Overproduction of Sirt reduces adipogenesis, and interference with Sirt RNA enhances fat production. SIRT4 functions in the mitochondria, represses glutamate dehydrogenase by AD2064-ribosylation, downregulates insulin secretion, and opposes the effect of caloric restriction in pancreatic β cells (Haigis MC et al 2006 Cell 126:941). SIRT1 and SIRT3 activate acetyl-CoE synthetase by deacetylation of the cytoplasmic or the mitochondrial enzyme, respectively, by targeting a lysine residue (Hallows WC et al 2006 Proc Natl Acad Sci USA 103:10230). Sirt1 docks with nuclear receptor co-repressor (NcoR) and silencing mediator of retinoid and thyroid hormone receptors (SMRT) leading to PPAR- γ repression. Reduction of fat by lipolysis enhances lifespan (Picard F et al 2004 Nature [Lond] 429:771). Sirtuins regulate aging and age-related diseases such as cancer, diabetes, and neurodegeneration (Longo VD, Kennedy BK 2006 Cell 126:257). In cell-based models of mouse for Alzheimer disease, amyotrophic lateral sclerosis and other tauopathies resveratrol, a SIRT1-activating molecule, promotes neuronal survival (Kim D et al 2007 EMBO J 26:3169). ▶[adipocyte](#), ▶[PPAR](#), ▶[longevity](#), ▶[aging](#), ▶[obesity](#), ▶[ARF](#), ▶[neurodegenerative diseases](#), ▶[silencer](#), ▶[resveratrol](#), ▶[PGC1](#), ▶[acetyl-CoA](#); Grozinger CM et al 2001 J Biol Chem 276:38837; Pandey R et al 2002 Nucleic Acids Res 30:5036; signaling and regulation of protein deacetylation: Sauve AA et al 2006 Annu Rev Biochem 75:435.

SIS: The simian sarcoma virus oncogene is located in human chromosome 22q12.3-q13.1 and mouse chromosome 15. The SIS protein has high homology to the β chain of the platelet derived growth factor (PDGF), KIT oncogene, FOS oncogene, and the colony stimulating factor. ▶[oncogenes](#), ▶[PDGF](#),

▶[colony stimulating factor](#); Liu J et al 2001 Nucleic Acids Res 29:783.

Sis1: The DnaJ structural homolog of budding yeast indispensable protein with multiple chaperone functions, including initiation of translation. ▶[chaperones](#), ▶[DnaJ](#), ▶[DnaK](#)

Sister Chromatid Cohesion: The juxtaposition of the sister chromatids until the end of metaphase in mitosis and until the end of metaphase II in meiosis. The inner centromere proteins (INCENP) and the centromere-linking proteins (CLiP) provide the physical basis of the cohesion. The multiprotein cohesion complex, which binds most tightly to the centromere, was named cohesin. A separation protein (separin, a cysteine protease) mediates sister chromatid cohesion, and the dissociation is achieved when the Scc1/Mcd1/Rad21 subunit of cohesin dissociates from the chromatids upon proteolytic cleavage. Rec8 is also a component of the meiotic cohesin complex. The Esp1 (separin) is tightly bound to the chromosomes by the anaphase inhibitor Pds1 (mammalian homolog Securin). Pds1 is ubiquitinated by the triggering effect of the anaphase-promoting complex (APC) and Cdc20. The sister chromatids are closely juxtapositioned until anaphase, indicating the presence of inter-sister connector structures. Sister chromatid cohesion affects proper disjunction of the mitotic chromatids but it appears important also for meiotic recombination. In mitosis, the separation of the sister chromatids and the splitting of the centromere take place during the single anaphase. In meiosis, at anaphase I, the sister chromatids separate but the centromere does not until anaphase II. This timing is apparently under the control of a specific protein(s). For the orderly segregation together of the sister chromatids during meiosis I, the protein monopolin is required in yeast.

Dominant and recessive mutations have been identified in plants, animals, and yeast that are defective in chromatid cohesion. In yeast, centromeric element III (CDEIII) is essential for sister chromatid cohesion and for kinetochore function. ▶[mitosis](#), ▶[meiosis](#), ▶[synapsis](#), ▶[asynapsis](#), ▶[desynapsis](#), ▶[sister chromatids](#), ▶[sister chromatid exchange](#), ▶[DNA polymerases](#), ▶[chiasma](#), ▶[centromere](#), ▶[cell cycle](#), ▶[cohesin](#), ▶[ORC](#), ▶[condensin](#), ▶[adherin](#), ▶[check-point](#); Nasmyth K et al 2000 Science 288:1379; Tóth A et al 2000 Cell 103:1155; Carson DR, Christman MF 2001 Proc Natl Acad Sci USA 98:8270; Lee JY et al 2001 Annu Rev Cell Dev Biol 17:753.

Sister Chromatid Exchange (SCE): Sister chromatid exchanges are detectable in eukaryotic cells provided with 5-bromo-deoxyuridine for (generally) one

cycle of DNA replication (see Fig. S67). Subsequently, at metaphase the chromosomes are stained with either the fluorescent compound Hoechst 33258 (harlequin staining) or according to a special Giemsa procedure.

Figure S67. Sister chromatid exchange. Right: Untreated control. Left: Exposed to the alkylating compound thiotepa during DNA synthesis. (Courtesy of Professor BA Kihlman)

If sister chromatids are reciprocally exchanged, sharp bands appear in mirror image-like fashion. The frequency of sister chromatid exchange is boosted by about a third by potential carcinogens and mutagens. This method has been successfully used in various animal and plant cells for identifying genotoxic agents. The data must be evaluated with care in comparison with the concurrent control because BrdU itself may break chromosomes under UV-B light.

In *Saccharomyces cerevisiae*, molecular and genetic evidence are available for meiotic sister chromatid exchange. When one of the bivalents had different number of ribosomal RNA repeats with an embedded LEU2 gene, duplication and deficiency of LEU2 and the repeats were detected. Similar observations were made with other chromosomes and markers. After the DNA double-strand breaks, histone H2AX is phosphorylated at serine 139 and facilitates the homologous recombination of chromosomal double-strand breaks by using the sister chromatids as template (Xie A et al 2004 Mol Cell 16:1017). ▶harlequin staining, ▶Giemsa staining, ▶bioassays in genetic toxicology, ▶ring chromosomes, ▶BrdU, ▶ultraviolet light, ▶genotoxic, ▶sister chromatids, ▶chiasma, ▶crossing over, ▶cohesin, ▶double-strand breaks, ▶DNA repair, ▶histone variants; Shaham J et al 2001 Mutat Res 491:71.

Sister Chromatids: Sister chromatids are attached to the same side of the same centromere but they seem to be coiled in opposite directions (see Fig. S68). Their separation in mitosis requires the activation of a proteolytic enzyme encoded by the *Cut2* gene in *Schizosaccharomyces pombe*. ▶chromatids; Nasmyth K 2001 Annu Rev Genet 35:673.

Figure S68. Sister chromatids

Sister-Strand Exchange: Same as sister chromatid exchange.

SIT: A family of protein phosphatases regulating diverse metabolic pathways. ▶PP2A

SIT (sterile insect technique): ▶genetic sterilization, ▶GSM

Site-Directed Immunization: ▶immunization genetic

Site-Directed Mutagenesis: ▶directed mutation, ▶localized mutagenesis, ▶targeting; Storici F et al 2001 Nature Biotechnol 19:773.

Site-Specific Cleavage: The site specific cleavage of nucleic acids is accomplished by restriction endonucleases, some special RNases, and oligonucleotide-phenanthroline conjugates, which may cut both strands of the DNA in the presence of Cu^{2+} and a reducing agent. EDTA-Fe^{2+} may do the same if tethered to triplex molecules, albeit with low efficiency. In the presence of light, ellipticine attached to homopyrimidines may cleave a double helix within a triplex (see Fig. S69). ▶restriction endonucleases, ▶triplex, ▶tethering; Gimble FS 2001 Nucleic Acids Res 29:4215.

Figure S69. Ellipticine

Site-Specific Mutations: Site-specific mutations occur at particular nucleotides in the DNA and RNA, respectively. ▶base substitution, ▶localized mutagenesis, ▶gene replacement, ▶site-specific recombination, ▶PCR-based mutagenesis, ▶cassette

mutagenesis, ►homolog-scanning mutagenesis, ►alanine-scanning mutagenesis, ►TAB mutagenesis, ►cysteine-scanning mutagenesis, ►Kunkel mutagenesis, ►targeting vector, ►oligonucleotide-directed mutagenesis, ►degenerate oligonucleotide directed mutagenesis, ►look-through mutagenesis

Site-Specific Recombinases: Site-specific recombinases are resolvases that attach at the two-base staggered cut sites. The enzyme is then covalently linked to the 5' ends and the PO₄ of the DNA is covalently linked to the OH group of the recombinase. Subsequently, the broken DNA strand releases the deoxyribose hydroxyl group. The PO₄ is joined to another deoxyribose OH group and the DNA backbone is reconstituted. The members of the integrase group of enzymes attach at sites 6–8-bases apart. The first breakage results in a Holliday juncture, that may lead to branch-migration and after a second strand exchange and rotation isomerization (►Holliday model steps H-J) the strands may be resolved either with an outside marker exchange (classical recombination) or in gene conversion (the constellation of the outside markers retained). It is conceivable that the broken ends are reconstituted without any change, or deletions may also take place, or the position of the broken ends are inverted by 180° resulting in what classical cytology called inversion. Resolvase and integrase reactions can be very specific for the sites and the reaction is secured by the assistance of additional proteins that bring into contact only the appropriate DNA stretches. These two enzymes act only on supercoiled DNA. The integrase family of recombinase enzymes is more liberal in choice, yet affected by various conditions. The Mu phage or the HIV integration does not require covalent association between the DNA and a protein. The phosphodiester bond of the donor DNA is hydrolyzed to generate an OH group. This group and a phosphodiester group of the receiving DNA then join, and thus the strand is integrated. Site-specific recombinase enzymes with new specificities have been engineered using bacterial resolvase domains combined with substrate recognition domains borrowed from a mouse transcription factor (Akopian A et al 2003 Proc Natl Acad Sci USA 100:8688). ►site-specific recombination, ►Holliday juncture, ►resolvase, ►Cre/loxP, ►FLP/FRT, ►integrase, ►phosphodiester linkage, ►transesterification, ►homing endonucleases; Woods KC et al 2001 J Mol Biol 313:49; Dhar G et al 2004 Cell 119:33; structural and biochemical mechanisms of tyrosine and serine types of recombinases: Grindley NDF et al 2006 Annu Rev Biochem 75:567.

Site-Specific Recombination: Site-specific recombination occurs when the recombination is limited to

a specific few nucleotide sequences. Homology may be present at the exchange region in both recombining molecules like at the integration–excision site of the temperate phage. Alternatively, the specificity is limited to only one of the partners like at the 25 bp termini of the T-DNA or the direct and indirect repeats of the transposable elements. In the latter cases, the recombinational target sites may have no or only minimal similarity. The IS30 insertion element can serve as site-specific recombinases when replacing the integration/excision genes of phage λ (Kiss J et al 2003 Proc Natl Acad Sci USA 100:15000). Peptide nucleic acids enhance site-specific recombination and DNA repair. ►lambda phage, ►gene replacement, ►Cre/Lox, ►FLP/FRT, ►switching, ►site-specific recombinase, ►peptide nucleic acids, ►knockout, ►targeting genes, ►chromosomal rearrangement, ►ligand-activated site-specific recombination, ►T-DNA, ►recombination, ►shoufflons, ►integrases, ►DD(35)E; Sauer B, Henderson N 1988 Proc Natl Acad Sci USA 85:5166; Pena CE et al 2000 Proc Natl Acad Sci USA 97:7760; Christ N et al 2002 J Mol Biol 319:305.

Sitosterolemia (phytosterolemia, STSL, 2p21): A rare, recessive hypercholesterolemia resulting in more than 30-fold increase of the level of this plant cholesterol in the plasma. Intestinal absorption of sterols is increased and the excretion of sterols into the bile is impaired. Initially, it causes xanthomatosis and later premature coronary artery disease. Actually, two genes encoding sterolin 1 and sterolin 2 are involved in opposite orientation separated by a short interval. Sterolins apparently regulate sterol transport. ►cholesterol, ►low-density lipoprotein, ►VLDL, ►xanthomatosis, ►familial hypercholesterolemia, ►coronary heart disease; Lee M-H et al 2001 Nature Genet 27:79; Lu K et al 2001 Am J Hum Genet 69:278.

Situs Inversus Ambiguus: Some of the organs situated at the common side of body axis, others are at a misplaced site regarding the axis. ►left-right asymmetry

Situs Inversus Totalis: Complete inversion of left-right body axis. ►left-right asymmetry

Situs Inversus Viscerum (7p21): A malformation of mammals, including humans, where the internal organs such as the heart are shifted to the right side of the chest (thorax). It is frequently accompanied by chronic dilation of the lung passages (bronchi) and inflammation of the sinus; the latter disorder is also called Kartagener syndrome, which is characterized also by the immotility of sperm and cilia. The anomaly may be either autosomal or X-linked recessive. Its incidence in the general population may

be about 1/10,000. In the mouse, the genes *iv* (chromosome 12) and the *inv* (chromosome 4) disturb left-right axis formation and cause 50 and 100% manifestation of situs inversus, respectively. In the chicken, the fibroblast growth factor (FGF8) mediates the determination of the right side and in Sonic hedgehog (SHH), of the left side. In the mouse, FGF8 is instrumental in the left side and SHH in the right side specification. ▶[dynein](#), ▶[heterotaxy](#), ▶[isomerism](#), ▶[Kartagener syndrome](#), ▶[asymmetry of cell division](#), ▶[axis of asymmetry](#), ▶[FGF](#), ▶[sonic hedgehog](#), ▶[left-right asymmetry](#), ▶[ciliary dyskinesia](#); Bartoloni L et al 2002 Proc Natl Acad Sci USA 99:10282; Bisgrove BW et al 2003 Annu Rev Genomics Hum Genet 4:1.

SIV (Simian immunodeficiency virus): a relative of HIV. ▶[acquired immunodeficiency](#), ▶[HIV](#)

Size: Size depends primarily on cell number and cell size and it is developmentally and genetically determined. (See Conton I, Raff M 1999 Cell 96:235). According to Kleiber's rule (1932 Hilgardia 6:315), the size of an organism (body mass) follows the $\sim 3/4$ power of the metabolic/respiratory rate. A morphogen gradient may determine the size of an organ in animals. It is not entirely resolved which way the gradient is controlled. One set of data of *Drosophila* wing size determination indicates that imaginal disk size is determined relative to the fixed morphogen distribution by a certain threshold level of morphogen required for growth. When disk boundary reaches the threshold, the arrest of cell proliferation throughout the disk is induced by mechanical stress in the tissue. Mechanical stress is expected to arise from the non-uniformity of morphogen distribution that drives growth. This stress, through a negative feedback on growth, can compensate for the non-uniformity of morphogen, achieving uniform growth with the rate that vanishes when the disk boundary reaches the threshold (Hufnagel L et al 2007 Proc Natl Acad Sci USA 104:3835).

It seems that plants differ in metabolism from animals extensive data (500 observations on 43 plant species) indicates that respiration (relative to nitrogen content) at a scaling exponent of ~ 1 better represents mass (Reich PB et al 2006 Nature [Lond] 439:457). ▶[body mass](#), ▶[body size](#), ▶[morphogen](#), ▶[imaginal disk](#)

Size-Exclusion Chromatography: In size-exclusion chromatography, molecules are separated by size; large molecules may not enter the surface of the matrix but small molecules may penetrate the core. The penetration depends on size and shape of the analyte and the nature of the matrix.

SJL Mouse: Non-inbred strain.

Sjögren-Larsson Syndrome: ▶[ichthyosis](#)

Sjögren (sicca = dry) **Syndrome** (SS) Autosomal recessive autoimmune disease leading to the destruction of the salivary and lacrimal glands by the production of autoantibody against the SS-A (RoRNA) and SS-B (La Sn RNA) particles. The affected individuals have dry mouth and dry eyes (no tears). The autoantigens have been identified and purified. The Ro autoantigen appears to be encoded in human chromosome 19pter-p13.2. The La autoantigen may be involved with RNA polymerase III. The 120 kDa α -fodrin appears to be the critical autoantigen that elicits the disease. Aberrant T cells with impaired class IA phosphoinositide 3-kinase signaling can lead to organ-specific autoimmunity in mice and resemble human SS (Oak JS et al 2006 Proc Natl Acad Sci USA 103:16882). ▶[autoimmune disease](#), ▶[fodrin](#), ▶[RoRNP](#), ▶[PIK](#), ▶[rosacea](#)

SK: Calcium-activated potassium ion channels. ▶[ion channels](#)

SK Oncogene: The SK oncogene probably regulates tumor progression; it was assigned to human chromosome 1q22-q24.

7SK RNA: A small (330 base) nuclear RNA (snRNA) of ubiquitous presence and involvement in the control of transcription by interfering with the RNA elongation factor P-TEFb. ▶[snRNA](#), ▶[RNA regulatory](#); Yang Z et al 2001 Nature [Lond] 414:317; Michels AA et al 2004 EMBO J 23:2608.

Skewed Distribution: In skewed distribution, the data are not symmetrical around the mean; either one or the other extreme flank is predominant (see Fig. S70). ▶[normal distribution](#), ▶[kurtosis](#)

Figure S70. Skewed distribution

Skewness: Asymmetry in the distribution frequency of the data. ▶[kurtosis](#), ▶[normal distribution](#), ▶[moments](#)

Ski (Sloan Kettering Institute): A protein discovered at the Sloan Kettering Institute, as a viral factor in tumorigenesis. Ski occurs in vertebrates and insects and, along with Sno (Si-related novel gene), regulates the effect of Smad4 and Smad3 proteins that in

response to the phosphorylation signals coming from TGF- β may negatively control gene expression. It interacts with Skip, a transcriptional activator. ▶**Smad**, ▶**TGF**; Prathapam T et al 2001 Nucleic Acids Res 29:3469.

Skin Cancer: Skin cancer constitutes about 40% of all newly diagnosed cancers. The incidence of melanoma is 4%, basal cell carcinoma 80%, and squamous-cell carcinomas 16% of the skin cancers. Sunscreen provides limited protection; conversely, it may even increase the risk because the assumed protection allows more exposure to the sun. The sensitive initial target of carcinogenesis by UV light is mutation in gene p53 and various protooncogenes. The UV-light damage starts with *initiation* in single cells that may be followed by the effects of tumor promoting agents (*expansion*), eventually leading to the *progression* of the tumor cells, resulting in cancer. UVB can enhance these three steps, each, by acting on the signaling molecules, epidermal growth factor (EGF), mitogen-activated protein kinases (MAPK), and phosphatidylinositol 3-kinase (PI3K). EGF activation leads to the production of reactive oxygen species (ROS). ROS effects can be mitigated by antioxidants. UV induces several transcription factors such as AP-1, JUN, FOS, etc., and cyclooxygenase-2. AP-1 activation may be inhibited by salicylate (aspirin) or perillyl alcohol (monoterpene). Several other promising chemical protective agents are under study. (See terms under separate entries; Bowden GT 2004 Nature Rev Cancer 4:23).

Skin Color: ▶**pigmentation of animals**; Sturm RA et al 1998 Bioessays 20(9):712; Barsh G 2003 PLoS Biol 1(1):e7; Lin JY, Fisher DE 2007 Nature [Lond] 445:843.

Skotomorphogenesis: Morphogenesis without dependence on light. ▶**photo-morphogenesis**, ▶**de-etiolation**

SKP (cyclin A-CDK2 associated protein): An intrinsic kinetochore protein (22.3 kDa) widely conserved

among species. It coordinates centromere, centrosomes, and other cell cycle factors. The Skp1p is a proteasome-targeting factor. Mice Skp2^{-/-} is viable, yet has reduced growth rate, has polyploid cells, and accumulates cyclin E and p27^{Kip1} proteins that it cannot efficiently eliminate during the S and G2 phases of the cell cycle (see Fig. S71). For the degradation, SCF^{Skp2} is required. Skp2 is up-regulated in some types of epithelial carcinogenesis. ▶**kinetochore**, ▶**cell cycle**, ▶**CDC4**, ▶**proteasome**, ▶**F-box**, ▶**cyclin A**, ▶**CDK**, ▶**SCF**, ▶**von Hippel-Lindau disease**; Nakayama K et al 2000 EMBO J 19:2069; Latres E et al 2001 Proc Natl Acad Sci USA 68:2515.

Figure S71. Skp2 disrupted mice is deficient in the F box protein and SCF ubiquitin ligase has enlarged nuclei, multiple centrosomes and reduced growth. They accumulate cyclin E and p27Kip. (From Nakayama K et al 2000 EMBO J 19:2069)

Skunk (*Mephitis mephitis*): 2n = 50; (*Spilogale putorius*), 2n = 64.

Sky: Same as spectral karyotyping. ▶**spectral karyotyping**

Sky: A cellular tyrosine kinase. It regulates B cell development. ▶**B lymphocyte**; Kishi YA et al 2002 Gene 288:29.

SL1, SL2 (spliced leader): SL1 and SL2 are involved in the transsplicing in *Caenorhabditis*. The 100-nucleotide leader donates its 5' end 22 nucleotides to a splice acceptor site on the primary transcript. Trans-splicing is very common (70%) among the nematode's genes. This mechanism is used for the coordinately regulated gene clusters, transcribed in polycistronic RNA. The nematode operons use SL2 whereas other genes use SL1. ▶**transsplicing**, ▶**coordinate regulation**, ▶**operon**

SL1: A transcription factor complex of RNA polymerase I. It is a complex of the TATA-box-binding protein (TBP) and the three TATA box associated

factors (TAF). The TBP protein binds exclusively, either SL1 (RNA pol I) or TFIID (RNA pol II). In the case of RNA pol III, TFIIIB is required for the recruitment of the polymerase to the promoter complex. ►pol I, ►pol II, ►TBP, ►TAF, ►transcription factors

Slicer: A structural homolog of ribonuclease H; it is also a domain of Piw. ►Ribonuclease H, ►piRNA

7SL RNA: An RNA component in the signal recognition protein (SRP) complex. ►signal sequence recognition particle, ►Alu

Slalom Library: The slalom library is based on a combination of the principles of linking and jumping libraries. ►jumping library, ►linking library; Zabarovska VI et al 2002 Nucleic Acids Res 30(2):e6.

SLAM (signaling lymphocyte activation molecule, CDw150): A T cell receptor protein (M_r 70K) of the immunoglobulin family, constitutively and rapidly expressed on activated peripheral blood memory T cells, immature thymocytes, and on some B cells. It is a receptor also for the measles virus. T cells carrying the CD4⁺ antigens produce increased amounts of interferon γ without an increase of interleukins 4 or 5. SLAM function is independent of CD28. ►T cell, ►interferon, ►interleukin, ►CD28, ►Epstein-Barr virus, ►SAP; Bleharski JR et al 2001 J Immunol 167:3174.

SLAM: The gene predictor program for the detection of homologous sequences in different species. ►gene prediction; Alexandersson M et al 2003 Genome Res 13:496.

SLAP (Fyb/Slap): One of the adaptor proteins that regulate TCR-mediated signal transduction. Cbl has an inhibitory effect. SLAP interacts with Sky, ZAP-70 and LAT. ►Fyb, ►TCR, ►signal transduction, ►CBL; Peterson EJ et al 2001 Science 293:2263.

SLD: A yeast chromosomal replication protein acting after phosphorylation during the S phase. ►GINS; Masumoto H et al 2002 Nature [Lond] 415:651.

Sleep: A circadian organization of rest after activity, controlled by several neural genes. Apparently, mutation of the human homolog of *Per2* (2q) may be responsible for the familial advanced sleep phase syndrome. In *Drosophila*, some *Shaker* (1.57.6) null mutants (*Sh*¹⁰², *minisleep*) involved in a voltage-dependent K⁺ channel controlling membrane polarization and transmitter release have reduced requirement for sleep and display apparently normal functions but shorter life span (Cirelli C et al 2005 Nature [Lond] 434:1087). The point mutation

(Ser→Gly) is within the casein kinase I ϵ and alters the circadian clock. Sleep may have a weak role in the consolidation of memory and frequently inspires insight. Insight is a mental restructuring leading to sudden gain of explicit knowledge (Wagner U et al 2004 Nature [Lond] 427:352). Sleep-deprivation seriously affects job-performance and cognitive abilities. The Ampakine (α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid, AMPA) drugs appear promising in non-human primates for alleviating the problems of sleeplessness (Porrino LJ et al 2005 PLoS Biol 3(9):e299). In aging organisms (humans or *Drosophila*) the sleep cycles are generally fragmented and it has been attributed of age-related oxidative damage (Koh K et al 2006 Proc Natl Acad Sci USA 103:13843). ►apnea, ►narcolepsy, ►circadian rhythm, ►memory; Siegel JM 2001 Science 294:1058; Shaw PJ et al 2002 Nature [Lond] 417:287; Pace-Schott EF, Hobson JA 2002 Nature Rev Neurosci 3:591; 2005 Nature [Lond] 437:1253–1289.

Sleeping Beauty (SB): An artificially constructed human mariner transposable element, equipped with a salmon transposase function enabling the otherwise non-mobile element to move in HeLa or other somatic cells by a cut-and-paste mechanism. Another type of transposon vector (pTnori) is outlined here in Figure S72. Another transposon (T2/Onc2), containing a larger fragment of splice acceptor sequence, is flanked by optimized transposons binding sites. It also contains a murine stem cell virus (MSCV) long terminal repeats and a splice donor site to promote gene expression when integrated upstream or within the gene. Low methylation in MSCV promoter and high copy numbers are also an advantage. A more active transposase was constructed to increase transposition frequency and to be expressed in all tissues. This new system generated transposon mutagenesis in many cancer genes and appears promising to shed light on cancer etiology of mammalian cells (Dupuy AJ et al 2005 Nature [Lond] 436:221; Collier LS et al 2005 Nature [Lond] 436:272). Transposition of Sleeping Beauty requires the presence of the Miz-1 transcription factor and the slow-down of the G1 phase of the cell cycle. The slow-down decreases D1/cdk4-specific phosphorylation of the retinoblastoma protein (Walisko O et al 2006 Proc Natl Acad Sci USA

Figure S72. IR: inverted repeats, PRO: promoter, Tn5: bacterial transposon, NEO: selectable marker, ORI: origin of replication (p Tnori)

103:4062). ▶*mariner*, ▶*transposase*, ▶*piggyBac*, ▶*cut-and-paste*, ▶*HeLa*, ▶*cyclin D*, ▶*CDK*, ▶*retinoblastoma*; Horie K et al 2001 Proc Natl Acad Sci USA 98:9191; Izsvák Zs et al 2002 J Biol Chem 277:34581.

Sleeping Sickness: A potentially fatal disease caused by *Trypanosomas*. The tse-tse fly spreads the disease. ▶*Trypanosomas*

SLG: Self-compatibility locus-secreted glycoprotein. ▶*self-incompatibility*

Sliding Clamp: A gp45 gene of phage T4 controls high speed of replication (processivity) by gp43 (DNA polymerase gene); gp44 and gp62 are the clamp loaders for gp45. The clamp hugs the DNA and slides along the duplex DNA. The replication complex is then attached to the clamp. The cellular homologs for p45 are the β units of the DNA polymerase III of prokaryotes and the PCNA of eukaryotes. The transcription may be coupled to replication and regulated by protein-protein and protein site-specific DNA interactions. In eukaryotes, the sliding clamp is PCNA. The τ subunit of DNA polymerase complex switches off the polymerase from the DNA as one Okazaki fragment is finished and then switches on again the β subunit to start a new Okazaki fragment (López de Saro FJ et al 2003 Proc Natl Acad Sci USA 100:14689). ▶*DNA polymerases*, ▶*PCNA*, ▶*replication factor*, ▶*clamp loader*, ▶*Okazaki fragment*; Fishel R 1998 Genes Dev 12:2096; Trakselis MA et al 2001 Proc Natl Acad Sci USA 98:8368; crystal structure: Jeruzalemi D et al 2001 Cell 106:417; Johnson A, O'Donnell M 2005 Annu Rev Biochem 74:283.

SLIK: ▶*SAGA*

Slime Molds: Slime molds are either of plasmodial (*Myxomycetes*) or cellular type (*Acrasiomycetes*) eukaryotes, of which *Dictyostelium discoideum* is perhaps the most important object for research. ▶*plasmodium*, ▶*Dictyostelium*, ▶*Physarum*

SLINK: A computer program for estimating linkage information by a simulation approach. ▶*SIMLINK*

Slippage: Usually, when homopolymeric sequences are embedded in the template DNA strand, the RNA polymerase may synthesize RNA strands that are much longer (by a few to thousands nucleotides) than the template; this is known as slippage. The slippage can be inhibited, however, when nucleotides, representing the next one to the homopolymeric stretch, are added. Frame shift mutations may be interpreted as the result of slippage. Slippage may occur during decoding at translation on the ribosome in case

the codon-anticodon interactions are weak at the ribosomal P site (Hansen TM et al 2003 EMBO Rep 4:499). Slippage during DNA replication may generate trinucleotide repeats, which can lead to neurodegenerative disease. Slippage may be the origin of base mismatches, which generate instabilities (Chi LM, Lam SL 2005 Nucleic Acids Res 33:1604). ▶*slipping*, ▶*attenuator region*, ▶*overlapping genes*, ▶*unequal crossing over*, ▶*microsatellite*, ▶*replication slippage*, ▶*decoding*, ▶*mismatch repair*, ▶*transcript elongation*, ▶*trinucleotide repeat*; Viguera E et al 2001 EMBO J 20:2587.

Slipped-Structure DNA (S-DNA): Incomplete pairing within intrastrand folds (hairpins) in not exactly opposite position to each other. Such a structure may form when there are variable number trinucleotide repeats in the DNA (see Fig. S73). ▶*trinucleotide repeats*, ▶*hairpin*

Figure S73. S-DNA

Slipping: A shifting of the translational reading frame. ▶*recoding*, ▶*hopping*, ▶*slippage*

Slip-Strand Mispairing: Slip-strand mispairing may cause replicational error if not corrected by repair; it is frequently the cause of micro- and minisatellite instability. The slippage may cause either additions to or deletions from the repeat sequences. This process is independent from the mechanism(s) of recombination (it is not unequal crossing over), and flanking markers are not exchanged here. In yeast, its frequency is about the same as at mitosis and meiosis. Defects in the genes controlling replication and repair of the DNA may increase the instability and cause more mutations in microsatellites than in other types of DNA sequences. The packaging of the DNA, the temperature, methylation state, base composition, cell cycle stage, etc., may affect its frequency. Its rate may vary among different species because of differences in the replicase and mismatch repair enzymes. CTG repeats in the lagging strands are less stable than in the leading strand. ▶*microsatellite*, ▶*minisatellite*, ▶*MVR*, ▶*unequal crossing over*,

Sma I: A restriction endonuclease; recognition site CCC↓GGG. ►[restriction enzymes](#)

SMAC (supramolecular activation cluster): CD4 T cells with antigen presenting cells, receptors, and intracellular proteins form SMAC. (See terms at separate entries; Potter TA et al 2001 Proc Natl Acad Sci USA 98:12624).

Smac (second mitochondria-derived activator of caspases): Smac inhibits IAPs and facilitates apoptosis by caspase-3. A small, synthetic Smac mimic potentiates the activation of TRAIL and TNFα, inhibits IAP activity, and promotes apoptosis (Li L et al 2004 Science 305:1471). Smac is homologous with Diablo. ►[IAP](#), ►[apoptosis](#), ►[DIABLO](#); Zhang XD et al 2001 Cancer Res 61:7339.

Smad: Signal transducing proteins, which when stimulated by TGF-β can enhance gene transcription and tumor formation (TGF-β signaling). The Smad binding element is GTCTAGAC. The facilitating effects of the bone morphogenetic protein (BMP, acting via the serine/threonine kinase receptor) determine the SMAD protein function and opposing epidermal growth factor (EGF, acting via the receptor tyrosine kinases). Smad2 is essential for the formation of the early embryonic mesoderm of the mouse. Smad3 is normally phosphorylated by the TGF receptor TβRI, and Evi-1 represses its transcriptional activator function. Smad4 controls the mesoderm and visceral endoderm. Other SMADs associated with various ligands of the TGF family control the expression of genes involved in embryonal tissue differentiation. Smad3 and Smad4 cooperate with Jun/Fos (A1) and bind to the TPA-responsive gene promoter elements. SARA (Smad anchor for receptor activation) retains Smad2 and 3 in the cytoplasm. Pancreatic, colon, and other cancers are frequently associated mutation(s) in SMAD2 and SMAD4/DPC4. Smad4 is a tumor suppressor in the gastrointestinal tract of mice (Kim B-G et al 2006 Nature [Lond] 441:1015). SMADs 6 and 7 are modulators/inhibitors of signaling by some SMADs and their mutation may cause hyperplasia of the cardiac valves and other structural anomalies of the heart as well as ossification of the aorta and high blood pressure in mice. The SMAD acronym was derived from the human SPA (spinal muscular atrophy genes, 5q12.2-q13.3) and the *Drosophila* gene *Mad* (*mothers against decapentaplegic*). Smad proteins are classified as R-Smads (receptor regulated), Co-Smads (common Smads), and I-Smads (inhibitory). ►[TGF](#), ►[EGF](#), ►[bone morphogenetic protein](#), ►[serine/threonine kinase](#), ►[receptor tyrosine kinase](#), ►[activin](#), ►[Evi oncogenes](#), ►[TPA](#), ►[API](#), ►[SARA](#), ►[DPC4](#), ►[Mad](#), ►[spinal muscular atrophy](#), ►[Gli](#), ►[Ski](#), ►[osteopontin](#); Wrana JL 2000 Cell 100:189; Zauberman A et al 2001 J Biol Chem 276:24719;

López-Rovira T et al 2002 J Biol Chem 277:3176; Derynck R, Zhang YE 2003 Nature [Lond] 425:577.

Small Cell Lung Carcinoma (SCLC): SCLC is associated with a deletion of the human chromosomal region 3p14.2; the susceptibility is dominant. It accounts for about 1/3 of all lung cancers. Lung cancer genes were located also to 3p21, 3p25, and to several other chromosomes. Smoking may be the major cause of the development of this condition. Surgical remedies are usually not applicable because of the rapid metastasis but it generally responds to radiation and chemotherapy. Deregulation of the MYC oncogene is the suspected cause. Recently, a gene for fragile histidine triad (FHIT) was found to be associated with SCLC and with some of the non-small cell lung carcinomas (NSCLCs). The product of FHIT splits Ap₄A substrates asymmetrically into ATP and AMP. Its metastasis may be inhibited by CC3/TIP30. The heterozygotes (T/C) for the checkpoint kinase gene (CHECK 2/CDS1, human chromosome 22q12.1) was associated with a highly significantly lower incidence of lung cancer than the common T/T genotype [relative risk (RR), T/C versus T/T, 0.44, with 95% confidence interval (CI) 0.31–0.63, $P < 0.00001$] and with a significantly lower incidence of upper aero-digestive cancer (RR 0.44, CI 0.26–0.73, $P = 0.001$; $P = 0.000001$ for lung or upper aero-digestive cancer). The results of this study, involving 4015 smoking patients and 3050 non-smoking individuals in several East-European countries, were surprising because earlier, mutation in the same gene showed an increase in the incidence of the Li-Fraumeni syndrome (Brennan P et al 2007 Hum Mol Genet 16:1794). ▶oncogenes, ▶cancer, ▶MYC, ▶p53, ▶ATP, ▶AMP, ▶semaphorin, ▶metastasis, ▶non-small lung cell carcinoma suppressor, ▶neuroendocrine cancer, ▶Li-Fraumeni syndrome, ▶smoking, ▶checkpoint; Zöchbauer-Müller S et al 2002 Annu Rev Physiol 64:681; Tonon G et al 2005 Proc Natl Acad Sci USA 102:9625.

Small Molecule Microarray: In small molecule microarray, polystyrene beads covered by presumed biologically active ligands are arrayed in micro-well plates. The molecules are released from the beads in a solution and are spread over glass plates and tested for biological function(s) by high-throughput technology. (Uttamchandani M et al 2005 Curr Opin Chem Biol 9:4; MacBeath G et al 1999 J Am Chem Soc 121:7967; Clemons PA et al 2001 Chem Biol 8:1183).

Small Nuclear RNA: ▶snRNA

Smallpox: ▶pox virus, ▶variola

Small RNA (sRNA): sRNA includes microRNA, RNAi, transcripts of small genes, pseudogenes, intergenic regions, and transposons. By the use of massively parallel signature sequencing in *Arabidopsis* plants, a library of a total of 104,800 distinct signatures of these RNAs have been identified. Of these, 77,434 could be matched with the genome (Lu C et al 2005 Science 309:1567). The enormous number of these sequences regulates several ways the expression of the genomes. In *Arabidopsis*, ~2% of the genes may be under the control of microRNAs. Many of these sequences match intergenic regions, indicating that so far, unannotated protein-coding genes, pseudogenes, and transposons are located there. Single miRNAs may regulate on the average five–six times as many genes (Vaughan MW, Martienssen R 2005 Science 309:1525). The small RNAs usually regulate genes by interference (RNAi). Transfection of some dsRNAs into human cell lines was found to cause long-lasting and sequence-specific induction of targeted genes. dsRNA mutation studies reveal that the 5' end of the antisense strand, or “seed” sequence, is critical for activity (Li L-C et al 2006 Proc Natl Acad Sci USA 103:17337). ▶microRNA, ▶RNAi, ▶piRNA, ▶U-RNA, ▶21U-RNA, ▶pseudogene, ▶intergenic region, ▶transposons, ▶RNA non-coding, ▶massively parallel signature sequencing, ▶transitivity; sRNA for cereals: <http://sundarlab.ucdavis.edu/smrnas/>.

Small t Antigen: ▶SV40

Small-Pool PCR: Small-pool PCR amplifies 20–100 molecules of minisatellite DNA from single individuals within a population, and thus reveals a mutation rate that is $>10^{-3}$ in the sperm germline at a number of loci. ▶minisatellite, ▶PCR, ▶MVR; Crawford DC et al 2000 Hum Mol Genet 9:2909.

Small-World Networks: Small-world networks can represent models of many types of self-organizing biological systems, including interaction of gene products. Although the networks can be completely regular or completely random, biological interaction networks are usually connected neither in a completely regular nor in a completely random manner, but in a fashion in between these extremes and thus represent “small-world networks.” Small-world networks display enhanced speed of propagation of signals and coordinated regulation and can be subjected to computational analysis (see Fig. S74). ▶networks, ▶genetic networks, ▶probabilistic graphical models of cellular networks, ▶synthetic genetic array, ▶model; diagram modified after Watts DJ, Strogatz SH 1998 Nature [Lond] 393:440.

SMGT (sperm-mediated gene transfer): In SMGT, the sperm internalizes DNA and by artificial insemination, transgenic pigs have been produced that carry the human decay accelerating (hDAF) gene. The efficiency of transformation is high (64%) and the expression is very good (83%). The presence of dDAF is expected to help in overcoming hyperacute rejection of xenotransplanted organs. ▶decay accelerating factor, ▶xenotransplantation, ▶transformation genetic; Lavitrano M et al 2002 Proc Natl Acad Sci USA 99:14230.

Smith-Lemli-Opitz Syndrome (SLOS/RSH): A high prevalence (2×10^{-4}) autosomal recessive anomaly involving microcephalus, mental retardation, abnormal male genitalia, polydactyly, etc., encoded in human chromosomes 11q12-q13 (Type I) and 7q32.1 (Type II). Prevalence in Northern European populations is 1×10^{-4} to 2×10^{-5} . It is caused by Δ^7 -reductase deficiency in the cholesterol pathway and by the accumulation of 7-dehydrocholesterol. Deficiency of the Δ^{24} -reductase results in similar

symptoms. The afflicted individuals show mevalonic aciduria. This condition may also involve holoprosencephaly. Some of the symptoms may overlap with those of the Pallister-Hall syndrome. Prenatal diagnosis in the amniotic fluids after 15 weeks of gestation is feasible. A non-invasive urine analysis may also be practical. ►mental retardation, ►dwarfism, ►head/face/brain defect, ►cholesterol, ►sonic hedgehog, ►holoprosencephaly, ►chondrodysplasia; Wassif CA et al 2001 Hum Mol Genet 10:555.
